EXPERIMENT STATION RECORD.

VOL. XVII. SEPTEMBER, 1905. NO. 1.

Public interest in the reclamation of land for agricultural purposes has become quite generally aroused. It is one of the topics uppermost in connection with the settlement of the newer portions of the country, and represents one of the most prominent features of agricultural development. Its most familiar form is reclamation by irrigation, which has already greatly extended the area of agricultural production, and is rapidly spreading under the influence of Federal and private enterprise. Another form closely allied to it is the extension of dry-land or arid farming, carried on with crops which, under improved cultural methods, can be grown with a minimum of artificially supplied water, or with the natural rainfall of the country. Extensive areas are being brought under cultivation in this way which were formerly considered unadapted to farming and practically useless except for grazing.

There is another class of reclamation work whose practicability has largely been lost sight of in the rush for new lands, but which is bound to increase in importance and magnitude as the public mind becomes aroused to its possibilities. This is reclamation by drainage. It embraces tracts which, owing either to natural or artificial conditions, have been rendered practically waste land or unsuitable for cultivation except in favorable seasons. Large areas of such land await the development of the drainage engineer north, south, east, and west. These areas are not confined to any section, but are found at the coast, along river courses, in the level countries of the Middle West, and in the arid and semiarid regions of the West. Some of the land has been under cultivation and abandoned, while other has remained in a wild state and received no attention because of the supposed difficulties it presented.

The area involved is sufficient to make this phase of reclamation second to none in importance. In many cases these lands lie at the very gates of the eastern markets, and can be reclaimed at far less cost than new lands can be brought under irrigation. It is estimated that there are about one hundred million acres now unproductive which can

be reclaimed through dikes and drains. This if reclaimed would have a productive capacity equal to four times that of the State of Illinois, and would considerably exceed the probable area which can be reclaimed by irrigation, the extent of which appears to be diminishing with later estimates. Indeed, considerable of this land lies within the irrigated area, and its present condition has come about as a result of irrigation. According to a recent report of this Office, "there is scarcely an irrigated valley in the State of Utah which has been cultivated for a term of years in which some of the best land has not become too wet for cultivation and abandoned, or from which only uncertain crops of inferior value are now obtained."

Similar conditions exist throughout the irrigated districts. In those regions, therefore, irrigation and drainage necessarily go hand in hand. Either through the leakage of canals or through lavish use of water by irrigators, many thousand acres have become bogs and marshes by the accumulation of surplus and seepage waters. The rise of the soil water tends to drown out the roots of trees and plants, and the seepage water, passing down from canals and overflowed fields, carries with it the soluble salts of the soil, becoming more and more concentrated until an alkalied condition is produced.

The drainage problems of irrigated districts are not the same as those of the eastern part of the United States, but involve many new and complicated questions. The quantity of water to be removed can not be estimated with the same accuracy as where merely the rainfall is to be removed, for the source of the water supply is often obscure. It is impossible, without a preliminary study of conditions, to give reliable advice to farmers as to how they can restore their damaged fields. The rapidity with which the soil water rises when irrigation begins must be known in order to fix the capacity of drains, and the sources of the accumulated water must be ascertained to determine whether relief can be had by intercepting ditches, or whether a system of open or under drains is required.

But it is in the East that reclamation by drainage finds its greatest possibilities, owing both to the value of the reclaimed land and its proximity to markets. Here extensive areas are to be found which have either never been brought under cultivation, owing to their water-logged condition, or have been seriously injured and often abandoned by reason of overflow and conditions which have been brought about artificially. Such conditions are found along the whole Atlantic coast, and extend to the Gulf States as far west as Texas. In southern Louisiana and southern Texas are vast areas of land which there has either been no attempt to utilize, or has given discouraging results under cultivation, owing to the nearness of the water table to the surface. Such land, although located under climatic conditions which are

very advantageous to production, can be purchased at a low price—much lower in fact than land remote from markets and involving constant expense for water supply.

The everglades of southern Florida are attracting attention on account of their ability, under proper drainage and management, to produce subtropical fruits and vegetables for the northern markets. Large amounts of money have been expended in drainage works to lower the water along the border of the glades sufficiently to grow vegetables during the winter season, this land being mostly under water the remainder of the year. It seems likely that the area available for this purpose can be extended by the use of dikes and pumping, but this presents experimental features and its extension would ultimately involve large problems in drainage engineering.

It is estimated that there are 300,000 acres of marsh land in Wisconsin which at present have little or no value. This land is to a considerable extent of a moss-peat character, and its reclamation therefore requires somewhat different methods of treatment from that of ordinary swamp land. Such lands in other places have frequently not responded to ordinary methods of drainage, and special methods have had to be devised. In Sweden, for example, it is reported that more money has been wasted upon the drainage of moss-peat lands than upon any other improvements attempted, but a new system has at length been devised which is successful.

Another class of reclamation by drainage is that along the Illinois River. Here levee districts have been organized to reclaim about 74,000 acres of land, the drainage water being lifted over the levees by pumps when the river is high. In some of these districts the expenses for ditches, levees, and pumps have amounted to as much as $14 an acre, and the cost of pumping has been as high as $1 per acre in some years. But even this is insignificant in comparison with the expense of irrigation. Many of these reclamation works have failed in recent years owing to faulty and ill-advised construction.

Although farm drainage has long been practiced as one of the important aids to increased production, the drainage of large areas calls for expert advice in solving both the legal and engineering problems. It is now recognized that in many localities much drainage work has been poorly done, and that more scientific and thorough methods are required in draining land for the more intensive cultivation demanded on high-priced land.

In other words, in this as in other lines of agricultural development, systematic investigation and the services of experts are required to furnish a safe basis for large enterprises, and to work out the special problems presented by different sets of conditions. The field is one of immense possibilities, viewed either from the standpoint of reclamation or of the important agricultural problems presented.

During the past year or two studies of drainage projects of various kinds on a quite extensive scale have been made under the direction of the Irrigation Investigations of this Office, and the scope of this work is now being enlarged. These studies and the data collected have thrown considerable light upon the cost of reclamation by drainage under various conditions, the causes of failures, and the best methods of procedure; and they have also attracted attention to the feasibility and advantages of such reclamation. They have made it quite apparent that the problems of drainage where large areas are involved are far from being thoroughly worked out, and that this field presents as important and promising a one for investigation as any branch of engineering. In many States it lies at the very foundation of future agricultural development, and in other sections it is already a very present need, upon which depends the continued maintenance of lands now under cultivation.

While these problems of land reclamation by drainage, diking, etc., are largely in the domain of engineering, they are agricultural in their relationships and applications. The planning and inauguration of such work calls for some agricultural knowledge. The man with an agricultural outlook, who knows in a general way the methods and needs of different kinds of farming, has a distinct advantage over the man trained merely as an engineer; and, moreover, such a man can see the problems of a section, the possibility of remedying them, and the practicability of such an undertaking. In development work of this sort, the ability to see the problems and the possibilities of a section are of prime importance to both the projector and the investigator.

What is needed, therefore, is a class of men who combine engineering training with a thorough knowledge of agricultural conditions and an understanding of the practical requirements of farm life. Such men are to be found in Europe, where agricultural engineers are a recognized branch of the profession. The establishment of this work in the Department of Agriculture has brought together a number of this class of engineers. In this way the solution of these special problems is having the advantage of their combined special knowledge. The reception this work has met with leaves no question as to the need for it, and the results already achieved show its practical value. Demands for expert advice regarding drainage plans and for expert study of unsolved problems are being received from all sections of the United States, and are far in excess of the ability of the Office at present to meet.

Engineering, like all professions, is being specialized. In this specialization there would seem clearly to be a field in this country for the agricultural engineer. Such a man would combine with his technical engineering knowledge a familiarity with agricultural methods, condi-

tions, and requirements which would make him specially suited to deal intelligently with enterprises of that sort. Indeed, there is at present no little difficulty in securing sufficient men who have the special qualifications to undertake investigations in this field, and who will be able to see clearly the problems of a locality without special supervision.

Agricultural engineering is now attracting more attention as a definite branch of agricultural science and practice. It embraces a sufficiently comprehensive field to set it off as a department by itself, and it is clearly within the scope of the agricultural college to develop instruction in this branch, which is bound to become of increasing importance. Moreover, the colleges of agriculture and mechanic arts are peculiarly adapted to training men in this line, and they afford facilities which are not to be had at the ordinary engineering schools. The present interest and activity in investigation and reclamation work of this sort, and the probabilities of development in the near future, make the outlook for such specialists very good. The advantages which men trained in agricultural engineering would possess would soon come to be appreciated.

With the beginning of the seventeenth volume of the Record, the classification of the abstract part has been slightly modified and several new departments added. The changes in arrangement are made with a view to conforming more closely to the classification of agriculture and relating the pure to the applied science.

Rural engineering, which is rapidly growing in importance, has been made a separate editorial department, and it is planned to materially strengthen the review in this line. Rural economics is receiving more attention as a branch of agricultural instruction and investigation, and matters within its scope now go to make up a considerable literature. As these writings are scattered through quite a variety of periodicals, their review will be especially helpful to those interested in following the progress in this relatively new department and showing its relationships.

It has frequently been suggested that more attention be given in the Record to matters relating to agricultural education. In the past notes upon various phases of the movement have been presented from time to time, but hereafter a review of the more important papers, books, and other contributions which mark the progress of agricultural instruction in its various grades will be maintained, and this material will be brought together in a regular department of the Record.

It is hoped that these developments will make the journal a more helpful review to its present readers, and possibly extend its usefulness in new directions.

RECENT WORK IN AGRICULTURAL SCIENCE.

AGRICULTURAL CHEMISTRY.

A contribution to the determination of phosphoric acid by the citrate method, a hitherto overlooked source of error and a modification to avoid it, V. Schenke (*Landw. Vers. Stat.*, *62* (*1905*), *No. 1–3*, *pp. 3–10*).—This is an account of comparative tests on bone meal, Thomas slag, and soils of Märcker's molybdic method, the official citrate method of the German Association of Agricultural Experiment Stations, and a modified citrate method in which the acid solution of the material was neutralized with concentrated ammonia before the citrate solution and magnesia mixture were added.

The results obtained by the modified citrate method agreed more closely with those obtained by the molybdic method than was the case with the ordinary citrate method. It is pointed out that the citrate method is a "compensation method" in which the errors due to impurities of silica, lime salts, etc., are supposed to be balanced by those due to solubility of the magnesium-ammonium phosphate precipitate in ammonium citrate. The modified citrate method apparently gives a more perfect balance in this respect, due to the fact that less ammonium citrate is used (50 to 64 cc. as against 100 cc. in the ordinary method).

On the determination of phosphoric acid in Thomas slag, F. Westhausser (*Ztschr. Analyt. Chem.*, *44* (*1905*), *No. 3–4*, *pp. 187–191*; *abs. in Chem. Centbl.*, *1905*, *I*, *No. 19*, *p. 1434*).—Comparisons of the official method of the Association of German Agricultural Experiment Stations, the original Kellner-Böttcher method, and of the Kellner-Böttcher method using Hallens ammonium citrate solution. The methods proved very unreliable in case of substances like Wolter phosphate containing large amounts of silica.

Phosphoric acid determination, F. Raschig (*Ztschr. Angew. Chem.*, *18* (*1905*), *No. 10*, *pp. 374–376*).—A series of tests are reported to show that the amount of water used in washing the magnesium-ammonium phosphate prior to its titration with tenth-normal hydrochloric acid may with safety and advantage be reduced to 10 cc. The details of manipulation in carrying out the method are described.

The Pemberton method of determining phosphoric acid, D. J. Hissink and H. Van der Waerden (*Chem. Weekblad*, *2* (*1905*), *pp. 179–184*; *abs. in Chem. Centbl.*, *1905*, *I*, *No. 16*, *pp. 1188*, *1189*).—A modification of the method insuring uniform composition of the precipitate and fixed requirement of sodium hydroxid solution for titration is described.

Quick methods for the determination of lime, potash, and phosphoric acid, E. H. Schultze (*Chem. Ztg.*, *29* (*1905*), *No. 37*, *pp. 508*, *509*).—Titrimetric methods for the determination of calcium oxid in calcareous substances and phosphoric acid in phosphates, and a short method of determining potash as potassium platinic chlorid are described.

Maercker-Bühring solution, Wagner's citrate magnesia mixture, and iron citrate magnesia mixture, H. Svoboda (*Chem. Ztg.*, *29* (*1905*), *No. 33*, *pp. 453–456*).—A series of comparative tests of these mixtures with reference to the error due to their solvent action on glass is reported.

On the estimation of free acid and its relation to total acidity in superphosphate, J. OSTERSETZER (*Chem. News, 91* (*1905*), *No. 2372, p. 215*).—The method of using alizarin sulphonic acid as an indicator in the determination of free acid in superphosphates is briefly described.

The determination of perchlorates, M. DITTRICH and H. BOLLENBACH (*Ber. Deut. Chem. Gesell., 38* (*1905*), *pp. 751, 752; abs. in Jour. Chem. Soc.* [*London*], *88* (*1905*), *No. 510, II, p. 281*).—In the method proposed the perchlorates are reduced to chlorids by fusion in sodium nitrite.

The determination of perchlorates and chlorates in sodium nitrate, D. TSCHERNOBAJEFF (*Chem. Ztg., 29* (*1905*), *No. 32, pp. 442, 443*).—From investigations which are reported the author recommends that chlorates and perchlorates be determined together by Lemaître's method of reduction with sodium sulphite, and the chlorates be determined separately by reduction in the cold by means of iron and sulphuric acid according to Hendrixson's method.

Contribution to the analysis of nitrate of soda, R. BENSEMANN (*Ztschr. Angew. Chem., 18* (*1905*), *No. 21, p. 816*).—A form of an old method based on reduction with oxalic acid and fusion until carbonate is formed and nitrogen and chlorin are expelled is described and comparisons of it with the Hamburg method are reported.

A new method of determining magnesium carbonate in limestones, W. F. KOPPESCHAAR (*Ztschr. Analyt. Chem., 44* (*1905*), *No. 3-4, pp. 184-187, figs. 3*).—The method described is based upon the fact that when limestone is dissolved in the least possible amount of hydrochloric acid and the lime precipitated as sulphate by adding concentrated sulphuric acid the magnesia remains in solution. The filtrate therefore contains relatively a large amount of magnesia and a small amount of lime which can be precipitated as calcium oxalate almost free from magnesia.

Notes on the determination of nitrous acid, especially by the Trommsdorff method, H. LEGLER (*Pharm. Centralhalle, 46* (*1905*), *pp. 181-183; abs. in Chem. Centbl., 1905, I, No. 14, p. 1048*).—Precautions to be observed and apparatus to be used in order to secure accurate results are described.

The electrolytic estimation of small amounts of arsenic, C. MAI and H. HURT (*Ztschr. Untersuch. Nahr. u. Genussmtl., 9* (*1905*), *No. 4, pp. 193-199, fig. 1*).—An improved method of estimating arsenic electrolytically is discussed.

The determination of boric acid, K. WINDISCH (*Ztschr. Untersuch. Nahr. u. Genussmtl., 9* (*1905*), *No. 11, pp. 641-660*).—This is a review of the different methods which have been proposed for the determination of boric acid, the foot-notes constituting a bibliography of the literature of this subject. Results obtained by the author with some of these methods are reported.

Gasometric determination of formaldehyde, G. B. FRANKFORTER and R. WEST (*Jour. Amer. Chem. Soc., 27* (*1905*), *No. 6, pp. 714-719, fig. 1*).—This method is based upon the fact that when potassium hydroxid is added to formaldehyde in the presence of hydrogen peroxid free hydrogen is liberated. The substitution of sodium peroxid for hydrogen peroxid gave slightly higher results.

The detection of hydrogen peroxid in milk, UTZ (*Milchw. Zentbl., 1* (*1905*), *No. 4, pp. 175-178*).—The author's experiments confirm the claims made for titanic and vanadic acids as suitable reagents for the determination of hydrogen peroxid in milk. The reaction may be obtained whether the milk is heated or not before the addition of the hydrogen peroxid. The hydrogen peroxid may be detected for a much longer period when the milk is heated before the preservative is added. An increase in temperature hastens the decomposition of the hydrogen peroxid.

The determination of water in foods and physiological preparations, F. G. BENEDICT and CHARLOTTE R. MANNING (*Amer. Jour. Physiol., 13* (*1905*), *No. 3, pp. 309-329*).—From comparative studies of different methods the conclusion was reached

that drying in a vacuum over sulphuric acid is the most satisfactory procedure in estimating water in foods and physiological products.

The high vacuum which is needed, the authors found, could be obtained by introducing a small quantity of ether into the desiccator containing the samples and exhausting with a suction pump. It is desirable, in the authors' opinion, to have a manometer in the desiccator and to dry the samples in aluminum dishes of special construction with covers, although suitable glass dishes with covers may also be used.

As regards the time required for drying, "a marked difference exists between materials of a vegetable and those of an animal nature, the former retaining their moisture persistently, while the latter have, in general, lost all but mere traces of their moisture after 2 weeks in a high vacuum. For animal materials, therefore, we may say that 2 weeks in a high vacuum suffices to remove practically all moisture. For the most accurate work a longer time is to be recommended, though the slight loss in weight subsequent to 2 weeks' desiccation can hardly effect ordinary physiological or chemical research. With vegetable materials, desiccation should proceed for a period longer than 2 weeks [as slight loss in weight was noted after this].

"As a matter of fact, however, it can readily be seen that the sample, as soon as prepared for analysis, can be placed in the vacuum and weighed as soon after 2 weeks as the results are needed. In general, the time between the preparation of a sample for analysis and the time when the results are imperatively needed is considerably over 2 weeks. For preliminary determinations in metabolism experiments, where an approximate knowledge of the water-content of foods is necessary, the usual five-hour heating will suffice, and the final calculations may be based on the determination by the vacuum method. For technical work, obviously the method is, as already stated, too time-consuming, though the advantages may appeal to the technical analyst and the method may possibly find some use in special cases. . . .

"The complete dehydration of butter in a high vacuum is of especial interest, when we consider the difficulties usually experienced in securing an equal distribution of the material in the sample dish and the passage of the water through the supernatant layer of melted fat. It is worthy of note that in several tests made with the vacuum method no special degree of importance could be ascribed to an even distribution of the sample. Desiccation was equally complete whether the sample was first melted in a thin layer on the bottom of the dish, or large irregular lumps of butter were used."

Studies were made of the effect of different degrees of rarefaction on the dehydration of samples. When the atmospheric pressure was reduced to 86 mm. the efficiency of dehydration was considerably increased over that noted in the desiccator at atmospheric pressure, and when the degree of rarefaction was less than 1 mm. of mercury the increased efficiency of desiccation became very marked. "This is easily explained by the fact that the tension of aqueous vapor at the laboratory temperature (20° C.) is about 17 mm. of mercury, and consequently a pressure of 86 mm. requires a considerably higher temperature to cause the tension of aqueous vapor to equal that of the gaseous medium. On the other hand, with the high vacuum, the temperature of the room is perhaps 20° above the boiling point of water at this degree of rarefaction, and consequently evaporation of water proceeds with great rapidity. A consideration of these facts explains the slow action of vacuum-drying as usually carried out, and also accentuates the importance of using a manometer inside the desiccator to indicate the pressure conditions after exhaustion."

In view of the results obtained the authors do not believe that drying in partial vacuum with heat is necessary or desirable.

The determination of water in molasses, G. Testoni (*Staz. Sper. Agr. Ital., 37 (1904), No. 4-5, pp. 366-369*).—Different methods of estimating water in molasses were compared.

The commercial analysis of cane molasses. I, Optical methods, H. E. SAWYER (*Jour. Amer. Chem. Soc., 27 (1905), No. 6, pp. 691-713, dgm. 1*).—In the method previously proposed by the author for dark materials the normal weight of molasses—26.048 gm.—is made up to a volume of 500 cc. instead of 100 cc., as customary. This method has been tested by the author for 4 years, and while no claim is made that precision is attainable, it is believed to be very suitable for practical purposes.

Different methods of fat determinations in milk, F. FRIIS, E. HOLM, and A. V. KRARUP (*Ber. K. Vet. og Landbohöjskoles Lab. Landökonom. Forsög [Copenhagen], 56 (1905), pp. 1-23*).—The report gives the results of an investigation of the reliability and comparative value of the extraction method of milk analysis and the Gottlieb-Röse method. The errors of analysis found in the case of the former method are of especial importance in the analysis of skim milk and buttermilk, in the case of which it may give from 0.1 to 0.2 per cent too low results.

The "sin-acid" method of fat determination in milk was also studied, the results showing that ordinary mixed milk containing formalin in the proportion of 1:2,000, if left for some time (14 days), will give too low results; also that the method is not applicable to analysis of skim milk and buttermilk. As the "sin-acid" method has, however, been modified since this work was done, it is felt that the method must still be considered in the experimental stage.—F. W. WOLL.

The new method of determining fat in milk, Sichler's "sin-acid" butyrometry, G. CORNALBA (*Staz. Sper. Agr. Ital., 38 (1905), No. 3, pp. 227-240*).—Comparative determinations by the Sichler and Gerber methods are reported. The results agreed very closely. The advantages and disadvantages of the new method are pointed out.

Detection of added water in milk, UTZ (*Milchw. Zentbl., 1 (1905), No. 5, pp. 209-211*).—The author discusses the detection of water in milk by means of tests for nitrates and by the index of refraction. The disappearance of nitrates in milk when added in water was believed to be associated with the development of lactic-acid bacteria, which could of course be lessened by pasteurization. It is believed that heating milk has no effect on the index of refraction.

Table for computing the total solids and the solids-not-fat in milk from the specific gravity and the fat content according to the Fleischmann formula, RÜTTNER and ULRICH (*Milch. Ztg., 34 (1905), No. 18, pp. 214, 215*).

Contributions to the examination of butter, M. SIEGFELD (*Milchw. Zentbl., 1 (1905), No. 4, pp. 155-171*).—The author reviews recent investigations relating to the methods of butter analysis and reports determinations of the Reichert-Meissl, Polenske, saponification, and iodin numbers and the mean molecular weight of the volatile and nonvolatile fatty acids in a number of samples of butter from 2 large dairies.

The results are discussed at some length as regards the value of the different determinations in detecting adulteration. While the addition of cocoanut fat to butter may be detected by means of the methods of Juckenack, Polenske, and Bömer, it is not believed that there is at present a satisfactory method for the positive detection of the addition of animal fats.

The extraction of tanning materials with various extractors, F. P. VEITCH (*Jour. Amer. Chem. Soc., 27 (1905), No. 6, pp. 724-729, fig. 1*).—This paper, which was presented before the Association of Official Agricultural Chemists at its meeting in 1904 (E. S. R., 16, p. 328), gives the comparative results obtained on different materials with 3 extractors.

The determination of ash in plant substances, E. GUTZEIT (*Chem. Ztg., 29 (1905), No. 40, p. 556*).—The method of incineration with basic calcium phosphate first proposed by Ritthausen is described.

On the use of sodium carbonate and oxalate in acidimetry, S. P. L. Sørensen and A. C. Andersen (*Ztschr. Analyt. Chem., 44 (1905), No. 3-4, pp. 156-184*).—Investigations are reported which, it is claimed, show the reliability of these substances as means of titrating acids if a gas flame containing sulphur is not used with the first, and corrections for impurities made for the second.

Report of the chemical department of the Swedish Moor Culture Station, 1903-4, H. von Feilitzen (*Svenska Mosskulturför. Tidskr., 20 (1905), No. 3, pp. 157-188, figs. 4*).—The report, which covers the period from November 15, 1903, to December 31, 1904, gives the results of analyses made during the year of soils, soil amendments, fertilizers, crops, and technical moorland products. Views of the laboratories of the station are also given, with plan of the rooms and invertories.—F. W. Woll.

Progress in the field of agricultural chemistry during 1904, A. Stutzer (*Chem. Ztg., 29 (1905), No. 20, pp. 257-261*).—A review, with numerous references to literature, of investigations in chemistry as applied to soils, plant production and physiology, fertilizers, animal physiology, feeding stuffs, soil bacteriology, and methods of agricultural analysis.

Review of foreign work in agricultural chemistry, C. W. Harrison (*Jour. Amer. Chem. Soc., 27 (1905), No. 6, pp. 761-776*).—This is a brief and partial review of articles relating to the chemistry of fertilizers, soils, field crops, dairying, and animal feeding which have appeared in foreign publications during the last few years.

METEOROLOGY—WATER.

Monthly Weather Review (*Mo. Weather Rev., 33 (1905), Nos. 1, pp. 1-40, figs. 3, charts 11; 2, pp. 41-84, figs. 3, charts 17; 3, pp. 85-126, figs. 3, charts 12*).—In addition to the usual reports on forecasts, warnings, weather and crop conditions, meteorological tables and charts for the months of January, February, and March, 1905, recent papers bearing on meteorology, recent additions to the Weather Bureau Library, etc., these numbers contain the following articles and notes:

No. 1.—Special contributions on Escape of Gases from the Atmosphere, by G. J. Stoney; The Coordinates of the United States Weather Bureau Station at Mount Weather, Va. (illus.), by H. H. Kimball; The Proposed Competition in Forecasting at Liege, by B. Brunhes; Solar Halo of February 3, 1905, at Washington, D. C. (illus.), by E. R. Miller; Meteorological Charts of the Indian Ocean, by C. F. Talman; Earthquakes of January and February, 1905, by C. F. Marvin; and Dr. J. O. Harris, by W. G. Burns; and notes on apparatus for instruction in physics and meteorology, a river and flood service on the Grand River of Michigan (illus.), Weather Bureau men as instructors, methods of measuring duration of rainfall, and low temperature at Thompson Hill, Conn.

No. 2.—Special contributions on A Relation Between Autumnal Rainfall and the Yield of Wheat of the Following Year—Preliminary Note, by W. N. Shaw (E. S. R., 16, p. 955); Contributions to Marine Meteorology; High Water in the Great Lakes (illus.), by A. J. Henry; Unusual Weather at Dodge, Kans., by E. D. Emigh; Studies on the Diurnal Periods in the Lower Strata of the Atmosphere—I, The Diurnal Periods of the Temperature (illus.), by F. H. Bigelow; and Mathematical Theory of Ice Formation, by S. T. Tamura; and notes on the fourth international conference on aerial research, the Meteorologia generale di Luigi de Marchi, Pernter's theory of the rainbow (illus.), meteorology in Haiti, and Weather Bureau men as instructors.

No. 3.—Special contributions on Application of Mathematics in Meteorology, by F. H. Bigelow (E. S. R., 15, p. 20); Tornado in Eastern Alabama, March 20, 1905 (illus.), by F. P. Chaffee; Studies on the Diurnal Periods in the Lower Strata of the Atmosphere—II, The Diurnal Periods of the Barometric Pressure, by F. H. Bigelow;

Snowfall and Water Equivalent, by H. C. Frankenfield; Earthquake of March 21, 1905, by C. F. Marvin; The Variations in Atmospheric Transparency during 1902, 1903, and 1904, by H. H. Kimball; Twilight Glows and Connected Phenomena Observed in 1902, 1903, and 1904 in the Pyrenees, by E. Marchand, trans. by Miss R. A. Edwards; and the Solar Eclipse of August 30, 1905, as Visible in the United States (illus.), by W. F. Rigge; and notes on Tornado near Bluff Springs, Fla., March 20, 1905, and Weather Bureau men as instructors.

Meteorological notes for the year ending September 30, 1904, A. Lander (*East Kent Sci. and Nat. Hist. Soc. Rpt. and Trans., 2. ser., 4 (1904), pp. 37–40, pl. 1, fig. 1*).—The weather conditions at Canterbury during the year are briefly summarized and the telluradiometer, "a new instrument for accurately measuring terrestrial radiation and foretelling the weather by indicating the variations in the amount of aqueous vapor present in the atmosphere," is briefly described.

Periodic variation of rainfall in the arid region, W. B. Stockman (*U. S. Dept. Agr., Weather Bur. Bul. N, pp. 15, map 1*).—This is a paper which was read before the Twelfth National Irrigation Congress at El Paso, Texas, November, 1904, and summarizes information relating to the character, distribution, and amount of precipitation throughout the arid region of the United States. Data are compiled "for a few stations in each State, selected so as to best show the average conditions that have obtained generally over the State and region, due consideration also being given to length and continuity of record and altitude of station."

Climate of the Province of San Luis, Argentine Republic, A. L. Cravetti (*An. Min. Agr. Argentina, Secc. Agr. (Agron.), 1 (1904), No. 5, pp. 67–83*).—This is one chapter of a detailed report on the agricultural conditions of this province, summarizing the meteorological conditions (temperature, pressure, rainfall, wind) of the region.

Climate of the Province of Buenos Ayres, Argentine Republic, R. J. Huergo (*An. Min. Agr. Argentina, Secc. Agr. (Agron.), 1 (1904), No. 2, pp. 72–88*).—This article forms part of a detailed report on the agricultural conditions of this province. It summarizes the available meteorological data with reference to diurnal variations in temperature, average and extreme monthly temperatures, mean temperatures for different stations, winds, atmospheric pressure and humidity, and rainfall.

The action of cannon used for protection against hail, J. Violle (*Compt. Rend. Acad. Sci. [Paris], 140 (1905), No. 6, pp. 342, 343*).—The results of hail protection experiments made during 1904 by the Syndicate of Beaujolais over an area of about 12,000 hectares. and also tests made in Côte-d'Or are summarized. It is claimed that the results are encouraging and indicate that the cannonading tends to restore the electrical equilibrium and so mitigates storm conditions.

Frost protection experiment in Hohenheim, 1904 (*Gartenwelt, 9 (1905), No. 24, pp. 285–287*).

Influence of the temperature of the earth's surface, of thermal inertia, and of radiation on errors in the determination of the temperature of the air, P. Borisov (*Izv. Moskov. Selsk. Khoz. Inst. (Ann. Inst. Agron. Moscou), 10 (1904), No. 3, pp. 546–594*).—This article reports data collected at the Moscow Agricultural Institute, which show that the temperatures registered by thermometers in shelters differ from those of the free air, being influenced by the temperature of the surface of the soil or of the plant cover, the direction and movement of the wind, radiation from the shelter, etc.; and it was further noted that the temperature in an ordinary wild shelter lags behind that of the air, sometimes to the extent of one hour.—P. FIREMAN.

On the presence of formaldehyde in the atmosphere of towns, A. Trillat (*Bul. Soc. Chim. Paris, 3. ser., 33 (1905), No. 7, pp. 393–395*).—Studies similar to those reported by Gautier and Lévy and Henriet (E. S. R., 15, p. 957; 16, p. 238) are reported. A method of preparing a neutral chlorhydrate of rosaniline test paper

which can be used for detecting the presence of formaldehyde in the atmosphere is described.

Evaporation observations in the United States, H. H. KIMBALL (*U. S. Dept. Agr., Weather Bur. Doc. 327, pp. 8, figs. 2*).—Reprinted from Monthly Weather Review for December, 1904 (E. S. R., 16, p. 954).

Copper as an algicide and disinfectant in water supplies, G. T. MOORE and K. F. KELLERMAN (*U. S. Dept. Agr., Bur. Plant Indus. Bul. 76, pp. 55*).—This bulletin is supplementary to Bulletin 64 of the Bureau of Plant Industry (E. S. R., 16, p. 238), and gives the results of treatment under the direct supervision of representatives of the Laboratory of Plant Physiology of a number of lakes and reservoirs during the summer of 1904. Definite recommendations are given regarding the methods of procedure, for the guidance of those having to deal with the question of contaminated water.

The results are summarized as follows:

"During the summer of 1904 over 50 reservoirs were successfully treated for the removal of algæ. From these results and from further experiments in the laboratory and elsewhere the following facts have been developed:

"Much less copper is required to eradicate algæ from reservoirs than would be necessary to destroy algæ under laboratory conditions.

"The effect of this metal upon fish is of considerable importance and requires more study.

"The physical and chemical constitution of a water are factors to be considered in determining the quantity of copper sulphate to use in a water supply.

"The elimination of polluting forms sometimes makes possible the development of other species, but so far these species have never been the cause of complaint.

"As a result of the sudden destruction of great numbers of polluting algæ for a few days immediately after treatment of a water supply there is sometimes an increase in odor and taste.

"The use of copper is an efficient emergency method for sterilizing water contaminated with the bacillus of typhoid fever.

"Metallic copper offers a convenient and efficient means of sterilizing small amounts of water.

"Copper may be useful in the proper disposal of sewage.

"Copper is of great value as a supplement to filtration in case of accident or mismanagement.

"Under certain conditions copper may be used to great advantage in connection with filtration.

"There is no authentic record of fatal copper poisoning, and many of the best authorities do not consider copper a true poison; they hold that it is a natural constituent of the body, and in minute quantities has no effect upon man.

"The suggested medicinal use of copper in cholera, typhoid, and related diseases seems important."

The copper sulphate treatment for algæ at Middletown, N. Y., J. M. CAIRD (*Engin. News, 53 (1905), No. 2, pp. 33, 34*).—The successful treatment of three reservoirs is reported.

Interpretation of a water examination, W. P. MASON (*Science, n. ser., 21 (1905), No. 539, pp. 648–653*).—A general discussion of this subject in which "blind adherence to cut and dried standards" is cautioned against, as is also the hasty adoption of the copper method of purifying water.

The softening of hard water by heating it under pressure, N. KNIGHT (*Engin. News, 53 (1905), No. 12, pp. 311, 312, fig. 1*).—The results of comparative tests of the effect on hardness of boiling water under normal pressure and under pressure of 6 or 7 atmospheres are reported.

It was found "that the precipitation of calcium carbonate is substantially the same in each case, while the precipitation of magnesium carbonate is increased by the difference between 8.52 and 4.61, or 3.91 by the greater pressure. Boiling for 20 minutes at the normal pressure removes 44 per cent of the temporary hardness; that is, the calcium and magnesium carbonates. At the increased pressure, 63.5 per cent is removed. The water, therefore, can not be said to be softened by either process. It was found . . . that on treating the raw water with lime water in the ratio of 6 to 1, 71.42 per cent of the temporary hardness was removed."

A study of the underground waters of the region of Cadereita Mendez, State of Queretaro, J. DE D. VILLARELLO (*Bol. Sec. Fomento* [*Mexico*], *2. ser., 4* (*1905*), *Propaganda No., Pamphlet 13, pp. 5–55*).

SOILS FERTILIZERS.

Investigations in soil management, F. H. KING (*U. S. Dept. Agr., Bur. Soils Bul. 26, pp. 205, pls. 4, figs. 9*).—The three papers included in this bulletin belong to a series of 6 papers constituting the report of the Chief of the Division of Soil Management of the Bureau of Soils for 1902 and 1903. The other three papers of the series were published privately by the author, and have already been noted (E. S. R., 16, p. 546). In recommending the papers for publication, the Chief of the Bureau of Soils explains that the Bureau assumes no responsibility for the opinions and conclusions they contain.

I.—Amount of plant food readily recoverable from field soils with distilled water (pp. 13–78, figs. 3).—This paper reports and discusses "the results of two seasons' investigations relating to the amounts of plant-food materials and other water-soluble salts which could be recovered from different soil types and from the same soil types under different conditions by bringing them into contact with distilled water for a very brief period only." The more important soil types in a number of the areas surveyed by the Bureau of Soils in Georgia, Maryland, New Jersey, North Carolina, Pennsylvania, South Carolina, Virginia, and Wisconsin were studied. "One of the most important objects of these investigations was to ascertain what relation, if any, exists between the character and amounts of the water-soluble salts present in a soil and the yield and quality of crop matured upon it at the same time. In planning and executing those studies the work was so shaped that as far as possible the investigations should be made in direct connection with some crop or crops whose yields could be definitely ascertained and whose growth was under observation."

Earlier investigations along the same line are reviewed. The methods of taking soil samples and preparing the soil and plant extracts are described. "In preparing the soil extract the cores of the soil sample were well broken down and thoroughly mixed in a granite-ware basin. Two 100-gm. samples were then weighed out on a Springer torsion balance, one being transferred to a Wedgwood mortar and the other to the dry oven for moisture determinations. In a graduated flask 500 cc. of distilled water were measured out, and enough was added to the sample in the mortar to work it into a thick paste with the pestle, breaking down the granulations, when the balance of the water was added and the whole stirred continuously with the pestle during 3 minutes. The supernatant turbid liquid was then transferred to a pint Mason jar and from here, usually inside of 15 minutes, to the filter chambers. . . . By means of compressed air in the reservoir the solutions were filtered, under a pressure of about 30 to 40 lbs., through Chamberland-Pasteur filters, and perfectly clear extracts obtained in from 5 to 20 minutes, depending upon the character of the soil or the amount of fine sediment remaining suspended in the solution to be deposited upon the walls of the filters. . . .

"In the preparation of plant extracts for the work here reported the samples were always taken at the places where the soil samples were procured, and at the same

time, in order that the observed soil and plant data might be as definitely related as possible. The plants were cut up when fresh, care being taken to avoid wilting, into fine pieces, to permit of reliable sampling. Then 100 gm. were dried for moisture determination, and 20 gm. were transferred at once to the mortar and thoroughly crushed with the pestle, after which 500 cc. of distilled water were added. The whole was stirred with the pestle during 3 minutes, and the solutions were decolorized and filtered." Decolorization was accomplished by the use of 3 to 5 gm. of carbon black to 100 gm. of soil, or to 20 gm. of green plant. This usually rendered the solution colorless after standing 15 to 20 minutes with frequent agitation.

The methods used in analyzing the extracts have been described in a previous bulletin of the Bureau (E. S. R., 15, p. 457). The earlier studies reported were made with fresh samples of soil. For reasons already noted (E. S. R., 15, p. 233) oven-dried samples were used in the later work.

The results show in general that relatively large amounts of salts are either actually in solution in the soil moisture of the fields examined, or are in such form that they at once enter solution when that moisture is diluted with distilled water, although there were considerable differences between the groups of soils from the different States in the amounts of solids which were recovered from them by extracting with distilled water. It was also shown that the application of fertilizers very materially increased the amounts of salts recovered from the soils.

"The largest amount of solids recovered from the surface-foot of any soil was 934.7 parts per million in the case of a Janesville loam, and the smallest amount, omitting three doubtful results, came from the Selma heavy silt loam, 140.9 parts per million of the dry soil. The first, or largest amount, represents well up toward 2 tons of soluble matter per acre-foot, or 0.3 per cent of the soil moisture, computed on a saturation equal to one-third the dry weight of the soil. . . . There appears to be no relation of amounts of water-soluble salts to the size of soil grains, unless possibly the phosphates recovered do increase as the size of the soil grains decreases." The total water-soluble salts recovered from 8 soil types ranged from nearly an even ton per acre in Norfolk sand to 3 tons in Janesville loam, distributed through the surface 4 ft. of soil.

Data are also reported showing the increased amounts of soluble matter obtained from soils by repeated washing and drying and by continuous percolation; the amounts of soluble salts carried by well and drainage waters, and plant food removed from soils by crops as compared with the amounts recovered by distilled water. The ground waters were found to have a higher content of nitric acid than running waters. It was also shown "that, from the surface 4 ft. of soil, there was recovered per acre enough nitrogen, by the three-minute washing, for a crop of 2½ tons of clover hay. Of potash, there was enough recovered for two, and of phosphorus enough for about five such crops."

II.—Relation of crop yields to the amounts of water-soluble plant-food materials recovered from soils (pp. 79–124, pl. 1, figs. 6).—This paper presents "a study of existing field conditions and relations, [including] a critical comparative study of 8 soil types, bearing the same 2 crops, where all of the conditions under control were made as closely similar as practicable. . . . The prime object was the fullest attainable knowledge of the character of the soil solution and a correlation of this character with different soil types, with different methods of soil management, and with the yields of crops. In carrying out that study the work was so planned that, as far as possible, the soluble-salt determinations were made in connection with some crop whose yields were ascertained and whose growth was under observation." Previous work of like nature, especially that done at Rothamsted and at the Wisconsin Station, is reviewed.

The investigations reported were made on 8 soil types in 4 different States. The crops experimented with were cotton, peas, beans, corn, and oats. The influence of manure and guano and of the moisture content of the soil was also studied.

By the method of washing the soils, carried through the season, and by examining the plant sap of the crops growing upon the soils, it was shown that the recoverable water-soluble salts were materially larger where the yields were also larger.

"The evidence here presented, taken all in all, makes it clear that, in so far as the soils investigated are concerned, there is a well-marked tendency for larger amounts of water-soluble salts to be recovered by the methods adopted from the soils upon which crops have made the largest yields. That the observed differences in yield are due to the observed differences in the salts present in the soils is a distinctly different matter."

There was shown to be "a rather remarkable concordance between the yields and the recovered potash, indicating that the variations in the amounts of potash, in soluble form in the soil, have been more influential in determining differences in yields than have those of the other ingredients studied."

III.—Relation of differences of climatological environment to crop yields (pp. 125–205, pls. 3).—This paper reports and discusses observations made during 1903, in connection with the investigations noted above, at Goldsboro, N. C., Marlboro, Md., Lancaster, Pa., and Janesville, Wis., on some of the climatological conditions affecting the soils and crops. They include records of rainfall, sunshine, soil temperatures and moisture, air temperatures at 4 ft. above the soil in a corn field, and evaporation from a soil saturated by capillarity, as well as "a comparative soil moisture study made on 8 soil types, in which the effect of limiting the capillary supply of moisture and of excluding the rainfall, upon the growth of corn and upon the water content of the soil, [was] determined. . . .

"In order to make a comparative study of the rate of evaporation from continuously moist soil surfaces a soil evaporimeter was constructed from galvanized iron in the form of a cylinder, with closed bottom, 2 ft. deep, which was sunk in the field. . . . The cylinder had a diameter of 4 ft. and was arranged in such a way that an automatic record of the rate of evaporation might be obtained by the use of a water register. . . .

The evaporimeters . . . were all filled with soil from the unfertilized subplots, using soil from the surface 9 in. The soil was introduced in layers about 2 in. thick and firmed so as to secure about the normal weight per cubic foot for the soil in place.

"At the bottom of the evaporimeter there was a water reservoir, rising to the height of 1 ft., upon which the shelter for the water register rested. Water could be added to or removed from the reservoir as desired. Upon this water surface rested the float of the water register. Before introducing the soil the bottom of the evaporimeter was covered with a layer of sand or gravel, thus providing a medium through which the water could spread easily and uniformly under the whole soil surface. The level of the surface of the soil in the evaporimeter was about 2 in. below that of the rim, and was left firm, smooth, and horizontal, and was kept free from all plant growth throughout the season. The level of the water in the reservoir was usually maintained at about 1 ft. below the surface, water being added once per week and removed when made necessary as the result of rains."

A set of similar evaporimeters 4 ft. deep and having a larger reservoir were used for studying evaporation from corn plants grown on the different soils.

In order "to ascertain in how far the soil moisture contained in the soil at the beginning of the growing season is capable of carrying a corn crop toward maturity when no rain is allowed to fall upon the ground, and what the yields would be . . . 2 blocks of soil on each of the 2 soil types at each of the 4 stations were cut off from

the adjacent soil of the field by digging trenches around them to a depth of 4 ft. and incasing these blocks in a framework of lath so as to shut them off from a supply of moisture through lateral capillary movement from the adjacent soil, and in one block in each set the cube was cut off from a capillary supply of water from below by a similar provision. After the blocks had been thus incased the soil was returned to the trenches about them, and corn was planted on the blocks in the soil in its natural field condition, holding the moisture which had been acquired during the rains which had preceded the beginning of the experiment. . . . There was thus secured, on each of the two types of soil at each station, one set of cubes, 4 ft. on a side, where the soil was left in its natural undisturbed condition, and which contained the natural amount of moisture of the field at the time, but from which all supplies of moisture from the sides and from the bottom were cut off, and a second set of cubes in which, while the supplies of moisture from the sides were cut off, there was free opportunity left for a capillary rise of moisture from below. . . .

"From the results regarding yields, the only conclusion which it appears legitimate to draw is that the moisture relations came to be so prejudicial to growth that in no case could the development be even approximately normal."

How to build up worn-out soils, G. W. CARVER (*Alabama Tuskegee Sta. Bul. 6, pp. 15, figs. 2*).—This is a discussion of this subject based upon the results of 8 years' study at the Tuskegee Station, "emphasizing the subject of crop rotation, deep plowing, terracing, fertilizing, etc., keeping in mind the poor tenant farmer with a one-horse equipment."

The results are thus summarized: "(1) It pays to make a good seed bed by preparing the soil deep and pulverizing it thoroughly; (2) swamp muck and leaf mold are valuable as a fertilizer and should be used whenever they can be gotten easily; (3) deep plowing permits the water to go into the soil, thus reducing the terracing to a minimum, which gives more area upon which to grow crops, and also renders cultivation much more easy; (4) peanuts should be grown by every farmer; (5) with proper manipulation our poorest soils may be made to produce an abundance of the staple crops."

The composition of West Prussian soils, M. SCHMOEGER (*Landw. Jahrb., 34 (1905), No. 2, pp. 145-164*).—The agricultural and geological characteristics and mechanical and chemical analyses of 30 soils with corresponding subsoils are reported and discussed.

Geological observations on analyses of some West Prussian soils, A. JENTZSCH (*Landw. Jahrb., 34 (1905), No. 2, pp. 165-176*).—The relations of the geological origin and character to chemical composition of 30 soils and subsoils are discussed.

The chemical nature of the soils of New South Wales with special reference to irrigation, F. B. GUTHRIE (*Jour. and Proc. Roy. Soc. N. S. Wales, Engin. Sect., 37 (1903), pp. LI-LXV*).—A general discussion of this subject, including analyses of typical soils from the semi-arid parts of New South Wales.

Soil investigations [in the Philippines], A. M. SANCHEZ (*[Philippine] Bur. Agr. Rpt. 1904, pp. 63-76*).—This report is largely devoted to a description of certain explorations in Benguet, Cagayan, Isabela, and Union Provinces, and to a history and description of the methods of cultivation of tobacco and other crops in these districts. Physical and chemical analyses of soil samples are presented and compared with soils in certain areas in the United States.

The rational classification of sand and gravel, A. ATTERBERG (*Chem. Ztg., 29 (1905), No. 15, pp. 195-198*).—A new classification of the different grades of soil particles which it is believed to be desirable to separate in mechanical soil analysis is given and discussed with reference to the bearing of mechanical analysis on productiveness of soils.

The mineralogical analysis of soils, J. DUMONT (*Compt. Rend. Acad. Sci. [Paris], 140 (1905), No. 16, pp. 1111-1113*).—The methods used by the author are

described in detail. These methods involve 2 series of operations, (1) the separation of the unaltered sand by means of chemical reagents, and (2) the separation of the different minerals which are present.

Denitrification of soil, III, G. AMPOLA (*Gaz. Chim. Ital., 34 (1904), II, pp. 301–315; abs. in Jour. Chem. Soc. [London], 88 (1905), No. 509, II, p. 194*).—Studies are reported which lead to the following conclusions:

Applications of calcium and sodium nitrates give better results than no nitrate, the calcium nitrate being more effective than the sodium nitrate. Green manures give better results than well-rotted stable manure, the latter better than fresh stable manure, and fresh stable manure better than straw. The general conclusion, confirming results previously obtained, is that calcium nitrate, a natural product of nitrification, is a better fertilizer than sodium nitrate. The calcium salt, moreover, offers greater resistance to the action of the denitrifying organisms than the sodium salt, denitrification depending mainly upon the character of the organic matter of the manure.

The author believes that danger from denitrification in the soil may be wholly or partially obviated only when the organic substances have been decomposed—that is, when the denitrifying organisms have been reduced to a state of inactivity.

Experiments on the accumulation and utilization of atmospheric nitrogen in the soil, E. B. VOORHEES and J. G. LIPMAN (*Jour. Amer. Chem. Soc., 27 (1905), No. 5, pp. 556–589*).—A series of pot experiments are reported which were designed to show the relation of leguminous crops, such as cowpeas, to soil nitrogen and to determine as far as practicable the value of such crops as a source of nitrogen to subsequent nonleguminous crops.

"The facts established in this experiment are of very considerable practical importance, even though the experiment itself was carried out under conditions more or less artificial. They demonstrate, in no uncertain manner, that the bacterial activities that concern the gain and loss of nitrogen in the soil are manifold and complex, and yet susceptible of differentiation. Evidently there was a gain of nitrogen in the box soils by means of symbiotic fixation where the cowpea crop was grown."

Substantially the same matter has been published as Bulletin 180 of the New Jersey Stations (E. S. R., 16, p. 1063).

The absorptive property of the leaf cover of the soil of forests, E. HENRY (*Bul. Soc. Sci. Nancy, 3. ser., 5 (1904), No. 2, pp. 105–115*).—Studies by Calas's method of the absorptive capacity for water of the undisturbed leaf cover of one square meter of forest soil showed that a cover of picea needles absorbed 418 gm. of water per 100 gm. dry weight of cover, and beech leaf cover absorbed 538 gm.

The varying absorbent power of soils for bone superphosphate and mineral superphosphate, C. MONTANARI (*Staz. Sper. Agr. Ital., 38 (1905), No. 3, pp. 253–258*).

Agricultural phosphate, BACHMANN (*Fühling's Landw. Ztg., 54 (1905), Nos. 2, pp. 49–51; 3, pp. 84–90; 4, pp. 136–142; 5, pp. 177–185*).—A series of comparative tests of this phosphate and Thomas slag on a variety of crops grown on loam and sandy soils are reported.

The "agricultural phosphate" used was a crude phosphate containing 22 to 24 per cent of total phosphoric acid. The Thomas slag contained about 20 per cent of total phosphoric acid, of which about 16 per cent was soluble in citrate solution. The results show that the two phosphates were about equally effective on the loam soils, but that the "agricultural phosphate" was somewhat less effective than Thomas slag on the sandy soils.

Fertilizer experiments with calcium cyanamid on common soils and on moor land, H. VON FEILITZEN (*Svenska Mosskulturför. Tidskr., 19 (1905), No. 2, pp. 100–110, figs. 2*).—Experiments conducted during the season of 1904 with barley, oats, wheat, and potatoes indicated that this fertilizer on certain soils, like clayey and

sandy soils, as well as on the better kinds of decomposed moor soils, gave considerably poorer results than nitrate of soda, and was not quite equal to sulphate of ammonia. On poorly decomposed white-moor soils its effect was insignificant, and its use on such soils can not therefore be recommended.—F. W. WOLL.

Manurial experiments with calcium cyanamid and garden plants, R. OTTO (*Gartenflora, 53 (1904), No. 20, pp. 534–538; abs. in Jour. Chem. Soc. [London], 88 (1905), No. 509, II, p. 196*).—"Calcium cyanamid was found to be equal to nitrates and ammonium salts in the case of spinach, although at first growth was somewhat retarded. Equally satisfactory results were obtained with lettuce when planted 12 days after manuring. The results of pot experiments showed that calcium cyanamid gave better results with white cabbage and maize than sodium nitrate. The manure seems to be suitable for garden plants, provided that it is applied a week or two before planting, or else dug in to a depth of 13–26 cm."

The action of nitrate of soda and sulphate of ammonia in connection with lime on sandy soils, BACHMANN (*Fühling's Landw. Ztg., 54 (1905), No. 6, pp. 219–223*).—Comparative tests of these 2 materials with and without the addition of lime on barley, oats, and beets are reported. The results show that the action of the ammonium sulphate was increased by the addition of calcium carbonate; that of nitrate of soda was not materially affected.

The use of leucin and tyrosin as sources of nitrogen for plants, L. LUTZ (*Compt. Rend. Acad. Sci. [Paris], 140 (1905), No. 6, pp. 380–382*).—Sand cultures with pumpkins and cultures in Raulin's solution with fungi (Aspergillus and Penicillium) indicate that leucin and tyrosin are readily assimilated by both phanerogams and fungi.

Inoculation of soil with nitrogen-fixing bacteria, A. F. WOODS (*U. S. Dept. Agr., Bur. Plant Indus. Bul. 72, pt. 4, pp. 10*).—In this publication the author briefly describes the commercial production of cultures of nitrogen-fixing bacteria, states when inoculation is necessary and when it is not to be recommended, and describes various conditions under which failures may be expected. Directions for the handling of the culture material are given, and certain dangers that may attend inoculation by soil transfer are pointed out.

On the results of four years' culture and liming experiments on moor soils, B. HARDT (*Deut. Landw. Presse, 32 (1905), No. 29, pp. 253, 254*).

On the injurious effect of an excess of lime applied to the soil, S. SUZUKI (*Bul. Col. Agr., Tokyo Imp. Univ., 6 (1905), No. 4, pp. 347–351*).—A series of pot experiments with rice to further elucidate the cause of the depression of availability of phosphoric acid in presence of large amounts of lime is reported.

It was found that an excess of calcium carbonate depressed the yield very decidedly notwithstanding the fact that phosphoric acid was applied in the easily available form of secondary sodium phosphate. On the other hand, the application of calcium sulphate under the same conditions resulted in an increased yield, indicating that the application of the carbonate depressed the assimilability of the phosphoric acid. The application of powdered magnesite at a rate furnishing three times as much magnesia as lime greatly depressed the yield. The application of moderate amounts of lime in connection with bone dust did not noticeably diminish the yield. This occurred, however, in a soil containing 11 per cent of humus.

The analyses of stone lime, prepared lime, oyster-shell lime, wood ashes, and marl, L. A. VOORHEES (*New Jersey Stas. Bul. 183, pp. 27*).—Chemical and physical examinations of a large number of samples of these materials are reported and discussed. Practical directions regarding the use of lime are quoted from Pennsylvania Department of Agriculture Bulletin 61 (E. S. R., 12, p. 627).

Analyses and other studies of West Prussian marl, lime, and other commercial lime fertilizers, M. SCHMOEGER (*Landw. Jahrb., 34 (1905), No. 2, pp. 177–232*).—A large amount of analytical data is reported and discussed.

Commercial fertilizers, A. Goss and W. J. Jones, Jr. (*Indiana Sta. Bul. 106, pp. 52, map 1*).—The results of analyses of 643 samples of fertilizers inspected during 1904 are reported and discussed.

Fertilizer inspection, C. D. Woods and J. M. Bartlett (*Maine Sta. Bul. 114, pp. 37-52*).—"This bulletin contains the analyses of manufacturers' samples of brands of fertilizers licensed before March 1, 1905."

Analysis of commercial fertilizers sold in Maryland, H. B. McDonnell et al. (*Md. Agr. Col. Quart., 1905, No. 27, pp. 52*).—This is a report on fertilizer inspection during the period from July, 1904, to January, 1905, inclusive.

Report of analyses of samples of fertilizers collected by the commissioner of agriculture during the summer and fall of 1904 (*New York State Sta. Bul. 266, pp. 231-261*).—Analyses of samples of fertilizers collected by the commissioner of agriculture of New York during the fall of 1904 and transmitted for analysis to the director of the State experiment station, in accordance with the proprovisions of Article XII of the new agricultural law. It is explained that the analyses are published by the station in accordance with the provisions of Chapter 570, Laws of 1904, and that discussion of the results of the inspection and the explanatory and informational matter heretofore accompanying the reports of the inspection of fertilizers are omitted in accordance with the ruling of the commissioner of agriculture.

Licensed commercial fertilizers, F. W. Woll and G. A. Olson (*Wisconsin Sta. Bul. 122, pp. 1-16, 22-24*).—Analyses and guaranteed composition of fertilizers licensed for sale in Wisconsin during 1905 are reported, with notes on composition, valuation, and purchase of fertilizers, and the text of the State fertilizer law.

The by-products of maritime fisheries: Fish oils and fertilizers, D. Bellet (*Rev. Sci. [Paris], 5. ser., 3 (1905), No. 16, pp. 488-492*).—A general discussion of this subject.

AGRICULTURAL BOTANY.

The regeneration of seedling roots after splitting, Lura A. Warner (*Rpt. Mich. Acad. Sci., 6 (1904), p. 78*).—An abstract is given of a report on experiments with roots of beans, in which the regeneration after splitting is noted. When the roots are split they assume a half-moon shape in cross section. This cross section becomes rounded out by the formation of callus over the cut surface, and the 4 to 7 fibrovascular bundles which are contained in the roots under normal conditions have their functions taken up by about 3 bundles after splitting. Otherwise the regenerated root acts in a perfectly normal manner.

Notes on the regeneration of the hypocotyl of flax, Mary E. Hedden (*Rpt. Mich. Acad. Sci., 6 (1904), p. 79*).—The effect of removing the cotyledons from flax seedlings is shown, and notes also given on the conditions influencing the regeneration of buds which develop below the cotyledons. Uninjured plants did not develop the buds in dry atmospheres, but where the cotyledons were cut off, in the course of a few days numerous buds were developed under both dry and moist conditions. The number of buds produced was influenced by the age of the plant, the young hypocotyls sending out from 1 to 60 buds, while on the old ones never more than 3 were formed. More buds developed in a saturated atmosphere than in a dry one, and they developed very quickly at a high temperature.

The experiments show that age, moisture, temperature, light, and season are all important factors in influencing the formation of hypocotyl buds.

The regeneration of the epicotyl in bean and pea seedlings, Arabel W. Clark (*Rpt. Mich. Acad. Sci., 6 (1904), p. 80*).—A brief abstract is given showing the results of experiments carried on to ascertain the ability of bean and pea seedlings to repair injuries.

Cotyledons were planted with a small piece of epicotyl left attached, and it was found that the whole plant was regenerated. This took place whether a whole cotyledon or only a piece of the cotyledon was left intact, indicating that regeneration is not wholly dependent on the food supply. When the epicotyl was injured or removed, buds which had been produced in normal growth developed, and upon the removal of these other shoots continued to appear until all the embryonic tissue was dead. After the epicotyl had attained a height of about 10 cm., regeneration became uncertain, and at 20 cm. only an occasional seedling was able to regenerate mutilated portions, even though the cotyledons were found to be rich in food supplies.

The author concludes that regeneration of the epicotyls of beans and peas is dependent more upon the age of the tissue than upon the amount of food supply at hand.

On different degrees of availability of plant nutrients, O. LOEW and K. ASO (*Bul. Col. Agr., Tokyo Imp. Univ., 6 (1905), No. 4, pp. 335–346*).—The results of studies on the chemical availability of lime and magnesia are given, from which the authors claim that the former ratio of lime to magnesia, or the lime factor as it was called (E. S. R., 15, p. 1062), was based on the idea of an equal state of availability of the lime and magnesia present in the soil.

It has since been learned that the ratio changes with the availability of the bases, and magnesia in the burnt form is more available than in the pulverized magnesite. The magnesium sulphate is still more available than either. The physiological action of lime and magnesia must be distinguished from the changes which these bases exert upon the soil. Gypsum acts indifferently on account of its low availability. The carbonate of lime is much more available for plant use.

Can aluminum salts increase plant growth? Y. YAMANO (*Bul. Col. Agr., Tokyo Imp. Univ., 6 (1905), No. 4, pp. 429–432*).—Experiments are reported with barley and flax grown with and without various amounts of ammonium alum, from which it appears that this salt exerts a stimulating effect when used in moderate quantities.

The action of poison on plants, E. VERSCHAFFELT (*K. Akad. Wetensch. Amsterdam, Proc. Sect. Sci., 6 (1904), pt. 2, pp. 703–707, dgm. 1*).—The author claims that the ability to absorb water through the osmotic properties of the protoplasm will continue until the cell walls allow no further expansion or the plant is killed.

When any part of an organ is previously killed no water is absorbed. On the contrary the dissolved substances in the cell sap are diffused out. This fact the author makes use of as a basis for determining the action of poisons on plants, and reports upon investigations with portions of potato tubers, beet roots, leaves of aloes, and leaf stalks of the begonia and other plants. A piece of tissue was considered undamaged if after having stayed in the poisonous solution for 24 hours and then in water for 48 hours it continued to gain in weight.

The effect of a number of substances on portions of plants is shown, indicating the harmful limit of concentration. This was determined for copper sulphate at between 0.002 and 0.003 grammolecule per liter. It was found also that the harmful limit of concentration may be determined for neutral mineral salts which in certain dilutions are not injurious. Sodium chlorid was found to partially neutralize the poisonous effect of a number of organic poisons, such as oxalic acid, chinine hydrochlorid, etc.

Concerning cauliflorous flowers and fruits, L. BUSCALIONI (*Malpighia, 18 (1904), pp. 50, pls. 2; abs. in Bot. Centbl., 96 (1904), No. 49, pp. 578, 579*).—A critical review is given of observations and theories regarding the direct occurrence of flowers and fruits on the trunks and larger branches of trees, such as cacao, calabash, and other tropical trees.

The author believes the production of flowers and fruit in this manner to be a primitive characteristic which persists in many plants that live in moist, hot regions. The

especial significance of this unusual method of fruiting is held to be a means of protection of the flowers against too much rain and also to protect them and the fruit from excessive heat, the trunks of the trees being usually the portion best shaded. These plants are also said to have especial devices for protection against insects.

The frost injuries of leaves, H. SOLEREDER (*Centbl. Bakt.* [*etc.*], *2. Abt.*, *12* (*1904*), *No. 6–8, pp. 253–262, figs. 8*).—A description is given of the anatomical changes caused in apricot and beech leaves by the action of frost.

Physiological drought in relation to gardening, I. B. BALFOUR (*Plant World*, *8* (*1905*), *No. 1, pp. 1–5*).—After discussing the water relationships of plants when grown under natural conditions, the author considers the water requirements of plants under horticultural practice, and states that in no direction has research in recent years provided more valuable data of significance to horticulture than in that of water relationship of plants.

The relation of soils to physiological drought is discussed, after which the author calls attention to a number of gardeners' problems and offers explanations concerning them. Among these may be mentioned the explanation of marsh plants growing in sand, epiphytic orchids grown in pots containing peat, the changed condition of epiphytic plants when grown in greenhouses, conditions of physiological drought caused by cold, pot cultivation, etc. A proper conception of the explanation of all these phenomena is held to be requisite for the rational cultivation of plants.

Anthocyanin and its biological significance in plants, L. BUSCALIONI and G. POLLACCI (*Atti Ist. Bot. Univ. Pavia, 2. ser.*, *8* (*1904*), *pp. 135–511, pls. 10*).—The authors present an elaborate memoir on the occurrence and biological significance of anthocyanin.

After a discussion of pigments and other coloring matters in plants, the authors give an account of the localization of anthocyanin in different parts of plants, its chemical composition, spectroscopic analysis, influence of media, climate, etc., on its formation, the relation of this coloring matter to various physiological activities of plants, pathological conditions, etc. Experiments are described at length on the distribution, localization, effect of various physical and other agents on the production of anthocyanin, etc.

The investigations are summarized and various hypotheses are offered regarding the rôle of anthocyanin in plants. A bibliography of nearly 1,000 references to literature is given.

Investigations on chlorophyll assimilation, G. POLLACCI (*Atti Ist. Bot. Univ. Pavia, 2. ser.*, *8* (*1904*), *pp. 1–66, pls. 3*). The results of a prolonged series of investigations on chlorophyll assimilation and the various factors which determine and modify photosynthesis are given. A considerable list of publications consulted is appended as a bibliography.

The importance of the removal of the products of growth in the assimilation of nitrogen by the organisms of the root nodules of leguminous plants, J. GOLDING (*Jour. Agr. Sci.*, *1* (*1905*), *No. 1, pp. 59–64*).—In order to ascertain the rôle of the host plant in the process of nitrogen assimilation the author planned a series of experiments, the main feature of which was the removal of the soluble products of growth in a way similar to that which occurs in nature. This removal was affected by the use of a porous Chamberland filter candle fixed in the culture vessel.

The leaves, stems, roots, and nodules of young bean plants, water extracts of young pea plants, and sterilized extracts of similar plants were cultivated. In the first experiments the plants were simply cut up and bruised in a mortar, the initial infection being provided by the organisms present in the crushed tubercles. In the later experiments with sterile liquids the cultures were inoculated from pure cultures of the organisms grown on agar. The details of the experiments are given and the amount of nitrogen fixed in each case is shown.

In conclusion the author states that his experiments showed that larger amounts of nitrogen were assimilated in artificial cultures than in any previous experiments, indicating that the conditions of growth obtaining in the culture vessels favored the assimilation of nitrogen. From this it seems probable that one of the functions of the host plant is the removal of soluble products of growth, which when present in previous artificial cultures have prevented the assimilation of nitrogen.

The fungicidal action of fungus cultures, Y. KOZAI and O. LOEW (*Bul. Col. Agr., Tokyo Imp. Univ., 6 (1904), No. 2, pp. 77-79*).—The authors cite a number of instances in which the inhibiting action of the growth of certain organisms toward others is shown and give brief notes on their investigations on the effect of cultures of fungi and bacteria on the development of other organisms subsequently added to the media.

The subject has an economic application in the failure to ferment miso, the Japanese vegetable cheese, during very hot weather. The explanation of this failure is the possibility of the inhibiting action of other organisms which readily grow at temperatures higher than the optimum for the miso organism.

Symbiosis between Azotobacter and Oscillaria, H. FISCHER (*Centbl. Bakt. [etc.], 2. Abt., 12 (1904), No. 6-8, pp. 267, 268*).—Notes are given on the symbiotic association of species of Azotobacter and Oscillaria, and the author points out the symbiotic relationships which exist between a number of other species of plants.

Relationship of Macrophoma and Diplodia, JULIA T. EMERSON (*Bul. Torrey Bot. Club, 31 (1904), No. 10, pp. 551-554, pl. 1*).—While making studies of fungi occurring on flower bud spathes of cocoanut, the author was led to examine the associated Macrophoma and Diplodia species.

Cultures taken from the spathes were reasonably sure to produce typical spores of each fungus. The different forms were isolated and studied, and the author concludes that the unicellular white spores in the pycnidia of Macrophoma are simply the immature form of mature Diplodia spores. The Macrophoma form of this species was described originally under the name *Sphæropsis palmarum*, a technical description of which is given.

Notes on the blackening of Baptisia tinctoria, JULIA T. EMERSON (*Bul. Torrey Bot. Club, 31 (1904), No. 12, pp. 621-629*).—The blackening of the wild indigo (*Baptisia tinctoria*) after the opening of the flowers is a phenomenon of common observation, the entire plant, even to its flowers, frequently turning black.

The author has made a study of the possible causes of this change, and arrives at the conclusion that the blackening is due to the action of oxidizing enzyms. There are said to be at least two enzyms present, an oxidase, which gives an opalescent blue with a gum guaiac solution and which is destroyed at temperatures of 83-84° C., and a peroxidase, which gives a deep blue with hydrogen peroxid and which has a thermal destruction point of 86-87° C. Both enzyms are destroyed by dilute solutions of citric acid and sodium hydroxid.

FIELD CROPS.

Report of the Upper Peninsula Substation for 1904 [Field crops], L. M. GEISMAR (*Michigan Sta. Spec. Bul. 31, pp. 1-23*).—The weather conditions of the season are noted and the results with the different field crops are reported. The work of former years has been previously described (E. S. R., 16, p. 250).

Wet weather in May and September favored rust attacks in the grain crops. In the experience of the station oats have been more affected by rust than the other cereals, and no so-called rust-proof varieties have resisted rust attacks. Early Champion oats was practically free from rust in 1904, but this was due to its early maturity. The yields of different varieties under test ranged from 25 to 47.5 bu. per acre. The leading varieties were Early Champion, White Shonen, University No. 6, and

American Banner, yielding 47.5, 46.25, 42.5, and 40 bu. of grain per acre, respectively. The lowest yield of straw, 2,280 lbs. per acre, was produced by University No. 6, and the highest, 5,920 lbs., by American Banner.

The most productive varieties of barley were Champion, Manscheuri 6-rowed, University No. 105, and Chevalier, the corresponding yields being approximately 48, 46, 39, and 35 bu. per acre. White Hulless barley gave the lowest yield of grain and the highest yield of straw. Dawson Golden Chaff winter wheat yielded over 25 bu. per acre, and Saskatchewan Fife and Velvet Chaff spring wheats about 20 bu. A plat of spelt or emmer yielded at the rate of 70 bu. of grain and 2,800 lbs. of straw per acre.

Buckwheat was very successful; the leading variety, known as Rye buckwheat, gave a yield per acre of 36 bu. Of the different varieties of field peas tested, French June has given the best results, the yield this season being at the rate of 30 bu. of peas and 2,440 lbs. of straw per acre. Canadian Blue and Scotch also gave good yields. The varieties of corn giving greatest promise of success were Will Dakota, Gehû, Golden Dent, and Early Adams.

Notes are given on the growth of lentils, flax, and hemp, and a list of grasses and leguminous forage crops. The heaviest yields per acre among the forage crops were as follows: German alfalfa 11,280 lbs., alsike clover 6,800 lbs., meadow fescue 6,720 lbs., Siberian millet 6,400 lbs., Hungarian millet 6,080 lbs., and tall meadow oat grass 5,680 lbs. German and American alfalfa gave better results than either French or Turkestan alfalfa.

Of 21 varieties of potatoes Dolsen ranked first, with a yield at the rate of 290 bu. per acre, and Carman No. 3, Sir Walter Raleigh, and Northlight ranked next. Potatoes planted June 6 yielded 4,106 lbs. and those planted November 6, 4,111 lbs. of tubers per acre. A culture test resulted in favor of level cultivation by 277 lbs. per acre. Spraying with Bordeaux mixture gave slightly better results than no treatment.

The sugar content of Friedrichswerther Elite and Jaensch Victrix sugar beets, grown in 1903, was 14.2 and 15 per cent, respectively. Sugar beets left unharvested in 1903 began to blossom the next season on July 13, when the plants were about 3 ft. high, and the first seed ripened the latter part of August. The plants continued to grow and blossom and were about 7 ft. high when injured by frost September 22. In 1904 Jaensch Victrix yielded at the rate of 20,328 lbs. per acre, and of 2 samples analyzed, one showed a sugar content of 18.8 per cent and the other of 15 per cent.

In addition to sugar beets, carrots, turnips, ruta-bagas, parsnips, kohl-rabi, mangels, and garden beets were grown. The approximate yields of the leading varieties in bushels per acre were as follows: Maud S. carrots 1,082, Yellow Stone turnips 1,540, Prize Winner ruta-bagas 1,115, Marrowfat parsnips 774, Purple Vienna kohl-rabi 968, Improved Dignity Red mangels 484, and Improved Long Dark Blood beets 420. A number of varieties of each crop are briefly described.

Root systems of field crops, J. H. Shepperd (*North Dakota Sta. Bul. 64, pp. 525–540, figs. 10*).—This study of the root growth of plants is in continuation of previously reported work (E. S. R., 12, p. 516).

The root systems of corn, potatoes, winter rye, wheat, barley, oats, emmer, flax, brome grass, slender wheat grass, red clover, crimson clover, and alfalfa are presented in the illustrations, and the manner of preparing the samples is described. The corn root samples secured at the station and at the Edgeley Substation showed that at Edgeley the roots did not penetrate the soil so deeply as at Fargo, which is considered as probably due to an underlying strata of shale. The observations made again point to the necessity of shallow cultivation. The potato root studies also indicated that shallow cultivation must be practiced.

The roots of the winter rye sample, taken July 7, reached a depth of only 3 ft., and their development was smaller than in other samples of cereals generally. It is

believed that early in the season the soil in that latitude is too cold below a depth of 3 ft. to admit of root growth. The roots of durum and bread wheat reached a depth of more than 4 ft., and showed that the system of rooting is vertical instead of lateral, as in corn and potatoes. The root development was greater in the durum than in the bread wheat samples. As observed by the station, the root development in cereals varied considerably during different years.

The samples of barley and oats showed a comparatively light and shallow root growth. The roots of emmer resembled those of wheat and extended to a depth of 3½ ft. The flax roots grew almost directly downward and branched very little. In the specimens studied they had reached a depth of 4 ft. The brome grass specimen taken from a 3-year-old sod showed the densest rooting of all samples. Native slender wheat grass, also from a 3-year-old sod, did not have the strong root growth of the brome grass, but its root system was heavier than that of any other crop studied. During 2 years of growth the roots of red clover had grown down over 4 ft. and had quite fully occupied the upper 3 ft. of soil. Crimson clover roots in a single season had attained a depth of 3 ft. by August 22.

Hand hoeing of grains, K. Kubis (*Deut. Landw. Presse, 32 (1905), No. 11, pp. 84, 85*).—Experiments conducted in 1903–4 are reported, and the results show that barley, oats, and wheat were profitably hoed with a hand hoe working two rows at a time. The larger yields are considered as resulting from preventing the formation of a crust on the surface of the soil, and in general to the conservation of soil moisture. The stubble on the hoed plats was plowed under easier and better than on the check plats.

The influence of seed, soil, and fertilizers on the endosperm of spring wheat and barley, H. von Feilitzen (*Jour. Landw., 52 (1904), No. 4, pp. 401–412*).—Experiments were conducted for 2 years on 4 different kinds of soils, and the results show that in the same sample of spring wheat or barley the hard glassy kernels are richer in protein than those of a mealy constituency.

Glassiness or mealiness in the seed produced no effect upon the yield or upon the size of the kernel, but apparently exerted a slight influence upon the glassiness and mealiness of the grain. The proportion of glassy kernels was found to be greater and the protein of the grain was higher, as a rule, on moor soil than on soil of mineral origin. The climatic conditions of the season are considered as producing a marked effect on the quality of the grain. Nitrogenous fertilizers, in general, increased the percentage of glassy kernels.

It is concluded that the soil, the fertilizers used, and especially the weather conditions, exert a greater influence upon the texture of the grain of either spring wheat or barley than the seed, and that the use of mealy seed can not be regarded as a factor in breeding a better barley for malting purposes.

The influence of fallow and pea culture on the nitrogen balance of soils and the growth of wheat, F. Wohltmann and P. Schneider (*Deut. Landw. Presse, 31 (1904), No. 102, pp. 853–855*).—The results of experiments showed that the fallowed soil was in a better physical condition and also furnished a larger supply of nitrates to the succeeding crop than the soil which had produced a crop of peas. The ammonia content of the soil did not show marked differences.

Fallow is considered more advantageous to a succeeding crop of winter wheat than pea culture on account of the greater amount of soil moisture it provides. Four varieties of winter wheat after fallow gave higher yields of grain and straw, and one variety a smaller yield than when grown after peas. The weight of the grain, as determined for 3 varieties, was in every case in favor of the wheat grown after peas.

Crops for the silo, cost of filling, and effect of silage on the flavor of milk, W. J. Fraser (*Illinois Sta. Bul. 101, pp. 627–644, figs. 7*).—This bulletin discusses the advantages and value of silage, the crops best grown for the purpose, the

time and method of harvesting them, and the essentials of silo filling. Records of the cost of filling the silo, kept by the station on 19 different farms in various parts of the State, show a range of from 40 to 76 cts. per ton, the average being 56 cts. The effect of silage on the flavor of milk is noted elsewhere.

Manurial experiments on permanent meadow land (*Harper-Adams Agr. Col. Bul. 2, pp. 3*).—Different fertilizer applications were compared on meadow land of a stiff clay loam resting on a deep bed of clay overlying red sandstone. The most profitable returns were obtained from the use of 2½ cwt. of superphosphate and ½ cwt. of sulphate of potash per acre. Nitrate of soda at the rate of 1½ cwt. per acre was ineffective, and 10 tons of barnyard manure per acre was also unprofitable. The use of barnyard manure reduced the quality of the herbage.

Range management in the State of Washington, J. S. COTTON (*U. S. Dept. Agr., Bur. Plant Indus. Bul. 75, pp. 26, pls. 3*).—This bulletin briefly reviews the history of the ranges in the State, suggests methods for their improvement, and discusses the management of pastures. The important species of forage plants growing on the different grazing areas are enumerated and their value briefly pointed out.

It is believed that the winter pastures in the arid regions may be restored by protection from overgrazing during the season when the native forage plants are producing seed, and by alternately grazing different sections so that part of the range or pasture may remain ungrazed during the winter and in the spring when the young plants begin to grow. Cases are cited which show that improvement of the range can be accomplished by this treatment.

Experiments carried on for 3 years in the Rattlesnake Mountains, where the annual precipitation is 13 in., have shown that bunch grass could be successfully grown on cultivated land, and that alfalfa and hairy vetch are of value for that section. The native grasses, such as bunch wheat grass, proved to be the best forage plants for the region. The author believes that the restoration of badly depleted ranges on the semiarid lands may be hastened by gathering the seed of bunch grass or giant rye grass and reseeding the denuded areas. He suggests that the seed might be either harrowed in or stamped in by sheep herded over the reseeded portions.

The mountain grazing areas or summer pastures, owing to a greater rainfall, are not as difficult of improvement as the semiarid lands. Experiments conducted in these regions for 2 years show that of the number of grasses sown timothy, mountain brome grass (*Bromus marginatus*), tall fescue, and brome grass, in the decreasing order of merit, proved adapted to the conditions. This work further demonstrated the value of harrowing in the seed, and showed that the use of the harrow also had a very favorable effect upon the native grasses and forage plants, especially upon *Bromus marginatus*, *Stipa occidentalis*, and *Vicia americana*.

Alfalfa or lucern, R. A. MOORE, A. L. STONE, and G. A. OLSON (*Wisconsin Sta. Bul. 121, pp. 22, figs. 8*).—A part of the work described in this bulletin has been noted from another source (E. S. R., 16, p. 763). In addition a method of protecting alfalfa with hay caps is given, and the results of comparative tests with alfalfa, clover, timothy, and brome grass, together with a determination of the water, protein, and fat in the green substance and the hay from these crops, are reported.

The total of 4 cuttings of alfalfa gave 32,376 lbs. of green substance, 10,800 lbs. of hay, 8,900 lbs. of dry matter, 1,996 lbs. of protein, and 288 lbs. of fat per acre. The weight of green forage obtained was approximately 2, 3, and 5 times that of clover, timothy, and brome grass, respectively, and the proportions for hay were nearly the same.

The analyses also showed that alfalfa yielded nearly 3 times as much protein per acre as clover, 9 times as much as timothy, and 12 times as much as brome grass, while the dry matter and fat were also greatly in favor of alfalfa. The average protein content in the alfalfa hay was 18.7 per cent and in the green forage 6.4 per cent,

while clover contained 13.28 per cent in the hay and 4.47 per cent in the green forage, timothy 4.47 per cent in the hay and 2.17 per cent in the green forage, and brome grass 6.7 per cent in the hay and 2.7 per cent in the green forage.

A summary of data obtained in tests with alfalfa by members of the Agricultural Experiment Association of Wisconsin shows that of 124 members reporting, 110 advocate sowing with a nurse crop, 99 using oats for this purpose, and 118 favor sowing 2 varieties. As compared with the Turkestan variety common alfalfa is considered best by 28, while 81 could detect no difference. The best rate of sowing as shown by these data is 20 lbs. of seed per acre.

Red clover from various sources, W. M. MUNSON (*Maine Sta. Bul. 113, pp. 28-36*).—A study of red clover from various American and European sources was made in cooperation with this Department in 1902 and 1903.

Germination tests made of all the seed showed that a high percentage of sprouting under favorable conditions, as in a seed tester or on blotting paper, is no proof that similar results will be obtained when the seed is sown in soil. Of the foreign seeds those from Upper Austria, Styria, Hungarian Transylvania, and Russia were apparently the most vigorous, and the American seed from Ohio and Illinois was the strongest.

In 1902, 29 different lots of seed were sown May 19 on plats of 2 square rods each, at the rate of 12 lbs. per acre. The plants began to appear May 26. Those from north European seed were later in maturing than those from seed grown farther south or from American seed. On August 30 the plats sown with seed from Indiana and Bohemia were in good condition for hay. The largest yields were obtained from seed obtained from Minnesota, Bohemia, Indiana, Wisconsin, Brittany, and Ohio, in the order given. The yields of hay per acre for the entire list of tests ranged from 1,040 lbs. for seed from Norway to 4, 040 lbs. for seed from Minnesota and Bohemia.

The shrinkage in curing for hay ranged from 68 to 82 per cent, the average being about 73 to 75 per cent. In 1903 the earliest plats were those from Indiana, Hungarian Mountain Region, and Ohio, being closely followed by plats from Bohemia, Italy, Illinois, and Wisconsin. The earliest plats were ready for cutting June 29. The highest total yield of hay for the season, 3.9 tons per acre, was obtained from Indiana seed, with seed from Bohemia standing second, with a yield of 3.28 tons.

Directions for the breeding of corn, including methods for the prevention of inbreeding, C. G. HOPKINS, L. H. SMITH, and E. M. EAST (*Illinois Sta. Bul. 100, pp. 599-625, figs. 2*).—Experiments to determine the effect of detasseling were carried on for 4 years in connection with corn-breeding work. For 3 years the even-numbered rows on 2 breeding plats containing 44 rows each were detasseled and each succeeding year the even numbered rows were planted with seed selected from the best detasseled rows and the odd-numbered rows with seed selected from the best tasseled rows. Each plat, therefore, contained 22 tasseled rows and 22 detasseled rows, and the seed was saved from the best 10 rows in each lot.

The detasseled rows had no influence upon the breeding of the tasseled rows, but they themselves were necessarily crossbred each year. The tasseled rows, however, in the nature of the case became more or less inbred. The benefits produced by this system of cross breeding are shown in tables; and in addition to general directions for the selection of corn and the management of the breeding plat, a plan for planting to avoid inbreeding is outlined.

Mechanically selected high protein and low protein Leaming corn was grown in these tests. The high protein Leaming showed an average increase in favor of the detasseled rows of 1.6 bu. per acre the first year, 10.1 bu. the second year, and 9.3 bu. the third year, while the detasseled rows of the low protein Leaming yielded 5.9 bu. per acre less than the tasseled rows in the first year of the test and 14.7 and 11.8 bu. per acre more the second and third years, respectively. The individuality of

seed ears was brought out in several instances by the yields of rows located near each other.

In 1902 rows 5 and 7 in the high protein plat produced 74.6 and 86.4 bu. per acre, and in 1904 rows 22 and 24 produced 79.2 and 96.4 bu. per acre, respectively. The results of mechanical selection of corn by different parties showed that in every case a gain was made in the average protein content of the selected ears. The authors recommend planting the breeding plat with the seed from 96 selected ears in 96 separate rows, to detassel completely every alternate row before the pollen matures, and to select all of the seed corn from the 48 detasseled rows. It is advised to allow the tassel to develop sufficiently to be separated alone at the top joint by a careful pull.

The breeding plat according to the proposed plan is divided into quarters, each containing 24 rows and each row representing a separate seed ear. The even-numbered rows are detasseled and 4 ears are selected for seed from each of the 6 best-yielding detasseled rows in each quarter, making 96 ears in all. "It is recommended that these 96 seed ears be numbered from 1 to 48 and from 51 to 98, the numbers 49 and 50 being omitted; also, that ears 1 to 48 be planted in one half of the plat and ears 51 to 98 be planted in the other half, preferably end-to-end with the first half, leaving one hill unplanted to mark the line between the two halves, also leaving one row unplanted to mark the line between rows 24 and 25 and between rows 74 and 75; that is, between quarters."

It is advised, however, to start the first year in the 100 series, numbering the ears to be planted in succession from 101 to 148, and from 151 to 198; the second year from 201 to 248, and from 251 to 298, and so on. The seed ears planted in the odd-numbered rows to produce tassels and to furnish pollen are referred to as "sire seed" and the seed ears for the even-numbered rows, which will contain the mother plants producing the future seed, are called "dam seed." Two of the 4 seed ears taken from each one of the selected rows are used for sire seed and 2 for dam seed.

"The dam seed ears for each quarter are ears which grew in the same quarter, while the sire seed is always brought from another quarter. For the first quarter (rows 1 to 24) sire ears are brought from the fourth quarter. For the second quarter sire seed is brought from the third. In each of these cases sire seed is carried diagonally across the breeding plat. For the third quarter sire seed is brought from the first quarter, and for the fourth, from the second, the sire seed being carried lengthwise of the breeding plat in these cases."

A definite arrangement for the planting of the seed ears in alternate years has been devised to entirely eliminate inbreeding or to bring its influence to a minimum. The order of planting in the even-numbered years is illustrated by considering the first quarter of the plat containing rows 1 to 24, of which numbers 2, 4, 6, 8, 10, and 12 were the 6 best-yielding rows, each furnishing 2 dam seed ears and 2 sire seed ears. The 12 ears of dam seed, bearing the same number as the rows from which they were taken, are used for planting the even-numbered rows of the quarter, the order, beginning with row number 2, being 2, 6, 10, 4, 8, 12, 2, 6, 10, 4, 8, 12, or the alternating even numbers repeated in sets of 3 and 6.

The odd-numbered rows of the quarter are planted with 12 sire ears representing the 6 selected rows of the fourth quarter. The numbers of these rows in the case given are 76, 78, 80, 82, 84, 86, and the order of planting the ears, beginning with row No. 1, is given as follows: 76, 80, 84, 78, 82, 86, 78, 82, 86, 76, 80, 84. The order is the same as for the dam seed ears, with the exception that the two sets of 3 are reversed in the second set of 6. For the odd-numbered years the two sets of 6 in planting the sire seed are transposed, which then makes the order as follows: 78, 82, 86, 76, 80, 84, 76, 80, 84, 78, 82, 86. Exactly the same system is used in each quarter of the breeding plat.

A form for registering the numbers and descriptions of all the seed ears used in corn breeding and also for recording their performance records is given, together with notes on the multiplying plat and the commercial field. Complete directions for describing individual ears are given and a method of keeping the performance record of field rows is illustrated.

The manuring of cotton, G. P. Foaden (*Khediv. Agr. Soc. [Pamphlet] 1, pp. 16, figs. 2*).—The manuring of cotton is described and the effect of the different plant food elements on the growth and development of the plant is pointed out. The results of two different experiments showed that commercial fertilizers were applied with profit. The application used consisted of about 200 kg. of superphosphate, 70 kg. of nitrate of soda, and 30 kg. of sulphate of potash per acre.

Notes on the bacteria active in flax retting, M. W. Beijerinck and A. van Delden (*K. Akad. Wetensch. Amsterdam, Proc. Sect. Sci., 6 (1904), pt. 2, pp. 462–481, pl. 1, figs. 4*).—The author discusses the subject of flax retting, which is due largely to the solution and softening of the rind of the flax stock by the removal of the pectose, in consequence of which the bast bundles are separated.

This retting is caused largely by the action of certain bacteria, and may be considered a form of pectose fermentation. Where the retting takes place in the field it is due to the action of various molds, bacteria, and other organisms, and the product is of an unequal character. When, however, it takes place in water the organisms are principally anaerobic bacteria, the chief of which is called *Granulobacter pectinovorum*. The action of this organism and its associated forms is described at length.

Selection of seed potatoes, F. Parisot (*Jour. Agr. Prat., n. ser., 9 (1905), No. 6, pp. 174–176*).—The results of the experiments here reported indicated that the selection of seed potatoes, based on the size, composition, and hereditary characters of the tubers and the number of eyes, is incomplete if no account is taken of a perfectly healthy condition of the seed. Of normal tubers 81.2 per cent produced plants, while of those not perfectly healthy only 41.6 per cent grew. The yield obtained from normal tubers was nearly again as large as from the inferior tubers.

Potato experiments at Parc des Princes, L. Grandeau (*Jour. Agr. Prat., n. ser., 9 (1905), No. 5, pp. 141, 142*).—Fertilizer experiments in 1904 with Thomas slag and Cierp phosphate, and either one of these substances in combination with nitrate of soda, sulphate of ammonia, and lime nitrogen are reported.

The phosphatic fertilizers were given in quantities furnishing 200 and 300 kg. of phosphoric acid per hectare, the larger quantity being applied in 1902 and the smaller being given in 2 equal portions, one in 1902 and the other in 1904. The nitrogenous fertilizers supplied 45 kg. of nitrogen per hectare. All plats had received a dressing of 200 kg. of potash per hectare.

The smaller application of Thomas slag produced a heavier yield than the larger quantity, but in the case of Cierp phosphate the larger application gave the heavier yield. The yields for the 2 phosphatic fertilizers taken together show the best results from the use of 200 lbs. of phosphoric acid per hectare. The plats receiving Cierp phosphate produced on an average 1,536 kg. of tubers per hectare less than the plats receiving Thomas slag. The yields on plats given nitrate of soda, sulphate of ammonia, and lime nitrogen were 11,258, 10,771, and 10,545 kg. per hectare, respectively. An average yield of 5,499 kg. per hectare was obtained on the check plats.

The degeneration of potatoes, P. Ehrenberg (*Landw. Jahrb., 33 (1904), No. 6, pp. 859–915, dgms. 4*).—This article discusses at some length the degeneration of potato varieties as possibly due to continued propagation by means of the tubers, to unfavorable local conditions, and to poor selection of seed tubers. The literature on the subject as well as experiments along this line are reviewed.

The author concludes that in all probability the age of a potato variety is not a factor in its degeneration, but that unsuitable environment, especially a poorly

adapted soil and insufficient care in the selection of seed tubers, are strong factors in reducing the vigor of a variety.

The degeneration of potato varieties, R. Tuckermann (*Mitt. Landw. Inst. Breslau, 3 (1904), No. 1, pp. 1-92, dgms. 5*).—The subject is considered from a cultural and a physiological standpoint and the conclusions drawn are based on the results of numerous experiments by different investigators.

The degeneration of varieties is considered as largely due to cultural and local conditions, while the superiority of new varieties over older sorts is regarded as indicating a greater adaptability to the particular region. Physiological degeneration of a variety is not believed to result from the asexual method of propagation through a series of years.

The fact that certain old varieties in particular localities retain their productiveness, in the opinion of the author, would seem to contradict such a conclusion. It is stated that a study of the principal factors of growth, especially climatic conditions in each locality, would throw much needed light upon this subject.

Commercial sugar-beet seed, J. E. W. Tracy (*U. S. Dept. Agr. Rpt. 80, pp. 177-183*).—The importance of good sugar-beet seed is discussed, and the work of establishing a pedigree strain of sugar-beet seed, carried on in connection with the New York State, the Michigan, and the Utah experiment stations and with private growers at Holland, Mich., and Fairfield, Wash., is described.

The work was begun by securing the best strains of European seed and also all known strains of American-grown seed and growing them for comparison. Of these the best 4 strains were selected as foundation stocks, and all beets of exceptional quality were saved and planted the next spring as mother beets for seed production. In 1904 one-half of the seed secured from these individual plants was planted and the best specimens of beets preserved for the production of the first crop of elite seed. The other half of the seed will be planted this year and from the beets produced the next year's supply of elite seed will be grown.

It is reported that during the last year a Washington State sugar-beet seed grower produced a lot of some 300 roots testing 21 per cent or more of sugar in the beet, with composite tests showing coefficients of purity ranging from 86 to 91.9. In this lot were included 15 roots containing 24 per cent, 50 with 23 per cent, and 100 with 22 per cent of sugar in the beet. Results of variety tests of sugar-beet seed from American and European growers in 1904 show a range of from 15 to 17.7 per cent of sugar in the beet and a range in coefficient of purity from 83.7 to 87.9. The low as well as the high figures were secured in Kleinwanzlebener sugar beet from American-grown seed. The highest yield per acre, 13.17 tons, was obtained from Kleinwanzlebener seed grown at Fairfield, Wash.

Last year this Department distributed some 4,000 lbs. of California-grown and 11,000 lbs. of Washington-grown Kleinwanzlebener sugar-beet seed, in order to compare it with the seed furnished to farmers by the factories. Of the reports so far received, 73 per cent of those planting Washington-grown seed and 63 per cent of those planting the California-grown seed found it to be of quicker, stronger, and healthier germination, and none found it inferior to the other seed. The returns from 561 acres showed that the sugar content of the beets from the Washington-grown seed was 15.4 per cent and from the California-grown seed, 14.4 per cent, as against 14.9 per cent for beets from the factory seed. The Washington seed yielded 10.7 tons, the California seed 9 tons, and the factory seed 9.1 tons per acre.

Single-germ beet seed, C. O. Townsend (*U. S. Dept. Agr. Rpt. 80, pp. 161-166, figs. 2*).—This article covers part of the work published in Bulletin 73 of the Bureau of Plant Industry of this Department, which has been previously noted (E. S. R., 16, p. 983).

Fertilizers and sugar beets, C. O. Townsend (*U. S. Dept. Agr. Rpt. 80, pp. 167–176*).—A general discussion on the use of green manure, stable manure, and commercial fertilizers in beet culture is presented and results obtained under different conditions with different kinds of fertilizers are reported.

The climatic conditions are shown by data taken from the monthly weather reports of the stations at Detroit, Mich.; Spokane, Wash., and Omaha, Nebr. The experiments were conducted in these localities. A comparison was made of two complete applications, the one consisting of 125 lbs. of dried blood, 100 lbs. of sulphate of potash, and 275 lbs. of South Carolina rock, and the other of a complete fertilizer containing 1 to 2 per cent of ammonia, 4 to 5 per cent of potash, and 8 to 10 per cent of phosphoric acid, applied at the rate of 325 and 200 lbs. per acre.

The amount received per acre for the beets shows an increase, apparently due to the fertilizer, ranging from 27 cts. to nearly $30. Each application proved highly profitable in two of the experiments and failed to increase the yields sufficiently to pay for the fertilizers used in the two other tests. In one case a low rainfall is considered as accounting for the small increase due to the fertilizers.

In another series of tests 300 lbs. of nitrate of soda per acre gave a large increase in the value of beets per acre. Applying one-half the quantity just before planting and one-half July 1, gave results a little better than when the entire quantity was applied just before planting. The quality of the beets did not seem to be affected. In studying the effect of different amounts and different combinations of fertilizer elements on sugar beets it was found that good results were obtained in each experiment by using 200 lbs. of nitrate of soda, 200 lbs. of phosphoric acid, and 100 lbs. of sulphate of potash per acre.

The results also seemed to indicate that the potash had no appreciable effect on the quantity or quality of the beets. None of the salts applied showed any injurious effect upon the quality. In one experiment common salt was applied at the rate of 200, 300, and 500 lbs. per acre. The result seemed to indicate a beneficial effect in helping the soil to retain moisture. In some instances there was no effect upon the yield, and in others 200 lbs. seemed as effective as 500 in increasing the tonnage. The heavier application did not appreciably affect the quality of the beets.

Variety tests with sugar and fodder beets, J. Hansen and K. Hofmann (*Deut. Landw. Presse, 32 (1905), Nos. 18, pp. 151, 152; 19, p. 163*).—The average yields of 11 varieties of sugar beets, each grown on 2 plats, ranged from 43,090 to 48,230 kg. per hectare, the best yielder among them being the Friedrichswert variety.

In average sugar content in the beet the varieties varied from 19.19 to 21.71 per cent in the Friedrichswert and Heine varieties, respectively. In average yield of sugar per hectare Schreiber Zuckerreichste stood first with 9,638 kg., and Rabethge and Gieseke Late Klein-Wanzleben last with 8,661 kg. The coefficient of purity in the different varieties varied from 88.35 in Friedrichswert to 92.61 in Schreiber Klein-Wanzleben. The test with fodder beets also included 11 varieties.

In productiveness Criewen Eckendorf stood at the head of the list with a yield of 79,320 kg. of beets per hectare, and Tankard Mangold, obtained from England, last with a yield of only 38,870 kg. The continental climate, and especially the dry summer, proved detrimental to the 2 English varieties grown in this test. The Eckendorf, Tannenkrug and Leutewitz varieties, given in the decreasing order of yield, ranked next to the Criewen Eckendorf variety in the production of beets. A heavy yield of leaves was not correlated with a heavy yield of beets.

The percentage of dry matter was quite high, ranging from 11.67 per cent in the Tannenkrug beet to 17.50 per cent in the Substantia Lank variety. In yield of dry matter the Leutewitz variety led with 10,755 kg. per hectare, followed by Substantia Lank and Oberndorf, each producing more than 10,000 kg. These varieties also stood in the same rank and order in the yield of sugar. The percentage of sugar

varied from 7.69 in Yellow Mangold, one of the English varieties, to 10.14 in Substantia Lank.

The experiment with fodder beets again called attention to the fact that the most productive varieties as a rule are low in dry matter and food value, which their greater yield does not always counterbalance.

Progress of the beet-sugar industry in the United States in 1904, C. F. Saylor (*U. S. Dept. Agr. Rpt. 80, pp. 1-160, pls. 4*).—This report is a general review of the successes and failures of the year, and a discussion of the influences and conditions acting on the development of the beet-sugar industry.

Beet sugar is now produced in 12 States, in 4 of which irrigation is practiced. In 1904, 48 factories and 4 slicing stations were in operation. The factories were distributed as follows: Michigan 16; Colorado 9; California 5; Utah 4; Nebraska, Idaho, and Wisconsin 3 each; and Minnesota, New York, Ohio, Oregon, and Washington 1 each. Three factories in California and 3 in Michigan were not operated during the year, and 3 plants were in the process of construction. In discussing the mistakes made and the obstacles met and overcome, the author considers the supply and character of labor, the competition with favored crops, the requirements of sugar-beet culture different from those of other crops, the influence of bad seasons, diseases and insects, the use of poor seed, and the methods of establishing factories.

During the year 4 large factories were installed in new localities, 2 in Wisconsin and 2 in Idaho. One of these factories is new, while the others are old ones removed from other localities. The development of conditions and prospects for new factories are discussed by States. In considering climatic conditions and farm and factory results for 1904 for the different beet-growing States, the author points out the methods of handling a crop of sugar beets, and calls attention to the injury done by hail and rain during early growth.

A field of beets, hailed and flooded out on June 27, was given a deep cultivation as soon after the rain as the soil conditions permitted, and the beets were straightened up with hand and hoe. On July 23 this field had fully recovered, showing healthful growth with abundant foliage. This crop yielded 16 tons per acre with high sugar content and purity. The statistics for the year show that 197,784 acres of beets were harvested, the average yield per acre being 10.47 tons. The total quantity of beets worked was 2,071,539 tons, and the quantity of sugar manufactured, 484,226,430 lbs. The beets had an average sugar content of 15.33 per cent and an average purity coefficient of 83.09.

The employment in the sugar-beet fields of young boys coming under the jurisdiction of the juvenile court in Denver, Colo., is discussed; and a description of the most improved methods of growing sugar beets is republished from a previous report.

Beet-sugar factories of the United States and Canada (*Amer. Sugar Indus. and Beet Sugar Gaz., 7 (1905), No. 11, p. 254*).—This is a list which gives the location and daily capacity of 7 factories in California, 9 in Colorado, 3 in Idaho, 17 in Michigan, 2 in Nebraska, 1 in New York, 1 in Ohio, 1 in Oregon, 4 in Utah, 1 in Washington, 3 in Wisconsin, and 3 in Canada, 4 not in operation, and 6 now building for the campaign of 1905.

The beet-sugar industry of Wisconsin, F. W. Woll (*Wisconsin Sta. Bul. 123, pp. 70, figs. 8*).—This bulletin briefly considers the manufacture of sugar from beets grown in Wisconsin, presents statistical and other information on the present condition of the industry, summarizes previous work, and reports the results of the more recent investigations at the station and in different parts of the State.

A summary of analyses of 2,994 samples of sugar beets grown by Wisconsin farmers from 1890 to 1901, inclusive, shows an average sugar content in the juice of 14.13 per cent, with an average purity coefficient of 78.6. The average yield is estimated at 14.8 tons per acre. In experiments at the university farm from 1890 to 1904, inclu-

sive, the average sugar content of the beets secured was 14.10 per cent. The average yields of beets and sugar as calculated amounted to 17.37 tons and 4,900 lbs. per acre, respectively.

According to the report on Wisconsin beet-sugar factories for 1904–5, 125,928 tons of beets, containing an average of 14.4 per cent of sugar with an average purity of 83.7, were worked. The total acreage in 1904 was 14,400. Reports on 75 culture tests in 1904 give information concerning methods of culture and show that, on an average, 2.8 acres of beets were grown in each test, the average sugar content in the beets being 15.1 per cent; the yield, 16.5 tons per acre; the net receipts, \$70.57, and the average expense, \$29.09 per acre.

Brief notes on the individual experiments and discussions on the soil and culture requirements of the crop are given. The expense of growing an acre of beets is considered and compared with the cost of growing cereals, potatoes, and tobacco. The fertility removed by different crops and the influence of a preceding crop on the yield and quality of beets are shown in tables. The text of contracts in force between the factory and the grower is given.

Culture of tobacco, G. M. Odlum (*London: British South Africa Co., 1905, pp. 185, pls. 8, figs. 101*).—A treatise on the culture of tobacco, in which the different phases of the production, preparation, and marketing of the crop are discussed. In addition to treating of the tobacco plant and its varieties in relation to soil, climate and cultural operations, its insect enemies, diseases, methods of curing, buildings for curing, grading, and fermenting the leaf, packing and marketing the product, and miscellaneous topics are considered. The book is a report on tobacco culture based mainly on an investigation of the tobacco industry in America.

Report on tobacco investigations in Wisconsin for 1903 and 1904, E. P. Sandsten (*Wisconsin Sta. Bul. 124, pp. 45, figs. 13*).—This bulletin is a report on work in the improvement of Wisconsin tobacco seed, on fertilizer experiments, and on growing Sumatra tobacco under cover. A preliminary report has been previously noted (E. S. R., 16, p. 68).

In addition to the experiments previously reported, fertilizer tests were made in 4 other localities. The soils and conditions were unlike, and the results are applicable only to the particular localities in which the work was carried on. At Rio and Westby the use of commercial fertilizers gave a smaller yield than that of barnyard manure. Early in the season the plats receiving commercial fertilizers showed the best growth, but later they were overtaken and outstripped by those receiving barnyard manure.

At Soldier's Grove on sandy-loam soil in a high state of cultivation commercial fertilizers gave better results than barnyard manure, the greatest gain, 508 lbs. per acre, or 36 per cent, being secured from the plat receiving 300 lbs. of nitrate of soda per acre. The plat treated with 200 lbs. each of nitrate of soda and sulphate of potash per acre gave a smaller yield than the barnyard-manure plat, the manure having been applied at the rate of 20 tons per acre. The results at Janesville were not conclusive on account of the poor physical condition of the soil at planting. The cost of commercial fertilizers and their influence on the burning quality of tobacco is discussed.

Experiments in growing Sumatra tobacco under cover were conducted in 1902 and 1903. Directions are given for tent construction, the culture of the crop, and its fermentation. The total cost of growing 2 acres of Sumatra tobacco in 1902 and 1903 was \$3,395.03, and the total net receipts were \$1,681.27, or a net profit of \$420.32 per acre per year. The total yield of fermented tobacco was 2,314 lbs. in 1902 and 2,110 lbs. in 1903, which was sold at prices ranging from 50 cts. to \$2 per pound.

Tobacco investigations in Porto Rico during 1903–4, J. van Leenhoff, Jr. (*Porto Rico Sta. Bul. 5, pp. 44, pls. 5, fig. 1*).—The methods of tobacco growing now practiced in Porto Rico are described.

The results of experiments in growing, curing, and fermenting tobacco are reported, and ways and means for the improvement of the Porto Rican crop are suggested. Mechanical analyses of soils and subsoils from typical Porto Rican tobacco fields, as determined by the Bureau of Soils of this Department, are given in tables and discussed. The mechanical analyses of subsoils from 2 Cuban tobacco districts are also given.

In seed-bed experiments it was found that the seed under shade came up from 2 to 4 days earlier than the seed without shade; but while the shaded seeds came up earlier and looked healthier during the first 3 weeks, those without shade were finally more vigorous and larger. The shade reduced evaporation, resulting in a quicker and more perfect germination of the seed, and also protected the beds from washing. Cloth was more satisfactory for shade than straw.

The burrows of changas in the seed bed were treated with a solution of 1 part of kerosene to 14 parts of water, and no further depredations were noticed. When the plants suffered from disease a dilute solution of Bordeaux mixture was applied with very beneficial results.

Transplanting experiments were made outside and under cover. In the open mamey and mango leaves were used for shading. The petiole of the leaf was stuck into the ground 1 to 2 in. south of each tobacco plant to shield it from the direct rays of the sun during the hottest part of the day. Of 445 plants protected in this way 125 died, and of the same number of unprotected plants 300 failed to grow. At harvest the shaded plants showed a much greater uniformity in growth than the unprotected ones. Of 300 plants wrapped in mamey leaves as a protection against cutworms and mole crickets 200 died, and of the same number unprotected 220 had to be replanted. Wrapping the plants is a protection against the crickets, but it is often detrimental to early growth because it confines the upper roots of the plant and allows water to collect within the leaf.

The poor results in these two experiments were largely due to insufficient care in planting and the use of unselected seed. In a trial under cheese cloth only about 5 per cent of 1,700 carefully set-out plants failed to grow, while in a plat of 800 plants planted in the usual native way the loss was much greater.

An experiment in shade-growing wrapper leaf suffered from delays and disease attacks, but the results of this test as well as those of a second experiment indicated "that shading increases the yield, quality, and percentage of wrappers sufficiently to make shading a profitable business, providing it is practiced only on soils suitable for growing wrappers and the crop is given the best of care throughout its growth and further treatment in curing and fermentation."

Fertilizer experiments carried on at Aibonito showed that on that particular soil acid phosphate was more efficient than sulphate of potash or nitrate of soda combined. The 3 substances were applied at the rate of 60, 20, and 20 lbs. per acre, respectively. The use of 200 lbs. of lime in addition to the complete application showed no improvement. In another test 2,000 lbs. of cotton-seed meal produced a better growth, especially in the young plants, than a liberal dressing of compost of horse manure and vegetable matter, including tobacco stems. The use of fertilizers for tobacco in Porto Rico is discussed.

Curing experiments were made in 3 curing sheds, the first a frame building constructed for a storehouse, the second a shed of poles and canvas covered by a straw roof, and the third a large shed constructed of board sides with a thatched roof on a pole framework. The daily temperature and relative humidity were ascertained in each shed from March 19 to April 23.

In the frame building, with a mean temperature of 80.2° F. and relative humidity of 68.3 per cent, the tobacco dried too quickly and the leaves when cured contained many green spots. In the cloth shed the temperature was at first much too high and the tobacco was badly damaged, but when the mean temperature was down to

78.26°, with a relative humidity of 70 per cent, the conditions for curing were more favorable than in the frame building. The best results were obtained in the large shed with a mean temperature of 77.67° and a relative humidity of 73.57 per cent. The slightly lower temperature and higher relative humidity in this shed were apparently more favorable to securing the best results.

Fermentation investigations were made and the temperature records of one pile of outside-grown tobacco with a high percentage of wrapper leaves are shown in a table. The suggestions for the improvement of Porto Rican tobacco include discussions regarding soil, seed and seed beds, time and method of transplanting, cultivation, topping, harvesting, curing, and fermentation.

Extermination of Johnson grass, W. J. SPILLMAN (*U. S. Dept. Agr., Bur. Plant Indus. Bul. 72, pt. 3, pp. 14, pls. 3, figs. 4*).—The results of investigations begun in 1902 for the eradication of Johnson grass, which is one of the most troublesome weeds in the Southern States, are given. These investigations are still in progress, but some definite results have been secured that seem to justify the publication of the data already at hand.

From the experiments already carried on it seems feasible to eradicate Johnson grass in a single year by plowing in the autumn, care being taken to turn the soil completely. After plowing the land should be harrowed immediately, so as to get it smooth and well pulverized, after which it is given treatment by root diggers, which tear out and collect the roots. In the spring the land should be plowed again and put in cotton, giving it ordinary good tillage. All plants of Johnson grass that remain should be pulled out by hand, and by repeating this whenever the grass gets about 6 in. high it can be eradicated during a single summer without an excessive amount of labor. These directions apply to cultivated fields and are not practicable along fence rows, ditch banks, etc.

HORTICULTURE.

Summary of experiments in practical horticulture, W. M. MUNSON (*Maine Sta. Bul. 113, pp. 21-27*).—A brief summary is given of the results of experimental work at the station, since its establishment, in the culture of vegetables, ornamentals, and fruits, including spraying.

With the tomato it has been found that earliness and productiveness stand in direct ratio to the earliness of setting in the field. Under favorable conditions the plants should be in the field by June 1. The yield has been increased a third by trimming the plants after a part of the fruit has set. Bagging the fruit has reduced the loss from rot. Crossing between early small-fruited prolific varieties and the common large-fruited ones has resulted in types well suited to seasons of short growth and for forcing under glass.

The increased yield of the Lorillard-Peach cross over the pure Lorillard has been nearly 50 per cent. Seed from plants grown under glass has in some instances given better results in forcing than seed of the same variety grown in the field. The results were not uniform, however, and there appear to be distinct varietal differences.

Cabbage plants handled 2 or 3 times before setting in the field have invariably given better results than plants handled but once or twice. Depth of setting has had very little influence on the size of the head produced by "leggy" plants. Trimming the plants at time of setting in the field has not been of apparent benefit. Handling the plants in pots before setting in the field has increased the percentage of marketable heads. Mulching has been found a very satisfactory substitute for cultivation for this crop.

Cauliflower plants handled in pots have made a more uniform growth and produced a higher percentage of marketable heads than when grown in boxes. Trim-

ming the plants has had no beneficial effect. Better results have been secured from frequent cultivation than from mulching. The most valuable sorts for culture appear to be Dwarf Erfurt and Snowball types, with Algiers for late in the season.

Early varieties of eggplants can be successfully grown in Maine, the requisites for success being early sowing, vigorous plants, late removal to the field, and warm, rich soil. Several crosses have been made between white-fruited and black-fruited types, but nothing of permanent value has been produced. The white-fruited types appeared to be stronger than the purple in their power to transmit form and productiveness.

In the case of radishes, 30 to 50 per cent more first-class roots have been secured from large seed than from small seed of the same lot. Subwatering increased the yield of first-class radishes 12 to 15 per cent in the greenhouse over surface watering. The loss from damping off was also greater on the surface-watered beds than on the subirrigated. The crop matured earlier and was of better quality when grown with a night temperature of 60° than when grown at a lower temperature.

In greenhouse work it has been found that one good man with occasional help should be able to do all the work in houses covering 4,000 sq. ft. of ground surface. "In general, solid beds are advocated for plants requiring no bottom heat, such as cauliflower, lettuce, and radishes, while for semitropical plants, like melons, beans, and tomatoes, benches are preferred." Steam heat for large houses and hot water for small houses are recommended.

Relative to fruit growing, it is believed that the opportunities in this line are greater than in any other line of commercial horticulture in Maine. With apples it has been found that in the case of the Gravensteins the number of trees producing some fruit was nearly 50 per cent greater when cultivation was practiced than when the land was mulched, while the average yield was as 72 and 59, respectively. The use of potash in different forms as a preventive of apple scab has given only negative results. Cultivation has had a marked beneficial effect in the renovation of the orchards.

In spraying experiments the amount of wormy fruit has been decreased by the use of arsenicals. Paris green has injured foliage less than London purple or white arsenic. While a pound of Paris green to 250 gal. of water reduced the amount of wormy fruit, a strength of a pound to 100 gal. of water was required to kill the tent caterpillar. Spraying with Paris green greatly lessened the number of windfalls and the proportion of wormy fruit among the windfalls.

With the larger part of the wormy fruit from sprayed trees the wormholes were at the side or base of the fruit, while in the case of fruit from unsprayed trees more worms entered at the calyx end. Three applications of ammoniacal solution of copper carbonate proved sufficient to control the apple scab fungus and resulted in saving 52 per cent of the crop, though the foliage and fruit were slightly injured. The most satisfactory and effective fungicide, however, is the Bordeaux mixture.

The improvement of blueberries by crossing, selection, etc., is under way at the station.

In the plant-breeding work evidence has been obtained which indicates that "the secondary results of crossing may be of fully as much importance as are directly inherited qualities. Among these secondary effects are the possible immediate influence of pollen upon the mother plant; the stimulating effect of pollen upon the ovary, and the influence of varying amounts of pollen."

Report of the Upper Peninsula Substation for 1904 [Horticulture], L. M. GEISMAR (*Michigan Sta. Spec. Bul. 31, pp. 23-36*).—A detailed account is given of experiments at the station in the culture and tests of a number of varieties of garden peas, beans, sweet corn, cucumbers, muskmelons, watermelons, tomatoes, cabbage, cauliflower, celery, onions, leeks, salsify, kale, collards, lettuce, spinach, radishes,

scolymus, globe artichoke, mustard, roquette (*Eruca sativa*), rampion (*Campanula rapunculus*), parsley, tobacco, peppers, sunflowers, and a number of flowers and honey plants. Similar notes are also given for strawberries and orchard fruits.

Nott Excelsior has proved the best of the medium early varieties of peas. Edible ears of Peep O'Day sweet corn planted June 10 were obtained September 1. Earliest of All was the next earliest variety. Vaughan Earliest of All is the most promising variety of tomato thus far tested. The husk tomato (*Physalis francheti*) was not killed by frosts until November and came up the following May from underground runners.

Extensive observations relative to the onion maggot indicate that it does not propagate in the wild leek, nor in the cultivated leek, nor on perennial onions. In onion sets which were shipped in from the outside 22 out of 26 onions contained 2 to 8 maggots each. Cedar birds were especially injurious in eating and destroying strawberries. Robins were less so. Their depredations were restricted to "the gathering of the seed from a few berries, and this only at a time when their young begin to feather out."

A number of orchard trees were injured by sun scald during the winter above snow line. Seven varieties which ripened fruit were Haas, Borowinka, Gideon, Hibernal, Patten Greening, Yellow Transparent, and Duchess.

Asparagus culture in California, R. E. SMITH (*California Sta. Bul. 165, pp. 5-18, figs. 13*).—This bulletin is primarily a report to certain asparagus growers, canners, and dealers in California, who provided a fund of $2,500 for investigating asparagus rust. That part of the bulletin dealing with the nature and control of asparagus rust is noted elsewhere in this number.

The commercial culture of asparagus in California has developed largely within the last 10 years, principally in the delta country between Sacramento, Stockton, and Port Costa. At present about 7,000 acres of asparagus are grown annually in California. The crop is grown on 2 classes of soils, sedimentary river deposits and island peat soils. In small field culture the rows may be as close as 5 ft. apart, but in the great island plantations they are 9 or even 10 ft. apart and about 2 ft. distant in the row. For canning purposes the blanched stalks are grown. These are produced by ridging dirt high up over the rows.

In marketing, the crop is trimmed to a uniform length of 7 in. and packed in bulk in 60-lb. boxes. Bunching is not practiced except to a limited extent and for shipment to eastern markets in a fresh condition. The average yield is placed at 5,000 lbs. of merchantable asparagus per acre, while good fields in prime condition may produce 7,000 to 8,000 lbs. without fertilization. The larger part of the crop is canned. The author states that the process of canning is clean and appetizing, "and the product healthful and delicious, being immeasurably superior to fresh asparagus bought in the market and cooked at home."

Tomatoes, L. C. CORBETT (*U. S. Dept. Agr., Farmers' Bul. 220, pp. 32, figs. 13*).—Popular directions are given for growing and marketing tomatoes, the subject being considered from the standpoint of tomatoes as a field crop at the North, as a field crop at the South, forcing of tomatoes, and the tomato as a field crop for canning.

Pruning tomatoes, W. T. MACOUN (*Country Gent., 70 (1905), No. 2720, p. 250*).—Two varieties of tomatoes were used in the experiment, Sparks Earliana and Matchless.

When the plants had developed 6 strong leaves in the hotbed the tops were nipped off and the plants given more room, being spaced 5.5 in. apart each way. "The object of pinching off the top of the plant was to cause new shoots to develop at the axils of the leaves, in order to have 6 branches bearing early tomatoes instead of the one cluster usually found on the top of the plant." These plants were set out in the field June 6 alongside of other plants which were left unpruned. On June 22

one-half of the pruned plants were again pruned, all laterals being taken out and the 6 main branches only being left. The remaining plants were left to grow at will.

The first ripe fruit on the unpruned plants was secured July 29, on the plants pruned once August 13, and on those pruned twice August 12. The heaviest yield of fruit was obtained from plants pruned twice in the case of the Sparks Earliana and pruned once in the case of Matchless. In both cases the pruned plants gave much heavier yields than the unpruned plants. The results are thought to be very promising and market gardeners are advised to give this system of pruning a trial.

A few notes on ginseng, M. HARRINGTON (*Trans. Iowa Hort. Soc., 39 (1904), p. 276*).—The author states that from beds of ginseng 40 ft. long and 5 ft. wide, including the path between the beds, he secured $55 worth of dried root and $16 worth of roots for replanting the bed. He believes that had he dried all the roots the cash value would have been at the rate of about $15,000 per acre. From one-seventh of an acre about $1,850 worth of ginseng seed was produced in 1903. In 1904 the same patch produced over 600,000 seed with an estimated value of $3,000 or at the rate of $21,000 per acre.

Planting-table for vegetables, E. L. FULLERTON (*Gard. Mag. [New York], 1 (1905), No. 3, pp. 110–113*).—A tabulated guide is given showing when and how to plant and cultivate 74 kinds of vegetables. Such matters as the depth to plant seeds and roots, distance apart, time required for the crop to mature, the use of the crop, etc., are included. The table is adapted to the use of those who make small home gardens which are cultivated by hand or by the wheel hoe.

Report on culture experiments carried out in 1904 on the sewage fields of Berlin, J. KLAR and O. MENDE (*Gartenflora, 54 (1905), No. 1, pp. 14–19*).—A general account is given of the results secured during the year in the growth of a number of flowers and of such vegetables as radishes, salad plants, tomatoes, cauliflower, and potatoes, including the swamp potato (*Solanum commersonii*). With reference to the latter it is stated that on account of the small yield of tubers obtained this potato at present can be designated only as "interesting."

The higher standard in American horticulture, G. T. POWELL (*West. N. Y. Hort. Soc. Proc. 1905, pp. 64–73*).—A number of suggestions are made relative to improved methods of fruit propagation, orchard management, harvesting, and marketing fruits to meet the better class of trade, special emphasis being given to the adaptation of soil to variety, the labeling of packages which shall give full information to purchasers as to the quality of the fruit and the best method of preparing it for the table, the improvement of soil, the improvement of trees through selection, and the need of organized effort in marketing fruits.

The progress of fifty years, L. H. BAILEY (*West. N. Y. Hort. Soc. Proc. 1905, pp. 6–14*).—The progress which has been made along different lines of fruit culture during the past fifty years, in methods of orchard management and the handling and marketing of fruit, is discussed.

Report of South Haven Substation for 1904, T. A. FARRAND (*Michigan Sta. Spec. Bul. 30, pp. 30*).—The usual account is given of the behavior of the varieties of fruits and nuts tested at the South Haven Substation, with further results of spraying experiments with different fruits and the use of cover crops (E. S. R., 16, p. 260).

The severity and length of the winter resulted in a loss of many peach trees from root freezing. In experiments at the station and in cooperation with a number of farmers, tests were made of the relative efficiency for scale insects of the lime-sulphur-salt mixture, made according to the usual directions, made without salt, or made with caustic soda substituted for the salt, in comparison with caustic soda and lime.

The results of these experiments indicated that the use of 6 lbs. of caustic soda and 5 lbs. of lime diluted with 50 gal. of water is without benefit in the control of the scale, while a stronger solution is dangerous to both man and beast. The lime and sulphur seem to be the elements in the mixture which destroy the scale. The addi-

tion of copper sulphate, caustic soda, and other materials is an added expense and gives no better results.

The usual method of mixing ingredients and boiling was found to be the most satisfactory way for preparing the wash. Experiments with this mixture on peaches showed that it is perfectly safe to spray on peach trees up to the time the blossoms open. The use of copper sulphate has again been found the most satisfactory method of controlling peach-leaf curl. It can be controlled equally well by the use of lime-sulphur-salt wash, but the latter is much more expensive and unless it is required for the scale should not be used.

Fall applications of the lime-sulphur-salt wash, copper sulphate, and Bordeaux mixture were compared with spring applications of these same fungicides. The spring applications gave slightly better results. In order to test the effect of a thick coating of lime as a protection for peach buds over winter they were heavily sprayed with whitewash in the fall. Neither beneficial nor injurious effects could be observed from the application. In the experiment 8 lbs. of salt was added to each 50 gals. of wash. The coating of whitewash and salt was without effect as regards leaf curl.

Experiments in the fall pruning of peach trees indicated that the heading in of the trees in late fall and early winter if continued may result in serious injury. Dust sprays proved inefficient in the control of apple-scab fungus and of pear leaf blight and scab.

In order to test the recommendation of a California fruit grower that crude petroleum could be used as a spray while the foliage was on if followed within 15 to 20 minutes with a solution of concentrated lye, a test was made in June. Six trees were sprayed on one side with petroleum. Immediately thereafter 2 of the trees were sprayed with a solution of 1 lb. concentrated lye dissolved in 9 gal. of water. Two other trees were sprayed with a solution of 1 lb. of caustic soda to 9 gals. of water, and the 2 remaining trees with 1 lb. of crude potash to 9 gals. of water. The foliage was killed whereever the oil was used. The trees were also seriously injured and many of the smaller branches killed. The caustic solutions also slightly burned the foliage but not sufficently to cause it to fall off.

A number of trees were treated by the Owen process for the control of insect pests and diseases. The treatment consisted of boring a hole into the heart of the tree, putting in a grayish black powder composed largely of sulphur and charcoal and then putting in a wooden plug. Up to the present time this treatment has proved entirely valueless, as was expected.

Japanese chestnuts at the station are proving of but little value. Two of the European varieties, Paragon and Comfort, are very promising and have given several noteworthy crops. In the test of cover crops in the orchard mammoth clover has proved especially valuable. It is most satisfactory when oats or barley are grown with it.

Pomology as a study, R. L. CASTLE (*Jour. Roy. Hort. Soc.* [*London*], *29* (*1904*), *No. 1-3*, *pp. 146-160*).—A paper showing the wealth of material which fruits furnish to students who wish to study them for pleasure or information. Specific suggestions are given for study and investigation along the following lines: (1) Flower-bud formation, controlling influences such as food supply and weather; (2) problems in fertilization and sterility; (3) the development of fruits; (4) fruit characters and description; (5) systems of classification.

Under flower-bud formation the author notes an experiment in root pruning 6 espalier pear trees which had made a very free growth but which were still unfruitful. Two trees were root pruned on both sides, 2 on one side only, and the remaining 2 were left untouched for controls. The root pruning was performed in January and February and nothing special was noticed during the current year.

The following year the trees root pruned on one side only produced a fair crop of good fruit; those more severely root pruned had very few fruits, while those which

had not been root pruned at all were unfruitful as usual. One of the latter trees was root pruned later and gave results similar to the earlier root-pruned trees.

In discussing the subject of fertilization and sterility, the author states that practically all varieties of strawberries in England, with the possible exception of the Hautbois type, bear both stamens and pistils, while in America many of these varieties are distinctly pistillate. Crescent Seedling is cited as a specific example. This variety, which is perfect in England, is generally pistillate in the United States.

The staminate portion of flowers has generally been held to be more easily injured than the pistillate portions, but this has not been found by the author to be the case with our principal fruits when the temperature falls below the freezing point. Under those circumstances the pistil and stigma are more quickly injured, though something depends upon the stage the flower has reached. But even with small unopened blossoms of apples, pears, peaches, apricots, plums, cherries, gooseberries, currants, and strawberries, the pistils have repeatedly been found destroyed when the stamens showed no damage. The greatest injury to stamens appears with sudden variations, especially from a low temperature to a high one with abundant moisture.

The author's observations indicate that "pollen production is the most serious tax upon the strength of the tree, and in consequence in the case of weakness or soil poverty the stamens or anthers are the first to suffer" This has been noticed in the apples Stirling Castle, Lord Suffield, and Cox Orange Pippin, and others, besides several plums, pears, and peaches. "In such cases sterility has been effectually removed by liberal application of complete manurial aids; but where the defect has arisen from some other cause it has been necessary to plant other varieties with the failing sorts in order to provide the requisite pollen."

Under systems of classification examples are given of a number of methods which have been adopted by English writers in classifying and describing fruits, with comments on the usefulness and defects of the different systems.

Plant food constituents used by bearing fruit trees, L. L. VAN SLYKE, O. M. TAYLOR, and W. H. ANDREWS (*New York State Sta. Bul. 265, pp. 205–223*).—Experiments were undertaken to ascertain the amounts of nitrogen, phosphoric acid, potash, lime, and magnesia used in one growing season by bearing fruit trees.

From 1 to 3 standard varieties each of apple, peach, pear, plum, and quince were examined. All the trees were typical representatives of their kind and in the full vigor of bearing. The plan of the work included the analysis of the fruit, leaves, and new growth of wood as represented by the tips of branches of each individual tree. A number of tables are given which show the data collected in the case of each tree as regards the plant-food constituents of the fruit, leaves, and new wood.

The varieties of apples used in the experiment were Rhode Island Greening and Baldwin; of peaches, Champion, Elberta, and Hills Chili; of pears, Kieffer and Angouleme; of plums, Grand Duke and Italian Prune; and of quinces, Champion. The fruit on the different trees was picked when ripe. The foliage was left until it showed a tendency to drop. The twigs of new wood were removed soon afterwards.

The following table shows the average amount of plant-food constituents used by each fruit tree of the different varieties studied:

Plant food used during a season's growth by a mature fruit tree in full bearing.

Variety.	Nitrogen.	Phosphoric acid.	Potash.	Lime	Magnesia.
	Pounds	*Pounds.*	*Pounds*	*Pounds.*	*Pounds.*
Apple	1.47	0.39	1.57	1.62	0.66
Peach	.62	.15	.60	.95	.29
Pear	.25	.06	.27	.32	.09
Plum	.25	.07	.32	.34	.11
Quince	.19	.06	.24	.27	.08

It may be determined from this table "that the relative proportions of the different plant-food constituents are approximately the same for these different varieties of fruit trees. This means that under like conditions of soil fertility a mixture of nitrogen, phosphoric acid, and potash which would meet the requirements of one variety would also meet the needs of the other varieties, so far as the supply of these plant-food constituents is concerned."

In some years fruit trees bear no fruit. It is, therefore, desirable to know the amounts of food constituents used by different parts of the tree. The following table gives these data:

Amounts of food constituents used per acre by different parts of a tree.

Part of tree.	Nitrogen.	Phosphoric acid.	Potash.	Lime.	Magnesia.
Fruit:	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*
Apple	20.0	8.5	45.0	3.9	6.4
Peach	17.5	8.6	36.0	2.2	4.1
Pear	9.0	3.2	20.2	2.2	2.6
Plum	13.3	4.7	18.5	4.4	3.0
Quince	22.0	10.0	44.4	3.4	6.0
Average	16.4	7.0	32.8	3.2	4.4
Leaves:					
Apple	30.3	4.8	9.5	49.7	16.3
Peach	50.4	8.0	32.9	94.6	28.5
Pear	18.5	3.0	10.7	30.7	7.2
Plum	13.2	2.9	17.6	26.8	8.5
Quince	20.4	4.1	9.8	46.1	11.0
Average	26.6	4.6	16.1	49.6	14.3
New wood:					
Apple	1.1	.4	.6	3.0	.6
Peach	6.6	1.6	3.4	17.4	2.6
Pear	2.2	.8	2.0	5.4	1.1
Plum	3.0	1.0	1.8	10.0	1.5
Quince	3.1	1.2	2.6	16.1	1.9
Average	3.2	1.0	2.1	10.4	1.5

The above table is calculated on the basis of 35 apple, 120 peach, 120 pear, 120 plum, and 240 quince trees per acre in each instance. An acre of peach trees uses considerably larger quantities of plant food than any of the other varieties of fruit trees. The amounts of the nitrogen and potash required per acre in the case of the different fruit trees are practically the same, while the amount of phosphoric acid used is only about one-fourth as much as of nitrogen or potash.

"In most commercial fertilizers used on fruit trees the phosphoric acid is present in proportions about 4 times the nitrogen. This is on the assumption that the soil contains more nitrogen relatively than phosphoric acid, which may or may not be true in individual cases. The question may be raised as to whether quantities of phosphoric acid are not frequently applied much in excess of the actual need of a season's crops. . . .

"In respect to the amounts of plant food used per acre by the fruit of the different varieties of trees, the amounts of nitrogen, phosphoric acid, and potash in the different fruits are in about the following order: Quinces use the most, and then follow apples, peaches, plums, and pears.

"Potash is present in the fruit in larger quantities than is any other plant-food constituent; nitrogen comes second, being present to the extent, approximately, of one-half the amount of potash. Then follow, in order, phosphoric acid, magnesia, and lime, all of these being present in much smaller amounts.

"In the leaves, the plant-food constituents used per acre are greatest in the case of the peach, the apple coming second, and then quince, pear, and plum.

"Lime is present in the leaves and also in the new wood in much larger quantities than any other plant-food constituents; nitrogen comes second, followed in order by potash, magnesia, and phosphoric acid.

"In the new wood, the plant-food constituents used per acre are greatest in the case of the peach trees, after which come in order quince, plum, pear, and apple."

Tabulated analyses showing amounts of plant-food constituents in fruits, vegetables, etc., L. L. Van Slyke, O. M. Taylor, and W. H. Andrews (*New York State Sta. Bul. 265, pp. 223-230*).—Analyses with reference to moisture content, nitrogen, phosphoric acid and potash, which have been accumulating at the station, are here brought together for a large number of fruits and vegetables.

The list includes apples, blackberries, cherries, currants, dewberries, gooseberries, grapes, peaches, pears, plums, quinces, raspberries, strawberries, asparagus, string beans, beets, cabbages, carrots, cauliflower, cucumbers, eggplant, lettuce, mushrooms, muskmelons, onions, parsnips, garden peas, pumpkins, radishes, rhubarb, salsify, sweet corn, tomatoes, turnips, watermelons, balm, dandelion, endive, horehound, hyssop, peppermint, pot marjoram, prickly comfrey, rose bushes and foliage, rue, sage, tansy, tarragon, thyme, winter savory, and wormwood.

Observations on the phenology of plants at Ames, Charlotte M. King (*Trans. Iowa Hort. Soc., 39 (1904), pp. 114-137, pl. 1, dgm. 1*).—Tabular data are given showing the blooming period of a large number of species of plants, including flowers and fruits, at Ames and other parts of Iowa for 1904 and in some instances for other years between 1886 and 1904. A bibliography of a number of papers on the phenology of plants is included.

Varieties of fruits in Thurgau in the year 1903, F. Schwyzer-Reber (*Mitt. Thurgau. Naturf. Gesell., 1904, No. 16, pp. 3-61*).—An account of the different varieties of orchard fruits now grown in Thurgau, with a statement of the condition of orchards in different sections based on replies to a letter of inquiry sent out to growers.

New York apples, S. A. Beach (*West. N. Y. Hort. Soc. Proc. 1905, pp. 44-53*).—A historical account is given of early orcharding in New York and of the introduction of Russian varieties and of the varieties of fruits that are now in the lead in New York.

Phases of orchard management in Wayne County as discovered by an orchard survey, J. Craig (*West. N. Y. Hort. Soc. Proc. 1905, pp. 54-64, figs. 6*).—In a fruit survey which was made in Wayne County it was found that the average yield of apples for 4 years in orchards where the trees were planted 30 ft. apart each way was 184 bu. to the acre. When the distance between the trees ranged from 31 by 31 to 35 by 35 each way the average yield was 222 bu. per acre and when the distance ranged from 36 by 36 to 40 by 40 ft. each way the yield averaged 229 bu. per acre.

Imperfect drainage was found to be a frequent cause of failure, in whole or in part, in many western New York orchards. The matter of ownership appeared to have an important bearing on productiveness of orchards. The average yield in orchards managed by the owners was 210 bu. per acre and in rented orchards 174 bu. per acre. There was also a considerable difference in the yield from sprayed and unsprayed orchards.

In 66 sprayed orchards the average yield was 280 bu. per acre and the selling price $2.02 per barrel, while 107 unsprayed orchards yielded at the rate of 253 bu. per acre and sold at an average price of $1.80 per barrel. These figures indicate a difference of about $14.84 per acre in favor of spraying. The trees were sprayed only once or twice, rarely three times, and no special effort was made to make it thorough and efficient.

The apple in Oregon, II, E. R. Lake (*Oregon Sta. Bul. 82, pp. 37, figs. 11*).—Part I in this series of bulletins (E. S. R., 16, p. 368) dealt with the history of apple

culture in Oregon, selection and planting of the trees, soil, and location of the orchard. In the present bulletin the subjects discussed are the varieties of apples for home use, pollination, cultivation, cover crops, and pruning.

In discussing the effect of soil and season on pollination the author states that the self-fertility of the Italian prune is considerably affected by these factors. Some years in western Oregon and western Washington orchards bear full crops in all sections. In other years only a few orchards bear, or one orchard may bear in a locality while all the others are barren.

The relation between the blooming periods of different varieties of apples has been found to vary considerably in Oregon in different seasons and localities. The period from first bloom to full bloom also varies in different seasons. Thus, "in 1896, Delaware Red and Dominie were in full blossom 17 days apart, but in 1897 they were in full blossom only 2 days apart." The time intervening between the period of first and full bloom in the case of Fameuse one year was 7 days, another year 3 days, another 12 days, another 9 days, another 14 days, and another 8 days. In one locality the Yellow Newtown bloomed 2 days before Northern Spy, while in another locality Northern Spy bloomed 5 days before Yellow Newtown. A table is given showing the period of first blossom, full blossom, and the fall of blossom, respectively, for 110 varieties of apples grown in the State for each of 7 years.

Hairy vetch appears to be a very satisfactory orchard cover crop in Oregon. In the discussion of pruning special attention is called to the losses among prunes as a result of injudicious pruning at setting-out time. The prunes are set out usually in the late fall or early winter and cut back to mere stubs, which exposes a large wound. These wounds should be painted over with white lead in which has been dissolved a little sulphate of copper.

In western Oregon fruit on low-headed apple trees is often of indifferent color, while that on trees of medium to high heads is of fair to high color. For this reason the author suggests that trees of late fall and winter varieties be headed or trained high in that section, while summer or early fall varieties may be headed low if desired.

The presence of abnormal quantities of starch in bruised apples, G. VARCOLLIER (*Cidre et Poiré, 1904, Aug.; abs. in Rev. Soc. Sci. Hyg. Aliment., 1 (1904), No. 5, pp. 578, 579*).—While ripe apples contain little if any starch, bruised apples were found to contain large amounts in the vicinity of the bruise. This injures their value for cider making, as the starch is not converted into sugar.

Experiments in girdling fruit trees, J. E. MAY (*Pract. Fruit Grower, 11 (1905), No. 195, p. 11*).—The author ringed a number of 8-year-old apple trees which had not borne fruit. The following seasons both ringed and unringed trees bloomed full. Soon, however, the blossoms on the ungirdled trees showed signs of blasting and within a few weeks there were scarcely any apples on them, "while on the girdled trees the blooms stayed and set large quantities of fruit, which hung on well and colored very much more than on the other trees."

In one instance a girdled York tree produced 9.5 bu. of fruit, while an ungirdled tree alongside produced but 1 bu. Attention is called to the necessity of carefully observing the trees after they have been girdled to see that the wound is healing over properly.

The olive tree; its geographical distribution and historical and agricultural importance, T. FISCHER (*Mitt. Justus Perthes' Geogr. Anst., Ergänzungsh, 147, pp. 87, map 1*).—There are 2 main divisions of this pamphlet. One deals with the history of the olive, its botany, cultural requirements, diseases, varieties, oil production, etc., and the other with the culture of olives in the different countries of the world, especially those districts bordering on the Mediterranean Sea.

The book of topiary, C. H. CURTIS and W. GIBSON (*London and New York: John Lane, 1904, pp. VIII + 80, pls. 34*).—The history is given of this method of training

plants, with directions for the management of topiary gardens and the training of young and old trees in this work. This is the eighteenth volume in the series of handbooks of practical gardening, edited by H. Roberts.

The effects produced by grafting or budding various kinds of fruit trees on different kinds of stocks, R. P. SPEER (*Trans. Iowa Hort. Soc., 39 (1904), pp. 249–252*).—During the period from 1866 to 1897 the author conducted a nursery and made extended observations on the interrelation of stock and scion with a number of different kinds of fruit, particularly apples. Some of these observations are recorded.

A wonder-worker of science. An authoritative account of Luther Burbank's unique work in creating new forms of plant life, W. S. HARWOOD (*Cent. Mag., 69 (1905), Nos. 5, pp. 656–672; 6, pp. 821–837, figs. 37*).—Descriptions are given of the many new forms of fruits, flowers, nuts, and other economic plants created or improved by Mr. Burbank, with an account of his methods of work. A fuller account of the spineless cactus and its fruits is given than has appeared heretofore.

Breeding grapes to produce the highest types, T. V. MUNSON (*Nebr. Farmer, 37 (1905), No. 12, p. 315*).—A paper read by the author before the American Breeders' Association, February 1, 1905.

The grape and its development, J. C. BLAIR (*Trans. Ill. Hort. Soc., n. ser., 38 (1904), pp. 412–427*).—A paper on this subject in which the manufacture of unfermented grape juice and the food value of the grape are discussed in addition to cultural methods.

The assimilation of phosphoric acid by grapes, E. ZACHAREWICZ (*Prog. Agr. et Vit. (Ed. l'Est), 25 (1904), No. 43, pp. 459–462*).—Experiments were made to determine what influence the use of superphosphates would have on the phosphoric acid content of the fruit and wine.

Physical and chemical analyses are given of the soils on which the experiments were carried out and the usual experimental details recorded. The amount of superphosphate used on the different plats varied from none on the control plat to 45, 90, and 135 kg., respectively, on the other 3 plats. The analyses of wines made from the grapes grown on the different plats showed that there was 10 times as much phosphoric acid in the wine from the plat which had been fertilized with 135 kg. of superphosphate as from the control plat.

The conclusion is drawn that phosphoric acid may be accumulated in part in fruit and contribute its beneficial influence to the wine made from it.

Planting-table for flowers, L. BARRON (*Gard. Mag. [New York], 1 (1905), No. 3, pp. 117, 118*).—Brief suggestions are given on the making of flower beds, planting and sowing of flowers, as well as a table showing when and how to sow 47 different kinds of flowering plants, period of flowering of the plants, and color of the flowers, with notes on soil, water, transplanting, etc.

On the hybridization of the genus Rosa, M. VIVIAND-MOREL (*Jour. Roy. Hort. Soc. [London], 29 (1904), No. 1–3, pp. 38–46*).—A brief treatise on this subject considered largely from an historical standpoint.

Pansy culture, W. TOOLE (*Trans. Ill. Hort. Soc., n. ser., 38 (1904), pp. 130–135, pl. 1*).—The author describes his methods of commercial outdoor pansy growing in Wisconsin.

FORESTRY.

A primer of forestry. II, Practical forestry, G. PINCHOT (*U. S. Dept. Agr., Bur. Forestry Bul. 24, pt. 2, pp. 88, pls. 18, figs. 47*).—Part 1 of this primer (E. S. R., 11, p. 855) dealt with the units which compose the forest and the character of the forest as a whole.

The present part deals with the practice of forestry, with the practical work in the woods in perpetuating forests and in lumbering, with the relation of forests to

weather and streams, and gives a short account of the historical development of forestry and of present forestry practices in foreign countries and in the United States.

Forestry experiments, F. W. RANE (*New Hampshire Sta. Bul. 119, pp. 51–68, figs. 8*).—A discussion is given of the prevalence and value of native pine seedlings, with an account of experiments in the digging, packing, and transplanting of pine seedlings and a comparative statement of the cost in reforesting with wild seedlings and nursery-purchased stock. Two earlier bulletins along similar lines have been published by the station (E. S. R., 14, p. 873; 16, p. 56).

In most sections of New England where the white pine (*Pinus strobus*) is native young natural seedlings in large numbers occur. The author urges the use of these in reforesting. The cost of digging and packing 2-year-old seedlings when moderately thick is placed at 75 cts. per 1,000, and is based on actual experiments by students at the station. One man can pack for shipment 20,000 of these seedlings in half a day. The Boston market bushel box has been found a very satisfactory package for shipment. One man under favorable conditions can transplant about 400 seedlings per hour.

The cost of setting the plants 8 by 8 ft. is placed at about 50 cts. per acre. If set 5 by 5 ft. the expense would be about $1.50 per acre. The total expense of digging and transplanting wild seedlings amounts to approximately $1.50 per 1,000. Early spring is considered the best time for transplanting pine seedlings. Seedlings not less than 2 nor more than 4 years old are recommended.

If a nursery stock is used for reforesting the expense will be considerably increased. In the station work the cost was $3 per 1,000 and 100,000 were used to cover an area of 43 acres. The cost for packing was $20, and the expense of planting in the nursery row and then transplanting, use of land, culture, etc., amounted to $280. The total cost, therefore, averaged about $14 per acre, which is considerably in excess of the cost when native seedlings were transplanted from the forest.

The shade trees of Denver, W. PADDOCK and B. O. LONGYEAR (*Colorado Sta. Bul. 96, pp. 14, pls. 13*).—Directions are given for the culture of shade trees in Colorado with descriptions of about 60 kinds of trees which are foreign to the State, but which are known to be growing in Denver.

The principal shade trees of Colorado are the cottonwood and box elder. These trees are popular because they are successfully grown under conditions of partial neglect. It is believed, however, that many other desirable varieties can be successfully grown if proper attention is given to details of planting and caring for the trees. Owing to the drying winds of winter it is believed that the best time for planting trees in Colorado is in the spring of the year.

Shade trees and ornamental shrubs and plants, G. MCCARTHY (*Bul. N. C. Dept. Agr., 26 (1905), No. 1, Sup., pp. 33–36*).—A list is given of deciduous flowering shrubs desirable for planting in the upland region of North Carolina.

The planted groves of Iowa, H. P. BAKER (*Proc. Iowa Park and Forestry Assoc., 4 (1904), pp. 36–45*).—Suggestions are given for the planting of different species of trees in Iowa and an account of different groves which have been planted for a number of years in different sections of the State.

Groves of Norway spruce at Conroy, Iowa, have made an average growth of 1 ft. 9 in. per year for the last 15 years. Two areas at Conroy were measured and the number of posts and poles ascertained. One area was estimated to have a value of $145.62 per acre and the other $144.04 per acre, giving an average annual gain since the groves have been planted of $8.04. With corn at 20 cts. per bushel the average annual gain per acre is $7.

What the college has done for park and forestry during the last thirty years, L. H. PAMMEL (*Proc. Iowa Park and Forestry Assoc., 4 (1904), pp. 51–70*).—An account is given of the different plantings of trees that have been made under the direction of college authorities at Ames during the past 30 years. A list is given

of the trees on the campus with dates when planted, character of the soil and subsoil in which they are growing, circumference of the trees in inches, height, and general remarks on the character and the culture given.

Our mountain chaparral, G. ROBERTSON (*Pacific Rural Press, 69 (1905), No. 21, pp. 324, 325*).—An account of the chaparral belts of San Bernardino, with descriptions of the principal species of shrubs growing in each of these belts, and practical suggestions regarding the preservation of chaparral belts.

Layering rubber trees, H. N. RIDLEY (*Agr. Bul. Straits and Fed. Malay States, 3 (1904), No. 11, pp. 441, 442, pls. 2*).—An illustration is given of a number of rubber trees that have grown from the trunks of trees blown down in a storm.

It is recommended that trees that are blown down in storms be laid prostrate on the earth and banked up along the fallen trunk about halfway and the top of the tree cut off. Shoots spring up along the tree in abundance, but should be thinned out until only about 8 are left.

Two little-kown caoutchouc-producing lianes, E. DE WILDEMAN (*Compt. Rend. Acad. Sci. [Paris], 140 (1905), No. 8, pp. 515–517*).—The author states that for a long time it was supposed that the caoutchouc exported in large quantity from tropical Africa was obtained from a single liane, *Landolphia florida*. Recent researches, however, have shown that caoutchouc from *L. florida* is not exported by the natives for this purpose.

The caoutchouc is mostly derived from two other species, *Baissea gracillima* and *Periploca nigrescens*. The latter seems to be the more important of the two. Caoutchouc from Periploca is black and of good quality. This liane is not very large. The stem is about as thick as the thumb and covered with a scaly bark. It produces seeds abundantly whose germination is not injured by the voyage from Africa to Belgium. The plant is also easily propagated by cuttings. Sprouts from the roots may be exploited commercially after 2 years' growth.

DISEASES OF PLANTS.

Report of the plant pathologist, E. MARCHAL (*Bul. Agr. [Brussels], 21 (1905), No. 1, pp. 73–80*).—During the season covered by this report the author investigated about 150 different plant diseases, a list of which is given. Notes are also given on a number of the more characteristic diseases and suggestions presented for their prevention.

Report of the consulting botanist, W. CARRUTHERS (*Jour. Roy. Agr. Soc. England, 65 (1904), pp. 258–269, figs. 2*).—A report is given of the investigations carried on by the consulting botanist for the year 1904. During this time a considerable number of samples of grass and clover seed were examined, and species of plants as well as diseases of the same were determined.

In connection with the diseases of plants investigated, notes are given on the economic habits of a number of fungi, none of which appears to be entirely new.

Concerning the root rot of cotton, V. MOSSERI (*Sur un pourridié du cotonnier. Cairo: Impremerie Nationale, 1904, pp. 22, pls. 2*).—A description is given of the root rot of cotton which has been attributed to *Ozonium auricomum*. The author believes that the disease in Egypt is different from that in the United States; at least it is not believed by him to be due to the above-named fungus as observed in Europe and which is believed by many authors to be an incomplete form of some hymenomycete.

Various methods of treatment are suggested, and among those considered most promising, the author calls attention to the securing of immunity by selection of plants. This is applied particularly in the case of cotton and banana, both of which are subject to the disease.

Some diseases of the potato, G. MASSEE (*Jour. Roy. Hort. Soc. [London], 29 (1904), No. 1–3, pp. 139–145, figs. 6*).—Brief descriptive notes are given of the potato rot

(*Phytophthora infestans*), winter rot (*Nectria solani*), black scab (*Œdomyces leproides*), bacterial disease (*Bacillus solanacearum*), and potato scab (*Sorosporium scabies*). The effect of these different fungi on the host plants is described, and so far as known the methods of distribution, infection, and means of control are given.

Potato spraying experiments in 1904, F. C. STEWART, H. J. EUSTACE, and F. A. SIRRINE (*New York State Sta. Bul. 264, pp. 95–204, pls. 16, map 1*).—In continuation of the 10-year spraying experiments for the control of potato diseases (E. S. R., 14, p. 875; 15, p. 781), a report is given of the operations carried on by the station during 1904.

The bulletin gives the details of 58 experiments in different parts of the State, in which increased yields of potatoes due to spraying are reported. At Geneva 5 sprayings increased the yield by 233 bu. per acre, while 3 sprayings gave an increase of 191 bu. At Riverhead the gain due to 6 sprayings was 96¾ bu. and to 3 sprayings 56½ bu. per acre. At this place the flea beetle was the principal enemy.

In the experiments carried on by farmers in different parts of the State, gains of 62¼ bu. per acre are reported in one series including 180 acres. This gain was made at an average cost of \$4.98 per acre, and the net profit, based on the market price of potatoes at digging time, was \$24.86 per acre. In another series of experiments carried on with 41 farmers throughout the State, including 363¾ acres, the average gain due to spraying was 58½ bu. per acre, the net profit received being \$22.01 per acre.

Different fungicides were tested in these experiments, soluble Bordeaux mixture and soda Bordeaux being compared with Bordeaux mixture made with lime after the usual formula. The results obtained were in favor of the use of the lime Bordeaux, as previously described. It is believed that the efficiency of the soluble Bordeaux mixture may have been reduced by the use of too dilute a solution.

The authors state that the practice of spraying potatoes for the control of blight is on the increase in New York, and many growers are preparing to spray who have hitherto disregarded this precaution. For 1905 the regular experiments will be continued at Geneva and Riverhead, and efforts made to extend the work through volunteer cooperative investigations.

Profits from spraying potatoes, F. H. HALL ET AL. (*New York State Sta. Bul. 264, popular ed., pp. 16, figs. 3*).—This is a popular summary of the above bulletin.

Notes on Cobb's disease of sugar cane, E. F. SMITH (*Centbl. Bakt.* [*etc.*], *2. Abt., 13 (1904), No. 22–23, pp. 729–736*).—The author gives the results of a study of a disease of sugar cane which was first recognized in Australia by N. A. Cobb (E. S. R., 7, p. 513). The disease is accompanied by a copious exudation of gum, and on this account is sometimes called the gum disease of sugar cane.

The author investigated the cause and behavior of the disease, concluding that it is of bacterial origin and due to the organism previously described but which by the present system of nomenclature becomes *Pseudomonas vascularum*. The organism was separated and grown in various media, after which successful inoculation experiments were carried on.

Attention is called to the resemblance between this disease and its cause and that which is known as the sereh disease of sugar cane in Java.

A bacterial wilt disease of tobacco, Y. UYEDA (*Centbl. Bakt.* [*etc.*], *2. Abt., 13 (1904), No. 9–11, pp. 327–329, figs. 3*).—A bacterial disease of tobacco is described which has been under observation at the experiment station at Tokyo, Japan, and which is attributed to attacks of *Bacillus nicotianæ*. The disease is said to cause much injury, especially when the transplanting is made late in the season.

Prolonged moist weather followed by a high temperature favors the development of the disease, which is characterized by a wilting and yellowing of the lower leaves, followed by a blackening of the stem and leaves and finally of the roots. The natural infection seems to take place through the roots, but the author believes that it may also occur through wounds caused by topping or suckering of the plants.

The bacteria have been isolated and cultivated on a number of media, their characteristics being described. It is believed by the author that this disease is the same as that reported under the name of the Granville wilt in North Carolina (E. S. R., 15, p. 684).

In a postscript the author states that experiments have shown the possibility of communicating the disease through the stomata, the characteristic blackening being observed in 8 days on plants whose leaves were sprayed with a solution containing the bacteria.

A Sclerotinia disease of tobacco, C. A. J. A. OUDEMANS and C. J. KONING (*K. Akad. Wetensch. Amsterdam, Proc. Sect. Sci., 6 (1903), pt. 1, pp. 48–58, 85, 86, pls. 2*).—A report is given on a disease of tobacco noted as occurring injuriously in the tobacco fields of Holland.

A study of the disease showed that it was due to a hitherto unknown fungus, to which the name *Sclerotinia nicotianæ* is given. It is said that the common practice in growing tobacco is to divide the fields into small areas by means of hedges of scarlet runner and other beans, the object being to protect the tobacco plants against wind by the high, dense growth of the beans. An examination showed that the disease was most prevalent near these hedges, and to the dampness and shading of the hedges are attributed the conditions necessary for the development of the fungus.

Plants affected by the fungus show limp, slippery leaves and discolored stems. If leaves of this character are carried to the curing shed, the fungus quickly spreads through the entire curing house. The authors separated the fungus and give its technical description, and as means for preventing its attack suggest that the use of the bean hedges should be abandoned and wherever the diseased leaves and stems are observed they should be removed and burned. When putting the tobacco leaves in the drying sheds they should be well separated and all suspected leaves should be destroyed.

The study of the diseases of some truck crops in Delaware, C. O. SMITH (*Delaware Sta. Bul. 70, pp. 16, pls. 2, figs. 6*).—The author describes the leaf spot of cucurbits caused by *Sphærella citrullina*, a leaf spot of eggplant due to *Ascochyta lycopersici*, and a leaf spot of beans and cowpeas which is attributed to the fungus *Phyllosticta phaseolina*.

The leaf spot of cucurbits was abundant during the autumn of 1903, the author finding it quite common on the leaves and fruit of squashes and pumpkins and to a limited extent on the leaves of cucumbers and cantaloupes. The fungus is of special interest on account of its resemblance to a disease reported as destructive to watermelons in Delaware (E. S. R., 5, p. 787). The author describes the gross and microscopic characteristics of the fungus, and gives the results of artificial cultures and inoculation experiments. He describes the different stages of the fungus, which in the perfect stage is designated as *Sphærella cucurbitacearum*, although the name adopted in the text of the bulletin is *S. citrullina*. This last combination would be displaced if strict attention to priority should be paid.

The leaf spot of eggplants is due to the fungus *Ascochyta lycopersici*, the different stages of which are described. The possible relationship between this fungus and *Phyllosticta hortorum* is pointed out, and the writer believes them to be identical. Inoculation experiments have shown that this fungus successfully attacks the eggplant, tomato, horse nettle, and jimson weed. A brief account is given of a Septoria attacking the fruit of the eggplant, and it is believed to be possibly an immature form of the Septoria occurring on tomatoes.

The leaf spot of beans and cowpeas caused by *Phyllosticta phaseolina* is described at some length. This trouble was first observed on Lima beans, but it has since been found on other varieties of beans and also on cowpeas, being particularly destructive to Lima beans and cowpeas wherever these plants are grown in Delaware. The

fungus is described at some length. By inoculation experiments it was found possible to transfer the organism from one variety of beans or cowpeas to another.

No work is being carried on for the control of these diseases by spraying, but the author believes that Bordeaux mixture properly applied would give beneficial results. An additional suggestion is offered that all diseased vines be collected and burned at the end of the season, so as to remove danger of infection as much as possible.

Asparagus rust in California, R. E. SMITH (*California Sta. Bul. 165, pp. 1-7, 18-99, figs. 33*).—This bulletin gives the results of continued investigations on the asparagus rust (E. S. R., 16, pp. 66, 986).

The previous results have shown that by careful attention to cultural methods and the relation of moisture to the development of the fungus the disease could be controlled to a considerable extent. Continued studies have shown that the rust can be almost completely controlled in California through careful attention to cultural methods and the use of treatments which are described at considerable length.

In 1904 an extended series of experiments was inaugurated to test the efficiency of sulphur, both as a liquid spray and as dry powder, for the control of the fungus causing the rust. These experiments are described at length. Summarizing the results the author states that sulphur either in dry or liquid form, acting largely by its gaseous fumes, is a satisfactory rust preventive when properly applied. It is shown that this treatment can be applied economically and practically in any of the districts covered by the investigations.

The use of contact sprays failed to give good results, but of those used resin Bordeaux was best and soap Bordeaux nearly as good. In general no spraying method should be resorted to until rust control by cultural means has been carried as far as possible, and it is probable that without reasonable attention to cultural methods the best of spraying will prove a failure.

The methods for the application of dry sulphur, time of treatment, amount of sulphur required, and the relative efficiency of different kinds of sulphur are discussed at some length, the cost of material and application being estimated at from $5 to $6 per acre for 2 applications during the season. Where the sulphur spray is used it is said to have some advantages and be more efficient, a single application being considered the most effective single treatment for the rust.

Brief notes are given on the rust parasites and on some of the insects affecting the asparagus plant.

Black rot of cabbage, W. BRENNER (*Centbl. Bakt. [etc.], 2. Abt., 12 (1904), No. 22-24, pp. 725-735, figs. 6*).—The author has investigated the black rot of cabbage and allied plants, and in the main agrees with Smith and Harding regarding the occurrence in Europe of this disease, its cause, and methods of infection (E. S. R., 9, p. 847; 12, p. 654).

The organism *Pseudomonas campestris* was isolated and studied in various media. Inoculation experiments produced the characteristic appearance of the disease in from 14 to 21 days. The relation of insects to infection was studied, and the author concludes that infection can take place only through wounds or through the water pores along the margins of the leaves.

A bacterial disease of cauliflower and allied plants, F. C. HARRISON (*Centbl. Bakt. [etc.], 2. Abt., 13 (1904), Nos. 1-3, pp. 46-51; 5-7, pp. 185-198, pls. 6*).—This is practically a reprint of Ontario Agricultural College and Experimental Farm Bulletin 137 (E. S. R., 16, p. 480).

Notes on a disease of cucumbers, P. MAZÉ and H. T. GÜSSOW (*Jour. Roy. Agr. Soc. England, 65 (1904), pp. 270-272*).—A description is given of an apparently undescribed disease of young cucumbers, which covered the fruit with a thick dark olive-green mass of hyphæ. In the specimens observed by the authors the portion

of the fruit next the stalk was little injured, while the distal portions were greatly reduced in size and killed by the parasite. The leaves showed no trace of disease.

An examination of the fungus on the part of the second author has led him to the conclusion that it is an entirely undescribed one, and he proposes for it the name *Corynospora mazei* n. g. and n. sp.

From the nature of the disease the authors recommend the use of a dilute solution of copper sulphate or other fungicide, and also the collection and burning of all débris about the places of cultivation.

Apple scab and cedar rust, R. A. EMERSON (*Nebraska Sta. Bul. 88, pp. 21, figs. 9*).—This bulletin while describing apple scab and cedar rust is intended principally to record observations showing the results of tests of spraying as a means for preventing these diseases. Brief descriptions are given of the appearance of the two diseases, and attention is called to the varying susceptibility of different varieties of apples to both these diseases.

Spraying tests were carried on with 6 varieties for the prevention of the apple scab and the rust, the fungicide used being a 4:4:50 solution of Bordeaux mixture. The results obtained showed that spraying reduced the proportion of rusted leaves, and the effect as shown on the yield of fruit indicates that the spraying was very beneficial in reducing the amount of scab. The rust was held in check even on the varieties that are ordinarily badly rusted.

The first application of Bordeaux mixture should be made when the so-called apples on cedar trees are becoming gelatinous and orange colored, followed by such applications as are needed, usually a second spraying after an interval of 10 days or 2 weeks. In addition to spraying the apple trees the removal of the cedar trees for a considerable distance about orchards or, where this is impossible, the cutting out and destruction of the cedar apples is recommended.

In experiments for the control of apple scab the 2 sprayings recommended for this purpose practically coincide in time with those suggested for the control of the rust. Some slight difference is noted in the efficiency of later applications for the prevention of the scab.

Apple and pear scab, M. C. COOKE (*Jour. Roy. Hort. Soc. [London], 29 (1904), No. 1-3, pp. 91, 92*).—Notes are given on the apple and pear scab (*Fusicladium dendriticum* and *F. pirinum*), the habit, external appearance, life history, development, and remedies for which are practically the same, the only difference being those of a microscopical character.

The author describes the effect on the host plant, and gives some estimates as to the injury caused by the fungi, after which an account is given of the methods by which the fungus is carried over winter, and the discovery of the perfected form (*Venturia inæqualis*) is noted. For the prevention of injury by the fungi the author recommends thorough spraying of the trees with Bordeaux mixture or modified eau celeste.

The brown or bitter pitting of apples, G. QUINN (*Jour. Agr. and Indus. So. Aust., 8 (1905), No. 6, pp. 305-309*).—Attention is called to what is apparently a physiological disorder of apples, which goes under the name of brown or bitter pitting.

This disease has been known in southern Australia for at least 20 years, and is characterized by the appearance at first of small, dark-green, depressed areas on the skin of the apple, beneath which the pulp cells become dull brown, dry, of a spongy nature, and dead for several layers of cells in depth. The most noticeable development of this pitting seems to follow the formation of sugar as the apple approaches ripeness.

A careful examination of diseased specimens failed to show any fungus or other organized cause for the disease. Marked differences are reported for different varie-

ties of apples. Based upon the observations of the author and others, it is believed that the pitting is due to unsuitable conditions of soil, moisture, and temperature, either separately or in combination.

To prevent the occurrence of the disease as much as possible, the author suggests that susceptible varieties should not be planted, and that planting on damp, rich soil should be avoided. Care should be taken in pruning, and the use of fertilizers should be given attention, so as to produce the most favorable growth of the trees.

A fruit disease caused by Fusarium putrefaciens n. sp., A. Osterwalder (*Centbl. Bakt. [etc.], 2. Abt., 13 (1904), Nos. 5-7, pp. 207-213; 9-11, pp. 330-338, pls. 2*).—A rot of apples and pears is described which is attributed to attacks of *Fusarium putrefaciens* n. sp.

The fungus was isolated, and inoculation experiments showed the readiness with which the disease could be produced on pomaceous fruits. The characteristics of the fungus and its effect on the fruits of the apple and pear are described at length. The author claims that the fungus is identical with that reported by Eustace as *Cephalothecium roseum*, which causes a rot of apples (E. S. R., 14, p. 1088). He agrees with Eustace and others on the ability of this fungus to cause a rotting of the fruits, in this way refuting the claims of a number of European investigators. The fungus, which is technically described, is believed to be a phase of the species previously noted.

Notes on canker and gummosis of fruit trees, J. Brzeziński (*Centbl. Bakt. [etc.], 2. Abt., 12 (1904), No. 19-21, pp. 632-640*).—A controversial article, in which the author criticises some of the conclusions of Aderhold regarding the relation between canker and gum flow of fruit trees, which the latter attributes to attacks of *Clasterosporium carpophilum* (E. S. R., 15, p. 591).

A new disease of figs (*Jour. Agr. and Indus. So. Aust., 8 (1904), No. 5, pp. 266, 267*).—A brief account is given of a disease of figs which is said to be caused by attacks of Botrytis. So far as observed only the Capri figs are attacked. The young wood will put out new leaves and fruit in the spring, but before they attain any considerable size they begin to droop and finally die. The fungus appears to be carried over in the Capri figs, the peduncle or stalk of the fruit being the point of attack.

Spraying has so far proved of little value in combating the disease, and the removal of the winter figs would involve in one case the loss of the crop and in the other the destruction of the fig insect, which is needed for the fertilization of the fruit.

Wither-tip and other diseases of citrus fruits, P. H. Rolfs (*Bul. Dept. Agr. [Jamaica], 3 (1905), No. 2, pp. 25-34*).—This is largely a reprint of a bulletin by the author which has been previously noted (E. S. R., 15, p. 974). It is claimed that the wither-tip, caused by *Colletotrichum glœosporioides*, has been recently observed as occurring in Jamacia on limes.

Notes on the Glœosporium disease of red currants, R. Laubert (*Centbl. Bakt. [etc.], 2. Abt., 13 (1904), No. 1-3, pp. 82-85, fig. 1*).—The author gives an account of the distribution of the Glœosporium disease of currants in Europe and elsewhere, showing the effect produced upon the host and giving technical descriptions of the fungus, particular attention being paid to a number of its forms.

The present aspect of the epidemic of the American gooseberry mildew in Europe, E. S. Salmon (*Jour. Roy. Hort. Soc. [London], 29 (1904), No. 1-3, pp. 102-110, map 1*).—The author describes the distribution of the gooseberry mildew (*Sphærotheca morsuvæ*) in Europe, and states that it occurs in epidemic form in Ireland and Russia, and has been reported as observed in other localities.

Notes are given on the efforts which have been made to control the disease in a number of localities, and the author recommends the continued and thorough application of fungicides, together with the pruning and burning of affected portions of the bushes.

Fungus diseases of the cranberry, C. L. Shear (*U. S. Dept. Agr., Farmers' Bul. 221, pp. 16, figs. 11*).—The cranberry is affected by 4 serious fungus diseases known as blast, scald, rot, and anthracnose.

The first 2 are due to the attacks of the same fungus, and represent different forms of one disease. Blast is a term used to refer to the form of the disease which attacks the fruits immediately after the blossoms fall. Scald has frequently been confused with the effect of flooding followed by hot sun. This disease first appears as small light-colored softened spots on the surface of the fruit. Cranberry rot has frequently been mistaken for scald. It is due, however, to another species of fungus which causes irregular black spots just beneath the skin of the diseased fruit. Anthracnose, while due to a distinct species of fungus, can usually not be distinguished from scald except by making cultures of the fungi. All of these diseases affect the fruit and leaves.

Remedies for these diseases must be of a preventive nature, and should consist in the regulation of the water supply, destruction of diseased vines, the use of resistant varieties, and spraying with standard fungicides, preferably Bordeaux mixture made according to the 6:4:50 formula, to which a resin-fishoil soap is added to make it adhere better. During the season 5 applications should be made at intervals of not more than 15 days, using about 4 barrels of the fungicide per acre. The cost of this treatment is about $15 per acre.

Preventive treatment of grape anthracnose, L. Degrully (*Prog. Agr. et Vit. (Ed. l'Est), 26 (1905), No. 5, pp. 132, 133, pl. 1*).—Attention is called to the efficiency of dilute sulphuric acid as a wash for grapevines for the prevention of anthracnose, and the author recommends the application of sulphuric acid in a dilution of about 6 liters of acid to 100 liters of water. This should be applied to the vines as late as possible in the winter, preferably 2 or 3 weeks preceding the swelling of the buds. This treatment is to be preferred over the use of sulphate of iron or other fungicides which have been recommended.

Diseases of cocoanuts (*Bul. Dept. Agr. [Jamaica], 3 (1905), No. 3, pp. 51, 52*).—A report is given of the successful use of Bordeaux mixture for protecting cocoanut trees against the bud disease which causes the death of the trees. The experiments are still in progress and will be continued, applications being made at intervals of 6 to 9 months until there is no trace of the disease.

An injurious disease of larch, C. A. J. A. Oudemans (*K. Akad. Wetensch. Amsterdam, Proc. Sect. Sci., 6 (1904), pt. 2, pp. 498–501, pl. 1*).—A description is given of a fungus disease of the common European larch, which is characterized by the discolored appearance of the leaves and twigs of the trees.

The discoloration of the leaves proceeds from the outer portion of the rosette toward the interior, so that for a considerable period needles of two colors will be found together. The fungus appears to be restricted to the leaves, and on this account the author recommends that all fallen leaves should be collected and burned to prevent the spread of the disease.

A study was made of the organism, and it is described as *Exosporina laricis*. The affinities of this new genus are discussed.

ECONOMIC ZOOLOGY—ENTOMOLOGY.

The economic value of our native birds, H. A. Surface (*Pa. Dept. Agr., Zool. Quart. Bul., 2 (1905), No. 4, pp. 67–102, pls. 4, figs. 4*).—The author discusses the feeding habits and economic relations of woodpeckers, including hairy woodpecker, downy woodpecker, *Sphyrapicus varius*, pileated woodpecker, red-headed woodpecker, and flicker.

Slugs and snails (*Bd. Agr. and Fisheries [London], Leaflet 132, pp. 6, figs. 2*).—The habits of *Limax agrestis* and *Helix aspersa* are briefly described. Thrushes and poultry

are considered the most effective enemies of these pests. Cultivated plants may usually be protected against the attacks of slugs and snails by dressings of soot and lime, salt and lime, caustic soda and lime, or powdered coke. Caustic soda should be used at the rate of 4 parts to 96 parts of lime. All materials used to destroy slugs should be in a finely pulverized form.

Reports of the deputy commissioner of horticulture, A. CRAW and E. M. EHRHORN (*Bien. Rpt. Comr. Hort. Cal., 1903-4, pp. 34-39*).—*Scutellista cyanea* is reported as continuing its successful work as a parasite of the black scale. The latter pest is completely controlled by the parasite in many localities. Notes are also given on *Saissetia oleæ*, a South African parasite of the black scale, and on the damage due to *Diaspis pentagona.*

Condition of orchards and nursery stock in Utah and Oregon, J. ISAAC (*Bien. Rpt. Comr. Hort. Cal., 1903-4, pp. 29-33*).—A brief account is given of the conditions which were found to prevail in orchards and nursery stock in Utah and Oregon, with especial reference to injurious insects which might be imported into California. Attention was called to the existence of eastern peach-root borer in both Utah and Oregon, and the necessity of quarantining against it.

Bug v. bug, J. ISAAC (*Bien. Rpt. Comr. Hort. Cal., 1903-4, pp. 79-107, pls. 4, figs. 18*).—In this article the author presents a general account of the value of predaceous and parasitic insects in the control of insect pests.

A list is given of the beneficial insects which were exhibited by the California commissioner of horticulture at the St. Louis Exposition. The illustrations of the value of parasitic and predaceous insects are largely drawn from the extensive experience which the fruit growers of California have had with this method of fighting insect pests. It is stated that in California the chief reliance is placed on the use of efficient artificial insecticides, but that in addition to the application of washes, dips, and fumigating methods every effort has been made to secure parasitic and predaceous insects to assist in the control of insect pests. Detailed notes are given on a large number of such beneficial insects and upon the effectiveness of their parasitism.

The cotton worm, G. P. FOADEN (*Jour. Khediv. Agr. Soc. and School, 6 (1904), No. 6, pp. 12*).—Detailed notes are given on the habits and life history of *Prodenia littoralis.* The eggs are laid on only one or two leaves of each cotton plant. Heavy irrigation while the caterpillars are in the soil is beneficial.

According to the author the main reliance is to be placed in picking and destroying leaves on which eggs have been deposited. The incubation period for the eggs is 3 or 4 days, and the infested leaves should be picked during this period. Chemical insecticides are believed to be of little avail against this pest.

The cotton bollworm in Georgia. Insects injurious to corn and truck crops, R. I. SMITH (*Ga. Bd. Ent. Bul. 16, pp. 25-53, figs. 15*).—For controlling the bollworm the author recommends planting corn as a trap crop in rows 200 to 300 ft. apart throughout the cotton field, and from May 15 to June 1. Poison should be applied as soon as the worms appear on the cotton. For this purpose Paris green is effective and should be dusted on the plants. The Paris green should be mixed with dust in the proportion of 1:4 and should be applied so as to use 2 lbs. Paris green per acre.

Biological and economic notes are also given on cotton caterpillar, *Diatræa saccharalis*, corn-root worm, squash-vine borer, squash bug, cucumber beetle, potato beetle, flea beetles, cabbage worms, and plant lice.

Beet worms and their remedies, C. P. GILLETTE and S. A. JOHNSON (*Colorado Sta. Bul. 98, pp. 22, pls. 2, figs. 2*).—The beet web worm (*Loxostege sticticalis*) causes more or less injury to sugar-beet fields in the State every year.

The insect feeds upon beets, cabbages, onions, pigweed, Russian thistle, alfalfa, and perhaps other plants. Eggs are laid in clusters or sometimes singly and the insect winters over in the larval or pupal condition. This pest may be controlled by deep

plowing in the fall or early spring or by spraying with an arsenical insecticide such as arsenate of lead, arsenite of lime, Paris green, or London purple.

Beet army worm (*Caradrina exigua*) resembles beet web worm quite closely. The injuries caused by this pest are also quite similar to those of the web worm. Apparently the insect may winter over in the adult condition, but as the larvæ are in the ground immediately after the removal of the beets they may be destroyed by surface elevation. During the growing season they may be killed with arsenical sprays. Notes are also given on cutworms, with a brief account of their habits, life history, parasites, and artificial remedies.

The destruction of locusts, C. W. MALLY (*Agr. Jour. Cape Good Hope, 26 (1905), No. 3, pp. 406–420, figs. 2*).—Attention is called briefly to the natural enemies of locusts, particularly of *Pachytylus sulcicollis*.

The artificial means of destroying these locusts consists in the collection of eggs, the destruction of the young nymphs, the use of poisoned bait containing arsenic, soda, and sugar, the use of contact insecticides such as soaps and other washes, and various kinds of traps, some of which are described in detail in connection with illustrations. When hopperdozers and other kinds of locust traps are used, large quantities of the insects are usually captured. It should be remembered that the food value of locusts is considerable, and they should, therefore, not be destroyed.

Poultry raisers and ostrich farmers are glad to pay a reasonable price for such material, and locusts are also readily eaten by horses, sheep, and pigs. No single method is sufficient to control entirely the locust plague. The newly hatched locusts may be destroyed by spraying or by the use of poisoned baits, and the cultivated fields may be protected by the use of locust fences.

The biology of the brown-tail moth and an account of its ravages, A. Y. GREVILLIUS (*Bot. Centbl., Beihefte, 18 (1905), No. 2, 2. Abt., pp. 221–322, figs. 8*).—This paper constitutes an elaborate and detailed monograph of the brown-tail moth.

An account is presented of the development of the insect, its appearance in the various stages, its food plants, and the injuries caused by the pest to various cultivated plants. A long series of feeding experiments was carried out for the purpose of determining so far as possible the preferred food plants of this insect. A large variety of plants was used in these experiments and the results are presented in a tabular form. It appears that the number of caterpillars present in any locality is one factor in determining the choice of food plants.

Analyses were made of a large number of leaves to determine their content of tannin. It appears that tannin is another important factor in the problem of food plants of the brown-tail moth. This insect does not voluntarily eat leaves which do not contain tannin. This was noted particularly in the case of *Stellaria media*. When the leaves of this plant, however, were sprinkled with tannin they were eaten by the caterpillars.

Light and heat as well as moisture of the air exercise considerable influence upon the brown-tail moth. As a rule, larvæ preferred to eat in bright light. The caterpillars ate quite actively at a temperature of 40° C., but ceased eating in some cases and were killed by a temperature of 45° C. In an atmosphere saturated with moisture they appeared to lose appetite to a considerable extent.

Experiments undertaken to show the effect of cold upon the brown-tail moth indicate that when exposed the caterpillars endure temperatures as low as −16° C. without serious loss; about 40 per cent of the caterpillars resist a temperature of −21° C. for a period of 2½ hours. Caterpillars in winter nests were able to withstand a temperature of −23 to −31° C. for 24 hours, but were destroyed when the temperature reached −35.5° C. The winter nests appeared to protect the caterpillars on account of their nonconductivity. A bibliography of the subject is appended to the article.

Some notes on the habits and life history of Bembecia marginata in western Washington, W. H. LAWRENCE (*Ent. News, 16 (1905), No. 4, pp. 117-119*).—The raspberry root borer has appeared in some parts of western Washington.

The life history of this insect was studied by the aid of breeding experiments in the laboratory and field observations. The insect hibernates in the larval condition just underneath the epidermis of the canes beneath the surface of the ground. Apparently they do not burrow into the canes and down into the roots. Usually infested canes are not killed outright but merely show a poor growth.

The injuries caused by Lytta vesicatoria to the flowers of the olive, D. MARIANI (*Staz. Sper. Agr. Ital., 37 (1904), No. 6, pp. 484-489, figs. 2*).—This beetle frequently feeds upon the flowers of the olive and *Syringa vulgaris*, doing great damage. In some instances the entire inflorescence is destroyed. Brief notes are given on methods of destroying these pests.

The orange maggot, A. L. HERRERA (*Bol. Com. Par. Agr., 2 (1905), No. 7, pp. 307-448, figs. 2*).—*Trypeta ludens* was found in some Mexican oranges imported into California and State quarantine was proclaimed against the importation of all Mexican oranges. This led to a general investigation of the subject by the Mexican government, and the results of this study are published in the present bulletin.

The distribution of the insect is discussed in great detail and notes are given on the importance of the orange industry in Mexico. The author discusses also the habits and life history of a number of insects related to the orange maggot. A large part of the bulletin is of a highly controversial nature. As the result of the investigation it is concluded that the orange maggot does not exist in all parts of Mexico, and that some provinces free from the pest produce large quantities of oranges suitable for exportation. It is argued that efficient means exist for the control of this pest and that they are being applied on the Morelos estate from which the infested oranges were imported into California.

The author maintains that the orange maggot has frequently been introduced into the United States, and has never been able to establish itself either in this country or in the northern part of Mexico.

The Morelos orange maggot, E. COOPER (*Bien. Rpt. Comr. Hort. Cal., 1903-4, pp. 43-50*).—*Trypeta ludens* was found in several shipments of Mexican oranges which arrived at San Francisco. On account of the dangerous character of this insect a strict quarantine has been established against Mexican oranges, and the railroads are assisting in preventing the introduction of the pest.

A new enemy of oranges, P. MARCHAL (*Bul. Mens. Off. Renseig. Agr. [Paris], 4 (1905), No. 2, pp. 143-148*).—*Chrysomphalus dictyospermi minor* is described with particular reference to its injuries to citrus fruits.

The difficulty of combating this pest is partly due to the great variety of plants upon which it feeds, the existence of several generations per year, the differences in the ages of caterpillars of each brood, and the existence of a protective covering by means of which caterpillars resist insecticides. They may be destroyed, however, by the use of kerosene emulsion, soap insecticides, and fumigation with hydrocyanic-acid gas.

The pineapple gall of the spruce: A note on the early stages of its development, E. R. BURDON (*Proc. Cambridge Phil. Soc., 13 (1904), No. 1, pp. 12-19*).—The galls produced by different species of Chermes all follow the same general plan of development, but in the present paper particular attention is given to the galls of *C. abietis*.

The life of the gall produced by this insect on spruce may be divided into 3 stages, the first of which is inclosed in the bud scales, the second beginning after the emersion from the bud and ending with the opening of the chambers, and the third including its death and decomposition. The life history of the gall insect is described in detail with special reference to its agency in the production of the galls.

North American Phylloxerinæ affecting Hicoria and other trees, T. PERGANDE (*Proc. Davenport Acad. Sci., 9 (1901–1903), pp. 185–273, pls. 21*).—The task of monographing this group of plant lice in America was begun many years ago with the intention of publishing the material in connection with a larger monograph edited by Dr. Dreyfus of Wiesbaden, Germany. The publication of the large monograph has been so delayed that a decision was reached to publish the present material separately.

A synoptical table is given for the identification of the species according to the character of the galls produced. All species of phylloxera known to occur in North America are described and notes are given on their habits, life history, and food plants.

A treatise on spraying, J. M. STEDMAN (*St. Joseph, Mo.: The Fruit Grower Co., 1905, pp. 123, figs. 35*).—This pamphlet is intended to furnish information regarding the more important insecticides in common use, together with notes on methods of making and applying them and a brief discussion of the common injurious insects which attack apple, peach, and strawberry. The remedies recommended and methods of treatment suggested, however, are capable of wider application than to the 3 mentioned plants.

Spraying tall trees, J. A. PETTIGREW (*Country Life Amer., 7 (1905), No. 4, pp. 375, 376, figs. 3*).—Attention is called to the injury done by San José scale and other insects to tall shade and ornamental trees, and various power sprayers especially suitable for treating such trees are described.

Composition of the lime, sulphur, and salt wash, J. K. HAYWOOD (*Jour. Amer. Chem. Soc., 27 (1905), No. 3, pp. 244–255*).—A study was made of this wash, adopting different periods of boiling and using chemically pure reagents for the tests.

Careful analyses were made for the purpose of determining the reactions which take place during the manufacture of the wash. It was found that the solid sulphur was not completely dissolved during a boiling period of 15 to 30 minutes, but only after boiling from 45 to 60 minutes. When the boiling was continued beyond the hour the mixture became thick, and apparently some of the sulphur was lost mechanically. Omitting the salt "had no material effect on the composition of the wash."

In the study of the compounds of sulphur formed in the wash under different conditions, the free sulphur and that as sulphids, as sulphates and sulphites, and as thiosulphates were determined. Concerning the reaction which takes place, the following conclusions are reached: "First, the lime and sulphur react and calcium thiosulphate and pentasulphid are formed; second, the calcium pentasulphid is partly changed to calcium thiosulphate and free sulphur; third, the sulphur set free recombines to a large extent with the calcium hydroxid; fourth, the calcium thiosulphate formed is changed to a slight extent to calcium sulphite and sulphur; fifth, the calcium sulphite is partly oxidized to calcium sulphate. All of the above reactions are well known and can be found in the leading books of reference."

The changes which take place in the sulphur compounds when the wash is sprayed upon the tree were studied by applying the wash to filter paper and exposing it to the air. Later, after several days or weeks, the dried wash was analyzed, and the results are presented, showing the amounts of sulphur in different forms. There was found to be a decomposition of the thiosulphate after a time, resulting in an increase of free sulphur, sulphates, and sulphites, and it is assumed that after 4 or 5 months only sulphur and calcium sulphate would remain. This finely divided sulphur and the sulphite which is gradually set free, the author believes to be the two active agents in killing insects. "This theory of the action of the wash would also explain why the action is not immediate and also why it continues over a great length of time."

In a wet climate a rain a day or two after the spraying would tend to wash out the thiosulphate, and no sulphite could be formed. The insecticidal properties would then depend upon the sulphur left upon the tree. "It is possible that the thiosulphate itself has some value as an insecticide. If so, it would be manifested much more strongly in a dry climate than in a wet climate, where the thiosulphate would be gradually or at once washed off."

An inquiry into the cyanid method of fumigating nursery stock, W. NEWELL (*Ga. Bd. Ent. Bul. 15, pp. 24, figs. 3*).—Nurserymen in Georgia have been for several years required to fumigate nursery stock with hydrocyanic-acid gas.

On account of the different results obtained from the application of this method under different conditions, the author undertook an investigation of the cause of this apparent variation in the strength of potassium cyanid. For this purpose analyses and tests were made of samples of potassium cyanid sold by various dealers. It was found as a result of this investigation that failure to secure satisfactory results in fumigation is frequently due to the use of adulterated potassium cyanid. The amount of gas generated when the cyanid is added to the mixture of acid and water is somewhat greater than when the latter mixture is poured over the cyanid.

It was found that the presence of common salt in the cyanid causes a reduction in the amount of gas available for destroying insects. Common salt is most frequently used in the adulteration of potassium cyanid. The effectiveness of a sample of cyanid is not indicated by an analysis which shows it to be high grade according to the amount of potassium cyanid present unless the analysis also shows the absence of chlorids, nitrates, and other adulterants.

In the study of the effect of temperature upon the formation of hydrocyanic-acid gas it was found that the temperature produced by the mixture of 2 fluid ounces of sulphuric acid and 4 fluid ounces of water is apparently the optimum temperature for the volatilization of the gas.

Notes on a light trap in Hertfordshire, P. J. BARRAUD (*Ent. Mo. Mag., 2. ser., 16 (1905), No. 182, pp. 43, 44*).—The author has made use of a lantern trap for catching lepidoptera since 1898. During this period over 300 species of lepidoptera have been captured. The trap is attached to a first-floor window about 14 ft. from the ground. The author believes that the want of success with traps in many cases is due to the fact that they are placed too near the ground. It is believed that an elevation of 20 ft. is desirable for a great many species of lepidoptera.

Report of the New Jersey State Agricultural Experiment Station upon the mosquitoes occurring within the State, J. B. SMITH (*New Jersey State Sta., 1904, pp. V+482, pls. 47, figs. 89*).—In this report the author summarizes the results of some investigations regarding the anatomical characters, habits, distribution, natural enemies, and means of combating the mosquitoes which occur in New Jersey.

Special chapters are devoted to the hibernation of mosquitoes, the agency of these insects in carrying diseases, a description of species of mosquitoes occurring in New Jersey, the classification of mosquitoes with a key as an aid to their determination, and various local problems in the eradication of the mosquito nuisances in different parts of the State. The author has collected a large fund of information which will be of value in the further study of the mosquito problem. This is particularly true of the sections on breeding places, natural enemies of the mosquitoes, and artificial insecticide measures.

Among the various insecticides which were used in the destruction of mosquitoes none proved more efficient against the larvæ than kerosene oil. Phinotas oil is useful in sewer catch-basins, cesspools, and other pools of water in which there are no fish. This oil, however, is not soluble in salt or brackish water and can not, therefore, be used in salt marshes. Carbolic acid and cresol preparations were found to be effective when used in their proper strengths, but were found too expensive. Permanganate of potash was carefully tested and found to be practically without any

destructive effect upon the mosquitoes. Chloronaphtholeum is found to be valuable as a general disinfectant, but is of little use in salt water. In experiments with copper sulphate the larvæ were killed in a certain percentage of cases, but quite gradually and apparently by an indirect rather than a direct action. The larvæ of *Culex pipiens* succumbed within 72 hours in water containing copper sulphate at the rate of 1 to 53,500. In some cases, however, the larvæ survived for 24 hours when the copper sulphate was used at the rate of 1 to 308 parts of water. The pupæ were not much affected by copper sulphate. The activity of copper sulphate was somewhat greater in salt water. A test of lime showed that this substance must be used in large quantities in order to be effective. Chlorid of lime was more effective, and when used at the rate of 14 grains in 1 qt. of water kills the larvæ but not the pupæ.

The use of sulphate of copper alone, and in combination with lime, for the destruction of mosquito larvæ, as a deodorant, and as a disinfectant, A. H. DOTY (*Med. Rec. [N. Y.], 67 (1905), No. 3, pp. 90–92*).—A test was made of the value of solutions of copper sulphate and lime alone or in combination in the destruction of mosquito larvæ in water.

The copper sulphate was used at the rate of 12 grains for each gallon of water, and lime was added in equal quantity. In these experiments it was found that the combination of copper sulphate and lime was considerably more effective than either substance used alone, although lime was quite effective alone. The action of these substances in the control of mosquito larvæ appears to be due to the destruction of the food substances upon which the larvæ live.

The effect of Aspergillus niger and A. glaucus on the larvæ of Culex and Anopheles, B. GALLI-VALERIO and JEANNE ROCHAZ-DE JONGH (*Centbl. Bakt. [etc.], 1. Abt., Orig., 38 (1905), No. 2, pp. 174–177, figs. 2*).—A number of bacterial and fungus organisms were studied for determining their effect upon mosquito larvæ in water.

It was found that the spores of *Aspergillus niger* and *A. glaucus* were capable of infecting mosquito larvæ and causing evident disease within from 24 to 48 hours. After infection with *A. niger* the intestines of mosquito larvæ were protruded in the form of a long tubular organ of a greenish or black color and filled with the spores and mycelium of the fungus. These experiments were made in glass vessels in the laboratory.

Similar experiments out of doors in pools containing stagnant water were less successful. A much smaller percentage of the larvæ became infected. Fish were not attacked by the fungi, and the authors believe that this method may be depended upon to assist in controlling mosquitoes.

Microscopic mites, C. FULLER (*Natal Agr. Jour. and Min. Rec., 7 (1904), No. 9, pp. 849–866, figs. 10*).—A brief general account is given of the anatomy and biology of mites injurious to animals. Special attention is devoted to *Sarcoptes scabiei* of man, and the varieties of this species which attack domestic animals causing scabies or scab. Biological and economic notes are also presented on various other species of mites parasitic on cattle, goats, dogs, cats, and poultry.

Cattle ticks and blood-sucking flies of the Dutch East Indies, J. C. KONINGSBERGER (*Veeartsenijk. Bl. Nederland Indië, 15 (1903), No. 2, pp. 141–147, pl. 1*).—A brief account is presented of *Rhipicephalus annulatus*, *R. decoloratus*, *R. australis*, *Amblyomma testudinarium*, and a number of blood-sucking flies including species of Tabanus and Stomoxys.

The biology of ticks, P. MÉGNIN (*Jour. Anat. et Physiol. [Paris], 40 (1904), No. 6, pp. 569–589, figs. 4*).—According to the present system of classification, 294 species are recognized as belonging to the family Ixodidæ. Of this number, 20 have been found on dogs. Nearly all species of ticks, however, may be found on a considerable variety of animals, since no strict choice in this matter is exercised by the ticks.

The author argues, at considerable length, that the agency of ticks in transmitting Texas fever has not been proved, and considers that in order to demonstrate this point it is necessary to find the pathogenic organism of Texas fever in the adult ticks, the eggs, larvæ, and nymphs.

Notes on Ixodidæ, L. G. NEUMANN (*Arch. Par., 9 (1905), No. 2, pp. 225-241*).—Detailed, descriptive notes are presented on a number of species of ticks, some of which are described as new.

Experiments regarding the attraction of flowers for bees, JOSEPHINE WERY (*Acad. Roy. Belg., Bul. Cl. Sci., 1904, No. 12, pp. 1211-1261*).—A historical statement is presented showing the views which have prevailed at different times regarding causes which determine the relative preference of certain flowers by bees.

An elaborate series of experiments was carried out by the author, during which care was exercised to study only one of the possible sources of attraction in flowers at each test. As a result of this investigation it is concluded that flowers possessed of bright colors have much greater attraction for bees than dull colored flowers. Nectar apparently does not attract the bees. It was found possible to attract bees quite successfully by means of artificial flowers.

Bees do not respond very readily to the perfume. Form, color, and perfume operating together, however, exercise a strong attraction for bees. It is believed that, as a rule, the attraction exercised by the form and colors of flowers is approximately 4 times as strong as that exercised by perfume, pollen, and nectar taken together.

A practical manual of sericulture, H. L. A. BLANCHON (*Manuel Pratique du Sériculteur. Paris: Charles Amat, 1905, pp. 144*).—In this volume the author covers in a concise manner the whole field of silk raising, including an account of the anatomy and physiology of the silkworms, silkworm nurseries and their disinfection, care of silkworm eggs, methods of incubation, the care of silkworm larvæ in their various stages, cocoons, the feeding of the larvæ, etc.

Notes are also given on the amount of space which should be allowed for the successful practice of silkworm raising, the ventilation of buildings, temperature to be maintained, humidity of the air, and related subjects. Special chapters are also presented on the various diseases of silkworms and on the cultivation of mulberry trees.

Attempts to increase the amount of silk in cocoons, F. LAFONT (*Ann. École Nat. Agr. Montpellier, n. ser., 4 (1905), No. 4, pp. 253-274*).—In a series of breeding experiments moths were reared from large and from small cocoons, and their progeny were compared for the purpose of determining whether the size of the cocoons could be thus increased. This method of selection gave little or no promise of success. Within a few generations the size of the cocoons was about equal in all cases. The author believes that better results are to be obtained by selecting cocoons on the basis of vigor rather than of size.

Spider-spun silk, W. H. HUNT (*Mo. Consular Rpts. [U. S.], 1905, No. 293, pp. 157-159*).—Considerable attention has been given in Madagascar to the use of the web spun by spiders in the manufacture of silk. The most promising species of spider for this purpose is *Nephila madagascariensis*. This is a large spider which spins an extensive web of more than usual strength. Several fabrics have already been made of this material, and it is believed that the spider silk is a promising material for commercial utilization. The habits of the spider are such that it may possibly be colonized and maintained under a state of semidomestication.

FOODS—HUMAN NUTRITION.

Potatoes: A cooking test (*Mark Lane Express, 91 (1904), No. 3822, p. 769; 92 (1905), No. 3833, p. 334*).—At Marks Tey, Essex, a test was made of the cooking quality of potatoes from Scotland, Lincolnshire, and Essex, 6 tubers weighing as nearly as possible 6 oz. each being selected from 12 standard varieties.

The potatoes were placed in cold water, then boiled slowly and steamed for a few moments before serving, each sample being cooked in a separate pot. Judged by flavor, texture, and appearance the Essex potatoes were markedly superior to the others, the highest score being made with Essex-grown Charles Fiddler and Sim Gray. The Scotch samples scored the fewest points. The need of a test in the spring also was pointed out by the judges.

After 12 weeks an additional test was made to learn the effects of storage on cooking quality. Factor and Warrior were the varieties which had the highest total score on the basis of flavor, texture, and appearance when freshly cooked. After standing for 24 hours the cooked potatoes were again examined, the above mentioned varieties and several others being unchanged, though the majority had deteriorated.

Does an egg change in weight in cooking? L. CAMUS (*Compt. Rend. Soc. Biol. [Paris], 57 (1904), No. 25, pp. 87-90*).—A number of tests are reported which showed that eggs cooked in hot water lost more or less in weight, the amount in all cases being small. This loss the author attributes to the evaporation of a little water through the porous shell. If the egg was cooled in the water in which it was cooked it increased a little in weight.

The "yolk cure" in the treatment of the underfed, H. STERN (*Med. Rec. [N. Y.], 66 (1904), No. 27, pp. 1049-1052*).—In a discussion of the use and importance of egg yolks in invalid dietetics, the author has reported some data on the digestibility of eggs obtained in experiments with healthy subjects.

It was found that raw or half-raw yolk was very readily digested, 2 to 4 raw-egg yolks leaving the stomach in from 70 to 100 minutes. One or 2 egg yolks taken in a cup of hot coffee with some sugar and milk left the stomach in 60 to 70 minutes. In the author's opinion the fat of egg yolks is especially well borne and readily assimilated, as is shown by the recovery of only 1.5 to 3.5 per cent of the yolk fat in the feces as compared with larger amounts in the case of milk fat and other animal fats.

In the author's opinion, the high digestibility of egg-yolk fat is probably due to the fact that it has a low melting point and is fluid at ordinary temperatures. The importance of the lecithin present is spoken of.

The examination and valuation of raspberry juice, P. BUTTENBERG (*Ztschr. Untersuch. Nahr. u. Genussmtl., 9 (1905), No. 3, pp. 141-145*).—The results of examinations of raspberry juice and sirup prepared in different ways are reported and discussed.

Concerning the examination and valuation of candied coffee, E. ORTH (*Ztschr. Untersuch. Nahr. u. Genussmtl., 9 (1905), No. 3, pp. 137-141*).—The results of a number of tests are reported on the amount of soluble material on the coffee beans, and the total amount of coffee produced when the coffee berry was treated with different amounts of sugar and heated for varying periods. The author states that other material awaits publication.

Note on a vegetable cheese from Kamerun, W. BUSSE (*Centbl. Bakt. [etc.], 2. Abt., 14 (1905), No. 15-16, p. 480*).—Brief notes are given on a cheese-like material prepared from the seeds of *Treculia africana*.

Studies of arsenic in a number of food products, F. BORDAS (*Rev. Soc. Sci. Hyg. Aliment., 1 (1904), No. 4, pp. 333-336*).—A summary of data regarding the occurrence of arsenic in food products, including the author's investigations.

Expenses for food in laborers' budgets, E. LEVASSEUR (*Rev. Soc. Sci. Hyg. Aliment., 1 (1904), No. 4, pp. 289-296*).—A summary of data regarding the proportion of the income of laborers which is expended for food.

Legislation relating to commerce in food products (*Rev. Soc. Sci. Hyg. Aliment., 1 (1904), Nos. 4, pp. 347-388; 5, pp. 538-553; 6, pp. 651-664*).—A summary of legislation enacted in Europe and America.

The value of nutrients (*Rev. Soc. Sci. Hyg. Aliment., 1 (1904), No. 5, pp. 453-457*).—Replies received from a number of investigators are summarized having to do

with the question of the isodynamic replacing value of fats and carbohydrates in a ration.

Criticism of the methods followed in establishing dietary standards, L. PASCAULT (*Rev. Soc. Sci. Hyg. Aliment., 1 (1904), No. 3, pp. 200-207*).—In the author's opinion, most of the studies used to determine dietary standards have been made with overnourished subjects, this being a common condition. He points out that investigations are needed which are not open to this criticism. He believes that it will probably be found that the physiological ration will vary considerably with the character of the diet.

On the absorption and utilization of proteids without intervention of the alimentary digestive processes, L. B. MENDEL and E. W. ROCKWOOD (*Amer. Jour. Physiol., 12 (1904), No. 4, pp. 336-352*).—In experiments with animals the absorption of proteids introduced directly into the small intestine, into the peritoneal cavity, and into the circulation was studied. The authors' summary of the investigation follows:

"Vegetable proteids (crystallized edestin from hemp seed and excelsin from the Brazil nut), slowly introduced in solution into the circulation of animals, can apparently be retained in the organism for the most part, even when the quantities introduced almost equal that of the globulins normally present in the blood. . . . When solutions of vegetable proteids are injected too rapidly or in too great concentration, toxic symptoms, including an inhibition of the cardiac and respiratory activities, may be observed, especially in cats. . . .

"The chemically similar proteids, edestin and excelsin, show slight differences in physiological action, a small amount of a proteose-like substance being found in the urine after intravenous or intraperitoneal (parenteral) introduction of excelsin, but not with edestin. The observation suggests the further possibility of applying chemicobiological reactions in distinguishing related proteids.

"The vegetable proteids soon disappear in considerable part when introduced into the peritoneal cavity. That they reach the circulation is made probable in the case of excelsin at least, by the appearance of the typical urine proteose-body noted after direct intravenous injections. For the most part, however, the proteids do not reappear in the urine.

"The unaltered proteids edestin and casein are absorbed to a very small extent, if at all, from portions of the living small intestine in which the ordinary digestive processes are excluded as far as possible. On the other hand, the proteoses and peptones obtained by peptic digestion of these proteids readily disappear from the intestine under the same conditions. It is not necessary to assume that in these cases they are first completely broken down by the intestinal enzym erepsin; for casein (upon which erepsin can act) may remain unabsorbed. Dissolved edestin could be recovered in crystallin form, i. e., unchanged after remaining in the intestine for several hours. The typical vegetable proteids show no marked differences from those of animal origin in their relation to the processes of metabolism.

"The attempts to learn the fate of the foreign proteids retained in the system have been rather unsuccessful. It will be of interest to ascertain something further regarding their destination and the exact mode of utilization which they undergo."

The passage of different food stuffs from the stomach and through the small intestine, W. B. CANNON (*Amer. Jour. Physiol., 12 (1904), No. 4, pp. 387-418, figs. 9*).—Different amounts of protein, fat, and carbohydrate foods were mixed with a small amount of subnitrate of bismuth and fed to cats. The processes of digestion were studied at regular intervals for 7 hours after feeding by means of a fluorescent screen and the Röntgen rays.

The investigations are summarized as follows:

"Fats remain long in the stomach. The discharge of fats begins slowly and continues at nearly the same rate at which the fat leaves the small intestine by absorption

and by passage into the large intestine. Consequently there is never any great accumulation of fat in the small intestine.

"Carbohydrate foods begin to leave the stomach soon after their ingestion. They pass out rapidly, and at the end of 2 hours reach a maximum amount in the small intestine almost twice the maximum for proteids, and two and a half times the maximum for fats, both of which maxima are reached only at the end of 4 hours. The carbohydrates remain in the stomach only about half as long as the proteids.

"Proteids frequently do not leave the stomach at all during the first half hour. After 2 hours they accumulate in the small intestine to a degree only slightly greater than that reached by carbohydrates an hour and a half earlier. The departure of proteids from the stomach is therefore slower at first than that of either fats or carbohydrates. An exception to this general statement was found in egg albumen, which, both in its natural state and in coagulated form, was discharged from the stomach at about the carbohydrate speed.

"When carbohydrates are fed first and proteids second, the presence of proteids in the cardiac end of the stomach does not materially check the departure of the carbohydrate food lying at the pylorus; but the presence of proteids near the pylorus, when proteids are fed first and carbohydrates second, markedly retards the onward passage of the carbohydrates which under these circumstances predominate in the cardiac end of the stomach.

"When carbohydrates and proteids are mixed in equal parts, the mixed food does not leave the stomach so slowly as the proteids, nor so rapidly as the carbohydrates—the discharge is intermediate in rapidity.

"In a mixture of fats and proteids in equal parts, the presence of the fat causes the proteid to leave the stomach even more slowly than the proteid by itself. Fat mixed with carbohydrate in equal amounts also causes the carbohydrates to pass the pylorus at a rate slower than their normal.

"Doubling the amount of carbohydrate food (50 cc. instead of 25 cc.) increases the rapidity of the carbohydrate outgo from the stomach during the first 2 hours; whereas doubling the amount of proteid food strikingly delays the initial discharge of proteid from the stomach.

"The process of rhythmic segmentation is seen with all three kinds of food stuffs, and the frequency of its occurrence corresponds roughly to the amount of food present in the intestine; a measurement of the length of the segmenting masses in a given number of cases shows that at the regular times of observation, during the first 7 hours after feeding, the amount of segmenting activity in the presence of carbohydrates was much greater than in the presence of either fats or proteids. Egg albumen is excepted in this general statement

"The interval between the feeding and the appearance of food in the large intestine is variable, but the mean for carbohydrates is about 4 hours, for proteids about 6 hours, and for fats about 5 hours. After time is allowed for the later start of proteids from the stomach, there still remains a probability that the proteids pass through the small intestine more slowly than do the carbohydrates."

Changes in the excretion of carbon dioxid resulting from bicycling, G. O. HIGLEY and W. P. BOWEN (*Amer. Jour. Physiol., 12 (1904), No. 4, pp. 311–335, figs. 7*).—A respiratory mask of special construction is described which fits tightly over the nose and mouth and contains valves for the separation of the inspired and respired air current.

The respired air is dried by passing through tubes filled with pumice stone and sulphuric acid and then through a gas meter, which is connected with the suction side of a blower, in order to relieve the lungs of the subject from the labor involved in forcing the expired air through the tubes and gas meter. The dry air containing carbon dioxid passes through an absorption apparatus attached to one arm of a counterpoised balance. As the arm sinks, owing to the absorption of carbon dioxid,

a pointer attached to the other arm traces a curve on a drum covered with blackened paper. After the apparatus was calibrated it was tested and found to be very accurate.

About 20 experiments were made to determine the general course of the changes in the output of carbon dioxid resulting from work, which was performed on a stationary bicycle. The working periods in some of the experiments covered 30 to 45 minutes. A large number of experiments were also made to show how soon the effect of muscular work is noted in the carbon dioxid output. The general conclusions which were drawn from the experiments follow:

"The problem of finding the changes in rate of output of carbon dioxid resulting from muscular work and other causes is practically solved by the method used in this research. The latent period of increase in output of carbon dioxid from the lungs in case of beginning work is in the close vicinity of 20 seconds, and the increase reaches its maximum in about 2 minutes. The output of carbon dioxid from the lungs is practically uniform from minute to minute during uniform muscular work, after the blood has had time to take part fully in the process of elimination. Upon cessation of work the output of carbon dioxid decreases to the normal amount in about the time occupied by its increase and after a like latent period. The results obtained show no indication of any connection of cause and effect between the production and elimination of carbon dioxid and the secondary rise of pulse rate."

The minimum amount of protein in the daily diet, H. LABBÉ (*Rev. Soc. Sci. Hyg. Aliment., 1 (1904), No. 4, pp. 311-328, dgm. 1*).—An experiment is reported in which the subject, a healthy man, lived upon a simple diet of bread, butter, chocolate, wine, chestnuts, vegetables, and fruits.

At the beginning of the test, which covered 38 days, the daily diet furnished a little over 14 gm. nitrogen. The amount was diminished until toward the end of the test it reached a minimum of 1.06 gm. It was then increased and on the last day reached 13.25 gm. The amount of nitrogen and urea eliminated in the urine and the income and outgo of chlorin are recorded. The energy value of the diet was also calculated at different periods. At the beginning of the test the subject weighed in round numbers 65 kg. and 3 days before the close 63 kg.

In the author's opinion the experiment showed that nitrogen equilibrium can be established and maintained for a long period on a limited protein ration derived entirely from vegetable sources. This indicates that vegetable protein is as valuable as that from animal foods. The nitrogen excreted in the urine other than in the form of urea is discussed, the author pointing out that the quantity is remarkably constant. The experiment is discussed with reference to the lowest protein limit in the diet.

Concerning the minimum amount of nitrogen required per day in a condition of rest and work, A. GAUTIER (*Rev. Soc. Sci. Hyg. Aliment., 1 (1904), No. 4, pp. 329-331*).—A critical discussion of the experiment reported above. The author does not agree with all the conclusions reached.

An excess of chlorin in the diet for fifty-one days, L. AMBARD (*Compt. Rend. Soc. Biol. [Paris], 58 (1905), No. 8, pp. 375, 376*).—Chlorin equilibrium was studied when an excess was consumed, and also the effect of sodium sulphate and potassium nitrate on the elimination of sodium chlorid, the author being himself the subject.

When about 1.75 gm. sodium chlorid was taken the daily excretion in the urine was fairly constant during two periods, being about 2.2 gm. per day. In a third period it was 1.55 gm. When 10 gm. sodium sulphate was added to the diet the chlorin elimination diminished somewhat. Three grams potassium nitrate daily did not increase the excretion of sodium chlorid appreciably. During part of the time the sodium chlorid in the feces was found to average 0.1 gm. per day.

ANIMAL PRODUCTION.

The feeding of farm animals, O. KELLNER (*Die Ernährung der landwirtschaftlichen Nutztiere. Berlin: Paul Parey, 1905, pp. VIII+594*).—This volume, which embodies the results of the author's investigations extending over many years, is an attempt to treat the subject of the feeding of farm animals from a comparatively new standpoint.

The author contends that as feeding stuffs differ in the ease with which they are assimilated by the body, they should be compared on the basis of the quantity of nutritive material which is available after the amount required for assimilation has been taken into account, rather than on the basis of proximate composition or the percentage of digestible nutrients present. For his comparison he has selected the starch equivalents of the feeding stuffs as a basis rather than energy values which have sometimes been used.

The book as a whole marks a distinct advance in the theoretical discussion of stock feeding, and will prove of value not alone to students but also to practical feeders and to all who are interested in discussions of such subjects. The volume is composed of 3 main divisions. The first is concerned with the composition, digestibility, and utilization of feeding stuffs and the second with the properties, preservation, preparation, and use of feeding stuffs, while the third takes up the feeding of farm animals with relation to different agricultural conditions.

In an appendix the author gives a number of tables showing the composition and digestibility of feeding stuffs, in which special attention is paid to the feeding values on the basis of starch equivalents. Feeding standards are also included. These, like the other tabular matter, embody the author's views regarding the use of data showing the real feeding value rather than values based on composition and digestibility only. A detailed index adds to the value of the volume.

Feeding stuff inspection, C. D. WOODS and J. M. BARTLETT (*Maine Sta. Bul. 115, pp. 53–70*).—Analyses of samples collected during the fall and winter of 1904–5 are reported, including cotton-seed meal, gluten meals and feeds, linseed meal, viscid oil meal, sugar and flax seed, distillers' grains, mixed grains, hominy feed, meat meal, ground beef scraps and similar feeds, mixed and proprietary feeds, wheat bran, bran and shorts, corn meal, flour, and condimental feeds.

In general, the cotton-seed meal was of good quality, but it was noted that the number of samples containing above 43 per cent protein was less than a few years ago. "Gluten products continue to be the most unsatisfactory of any concentrated feeds on the market. This is partly because different lots of the same brand vary somewhat in composition, but is chiefly because certain companies persist in putting a guarantee upon their goods that the goods do not come up to in any instance."

As shown by composition, the viscid oil meal, an old-process linseed meal, had a fairly high feeding value, but the taste was unpleasant, "and it would seem doubtful if cattle would eat it readily." As regards adulterated mixed feeds the authors note that "there is so much profit in selling ground corn cobs, broom corn, and other valueless materials at the price of wheat bran, that the consumer must ever be on the watch against this fraud. The safest thing is to buy only well-known, reliable brands of this class of goods. If consumers will see to it that all of this class of feeds which they buy carries the name of the miller, there will be little likelihood of their being defrauded."

The condimental feeds examined were found, as was previously the case, to consist of wheat bran or some similar concentrated feed, with small amounts of fenugreek, charcoal, sulphur, salt, copperas, and similar bodies added. Attention is directed to the very high cost of these foods in proportion to their nutritive value or in proportion to the amount and value of the materials used in their manufacture for their supposed medicinal properties.

Low grade and high grade cotton-seed meal compared, J. M. BARTLETT (*Maine Sta. Bul. 115, pp. 71-76*).—Different grades of cotton-seed meal are discussed, and brief directions given for judging the quality of such goods.

A first-class meal, according to the author, should contain over 40 per cent protein and about 9 per cent fat, and should be of a light yellow color. Dark color and the presence of many fine black specks is an indication that ground hulls have been added. A rusty brown color indicates that the meal is old or has undergone fermentation. Such meals are not safe to use. Cotton-seed meal should have about the same texture as corn meal, and should be practically free from lint.

The amount of lint can be determined by sifting a portion of the meal. Lint and hulls can also be detected by stirring the meal in water, when the black hulls will settle to the bottom, the good meal will be in the next layer, and the lint on top. A first-class meal should have only a few black hulls and scarcely any lint. The quality of the cotton-seed meal can also be judged by tasting it. "The best fresh meals have a very agreeable nutty flavor not found in inferior goods. The presence of much fiber is readily noted by the sense of touch in the mouth. The absence of the nutty flavor and the presence of a rancid taste indicates that the meal is old."

The author roughly divides cotton-seed meals into 4 grades, analyses and the digestion coefficients of which are given. The results of the digestion experiments follow:

Average coefficients of digestibility of different grades of cotton-seed meal—Experiments with sheep.

Kind of meal.	Dry matter.	Organic matter.	Protein.	Fat.	Crude fiber.	Nitrogen-free extract.
	P. ct.	*P. ct.*	*P. ct.*	*P. ct.*	*P. ct.*	*P. ct.*
Very high grade cotton-seed meal	90.0	95.3	83.3	100.0	....	95.9
Dark colored cotton-seed meal	85.8	89.9	82.2	97.2	....	94.7
Medium grade cotton-seed meal	73.0	78.0	83.6	94.6	43.5	82.1
Low grade cotton-seed meal	61.4	64.1	72.6	90.1	37.8	67.8

The author points out that although the different grades of meal did not differ much in chemical composition yet the digestion experiments showed that the low-grade meals were decidedly inferior.

Licensed concentrated feeding stuffs, F. W. WOLL and G. A. OLSON (*Wisconsin Sta. Bul. 122, pp. 16-21, 25-28*).—The percentage of protein and fat in 58 brands of concentrated commercial feeding stuffs licensed for sale in Wisconsin for the year ending December 31, 1905, is given, and the text of the Wisconsin feeding-stuff law is quoted.

The cost and value of concentrated feeding stuffs, G. FAYE (*Landmandsblade, 37 (1904), No. 29, pp. 405-408*).—The value of the various concentrated feeding stuffs used in Denmark is calculated on the basis of their average chemical composition and relative cost of nitrogenous substances, fat, and nitrogen-free extract of 1.5:2:1, as obtained by Stein (Ugeskr. Landm., 1904, p. 211).—F. W. WOLL.

The identification and adulteration of feeding cakes, G. D'IPPOLITO (*Staz. Sper. Agr. Ital., 37 (1904), No. 4-5, pp. 309-324, pls. 3*).—The data reported have to do with the detection of adulteration in feeding cakes by microscopical methods.

Poisonous Italian linseed cakes, J. HUGHES (*Mark Lane Express, 92 (1905), No. 3830, p. 235*).—Castor beans were identified in some Italian linseed cake which was found to be poisonous when fed to steers.

Peat-molasses, H. PELLET (*Sucr. Indig. et Colon., 64 (1904), No. 11, pp. 325-330*).—Experiments on the digestibility and feeding value of peat-molasses are summarized.

The value of amids in animal nutrition, W. VÖLTZ (*Fühling's Landw. Ztg., 54 (1905), Nos. 2, pp. 41-49; 3, pp. 96-100*).—Investigations which have to do with

the nutritive value of amids are summarized and the following general conclusions drawn:

In the case of herbivora and birds, asparagin acts as a protector of protein when the nutritive ratio of the ration is wide, though this is not generally the case when the ration furnishes large or medium amounts of protein. In the case of milk-producing animals, asparagin and other amids within limits can apparently replace protein without lowering the quantity or quality of the milk.

In the case of omnivora the protein-protecting power of the asparagin is smaller and as regards nitrogen metabolism it is practically an indifferent body. It can not be said that asparagin exercises a protein-protecting power in the case of carnivora. It seems rather to increase the cleavage of protein.

Grape pomace in the feeding of farm animals, H. Blin (*Jour. Agr. Prat., n. ser., 8 (1904), No. 50, pp. 766–768*).—On the basis of the work of other investigators and his own experience, the author states that 10 to 12 kg. per head per day may be fed to horses, 20 to 25 kg. to cattle, 5 or 6 kg. to sheep, and 5 to 10 kg. to pigs.

Report on feeding experiments with rough cotton cakes from Indian cotton seed, D. A. Gilchrist (*County Council Northumb., Ed. Com., Ann. Rpt., 8 (1903–4), pp. 10–26; Bul. 1, pp. 19*).—Some data are recorded regarding the amounts of cake, oil, and refuse obtained from crushing rough decorticated and delinted Indian cotton seed, and feeding trials with sheep and steers are reported in which Indian and Egyptian cotton-seed cakes were compared.

The conclusion is drawn that "Indian (Bombay) rough cotton-seed cake, when of good quality, gives satisfactory results with stock fed indoors or on pasture, and that its high manurial value makes it a desirable manurial agent, especially for improving poor pasture."

Feeding value of swedes, D. A. Gilchrist (*County Council Northumb., Ed. Com., Ann. Rpt., 8 (1903–4), pp. 27–34*).—The feeding value of Arctic, XL All, and Best of All swedes, containing respectively 11.48, 10.75, and 11.31 per cent dry matter, was studied with 3 lots of 4 calves 29 weeks old, the turnips being supplemented by hay and a mixture of Egyptian cotton-seed cake, barley meal, and linseed cake.

In the 4 months of the test the gains ranged from 208 lbs. with XL All swedes to 243 lbs. with Best of All swedes. From this and a test with sheep previously reported (E. S. R., 15, p. 897) the conclusion is drawn that in general the Swedish turnips with a high percentage of dry matter had a correspondingly high feeding value.

Digestibility of vetch hay and corn silage, J. Withycombe and A. L. Knisely (*Oregon Sta. Bul. 85, pp. 13*).—Digestion experiments were made with vetch hay (*Vicia sativa*) and with corn silage, using 3 cows. The tests were each of 7 days' duration.

The average coefficients of digestibility found for vetch hay were: Dry matter 66.05, protein 69.91, ether extract 71.21, nitrogen-free extract 71.59, crude fiber 57.56, and ash 52.23 per cent. The values for corn silage were: Dry matter 73.08, protein 55.03, ether extract 89.91, nitrogen-free extract 75.65, crude fiber 75.34, and ash 47.98 per cent.

The prickly pear and other cacti as food for stock, D. Griffiths (*U. S. Dept. Agr., Bur. Plant Indus. Bul. 74, pp. 48, pls. 5, fig. 1*).—The geographical distribution of cacti, methods of feeding, machinery for preparing prickly pear for feeding, the effects of prickly pear upon stock, pear thickets and their destruction, the yield of prickly pear, and other questions are considered, and data collected in the cactus regions of the United States are summarized and discussed with special reference to the value of cacti as forage plants.

The so-called "prickly pear" is the variety of cactus usually referred to in considering cacti as forage plants, but according to the author, "any cactus growing

large enough to be fed with economy can be used as roughage, or as a succulent for milk production."

Prickly pear is very succulent and hence necessarily has a low nutritive value. The data summarized lead to the conclusion, however, that it may be fed to cattle with decided advantage during prolonged drought when more nutritious feed is scarce, and that it may be used to fatten cattle if fed with some coarse fodder and with some concentrated feed. Supplemented by concentrated feeds and some hay or pasturage, it is regarded as a valuable accessory to the dairy ration, supplying succulence which it is difficult to secure in semiarid regions. A ration of from 40 to 70 lbs. per day with plenty of other nutritious feed is recommended for cows, though up to 100 lbs. may be fed.

Oxen, it is stated, can be worked indefinitely on a ration consisting largely of prickly pear and require watering only 2 or 3 times a week in summer. A full-grown steer on pear alone will consume from 125 to 200 lbs. daily. The liability of forming fiber balls when fed whole and exclusively is mentioned. Hogs fatten well on the fruit of the prickly pear and take kindly to a ration of prickly pear when the thorns are properly singed off.

The methods of preparation for feeding by singeing, by slicing, and by steaming are described. Ensiling is also mentioned, but is not considered advantageous. When the pear is burned it scours cattle much worse than when scorched sufficiently to take the thorns off. Chopped pear sours quickly and hence must be fed at once. Pear cut and piled up under cover will keep in good condition for a month or more.

The uses of cacti for other purposes are pointed out, including the preparation of jellies from the fruits, the use of the joints by the Mexicans as pot herbs and for pickles, and the manufacture of a sort of candy from the pulp.

Feeding steers on sugar-beet pulp, alfalfa hay, and farm grains, W. L. Carlyle, C. J. Griffith, and A. J. Meyer (*Colorado Sta. Bul. 97, pp. 13, figs. 8*).—Using 3 lots of 50 steers each, the value of sugar-beet pulp and alfalfa, with and without grain, was studied.

In the 25 weeks of the test the average daily gain on the ration containing oats and barley was 1.9 lbs. per head, on the ration containing corn 2 lbs., and on that containing no grain 1.57 lbs. The greatest range in the cost of a pound of gain was noticed in the first and last mentioned lots, being 6.53 cts. and 3.79 cts., respectively. Data are recorded regarding the shrinkage in shipping, as well as some of the details of the slaughter test.

The authors state that no appreciable difference was noted in the quality or grade of the meat of representative carcasses selected from each lot. Judged by the results of cooking tests, the meat from the lot fed beet pulp and alfalfa hay only was as good or better than that from the other lots.

The principal conclusions drawn regarding the feeding value of sugar-beet pulp were in effect as follows:

In feeding sugar-beet pulp absolute cleanliness should be observed. It should be fed in troughs or "bunks" provided for the purpose, only such an amount being given at one time as the cattle will clean up with reasonable waste, and the bunks should be cleaned daily. Unless this be done they will gradually become filled with frozen pulp in cold weather and with decaying pulp during warm weather. Pulp should never be fed late in the afternoon during cold weather. The cattle generally refuse to eat after nightfall and whatever remains in the bunks freezes before morning.

Pulp has a laxative tendency. On this account it is well to feed good alfalfa hay of the first cutting with it, if convenient. The feed racks for hay and bunks for pulp should be near together. Cattle seem to be particularly fond of well-cured ensiled pulp, preferring this to fresh pulp. In order to secure the pulp in its best form, it is desirable to have it placed in the silo fresh from the factory and fed directly from

the silo. After fermentation has once begun exposure to the air in handling causes the pulp to deteriorate rapidly. Cattle relish it less after a continual exposure to the air, and reject a larger percentage than they would in the case of pulp direct from the silo.

Cattle-feeding experiment, W. Bruce (*Edinb. and East of Scot. Col. Agr. Bul. 4, pp. 18–35*).—The value of Bombay cotton-seed cake with damaged oats 3:1 in comparison with compound cake was studied with 2 lots of 8 steers each, the feeding test covering 6 months.

The ration was so arranged that the amount of compound cake fed was equivalent in money value to the cotton-seed cake mixture. The compound cake gave the lesser increase, the total gains made by the two lots being 1,832 and 1,631 lbs. In a second test 2 lots containing 8 cattle were fed large rations containing Bombay cotton-seed cake and other grains for 5 months. One of the lots was given fewer turnips than the other, but received some potatoes in addition. With the ration containing a smaller amount of turnips the gain was 2,387 lbs., and with the other 2,583 lbs. The effect of the different rations on the quantities of turnips consumed is taken into account in discussing the tests.

The studies show, according to the author, that supplying a moderate amount of concentrated feeding stuffs as a supplement to the home-grown products "at current prices brings the greater direct profit to the farmer, and that in intensive feeding a very considerable part of the return for the turnips must be accepted in the form of the manuriai residue derived from the feeding stuffs."

Feeding cattle with different quantities of the same concentrated foods, T. Winter (*Bd. Agr. and Fisheries [London], Ann. Rpt. Agr. Ed. and Research, 1903–4, pp. 66–68*).—A lot of 5 steers fed 10 lbs. of grain per head per day gained 2.37 lbs. each in 50 days, as compared with 2.55 lbs. gained by a lot fed 15 lbs. of concentrated feed.

With both lots the grain at first consisted of decorticated cotton-seed cake and maize meal; later linseed cake replaced the cotton-seed cake. The 2 lots consumed practically the same amounts of coarse fodder. The extra gain, according to the author, was not sufficient to compensate for the extra cost of the larger ration.

Sheep-breeding experiments, T. Winter (*Bd. Agr. and Fisheries [London], Ann. Rpt. Agr. Ed. and Research, 1903–4, pp. 68–72*).—At the University College of North Wales sheep-breeding experiments were continued along the same lines as in previous years (E. S. R., 15, p. 805). Mountain ewes were crossed with Southdown, Kerry Hill, and Leicester rams. The Southdown crossbred lambs averaged 70 lbs. in weight when sold at the age of about 9 months, being, according to the author, somewhat riper and in better condition than the others. The Kerry Hill cross weighed on an average 66 lbs. and the Leicester cross 74 lbs.

In a test of the value of various crosses with crossbred ewes for the production of fat lambs, Hampshire-down, Leicester, Lincoln, Suffolk-down, and Wiltshire rams were used. The best results were obtained with the Hampshire cross. The Leicester and Lincoln crosses were regarded as only moderately successful. The Suffolk-cross lambs reached good weight and were of good quality, but were slow in fattening. The Wiltshires did not give as good results as usual, probably owing to the fact that the weather was cold.

Welsh mountain ewes were crossed with Southdown and Wiltshire rams. Judging by the length of time required to feed the lambs for market and the average live weight when sold, the results were in favor of the Southdown cross, though the differences were less marked than in the last year's test.

Sheep-breeding experiments for the production of early fat lambs, P. H. Foulkes and W. Vaughan (*Harper-Adams Agr. Col. Bul. 1, pp. 8*).—Welsh ewes were crossed with Welsh, Southdown, and Shropshire rams, with a view to determining the most satisfactory crosses for breeding lambs for market. Owing partly to the

larger proportion of lambs reared and sold, the best results were obtained with the pure Welsh breed. At lambing times the Welsh lambs were hardier and stood conditions of the weather, etc., better than the heavier crossbreeds and were also ready for market about 3 weeks earlier than the others. Additional experiments are considered necessary before definite conclusions can be drawn.

Breeding for fat lambs, W. T. LAWRENCE (*Agr. Dept. Durham Col. Sci. Ann. Rpt., 12 (1903), pp. 78-80*).—In experiments at Newton Rigg, an Oxford-down, a Wensleydale, and a Border Leicester ram were each crossed with 19 Cheviot Border Leicester ewes.

The average weight of the lambs when sold ranged from 74.8 lbs. with the Oxford-down cross to 77.2 lbs. with the Wensleydale cross. The average value per pound with the Oxford-down cross was 9.66 cts. and with the Wensleydale and the Border Leicester cross 9.48 cts. The Oxford-down lambs matured most quickly for market and cost less for maintenance than the others, consequently their dams could be fattened and sold more quickly than the other ewes. When the earlier maturity of the Oxford-down lambs is taken into account, according to the author, the results obtained with them must be considered the most satisfactory.

Feeding experiments with lambs, 1903-4, B. C. BUFFUM (*Wyoming Sta. Bul. 64, pp. 20, pls. 3*).—In continuation of a test previously reported (E. S. R., 14, p. 382), a lot of 60 lambs was pastured on 11.6 acres of field peas raised on sod without irrigation, while 4 similar lots were fed alfalfa, turnips, and linseed meal, with and without corn; alfalfa and corn; and alfalfa with a mixture of barley, wheat, and oil meal. All the lots contained both large lambs and small scrubs.

The test proper covered 100 days, being preceded by a preliminary period in which all the lots received uniform treatment. On field peas the average gain per head was 24.9 lbs. With the other lots the gains ranged from 18.7 lbs. on alfalfa, turnips, and oil meal to 27.2 lbs. on alfalfa, turnips, corn, and oil meal. With all the lots the digestible nutrients per pound of gain ranged from 0.83 lb. protein and 4.04 lbs. carbohydrates and fat on the alfalfa, turnips, corn, and oil meal ration, to 1.43 lbs. protein and 6.65 lbs. carbohydrates and fat on field peas.

The gain was most expensively made with the lot fed peas, costing 6.22 cts. per pound, and most cheaply with the lot fed alfalfa, turnips, and oil meal, costing 3.35 cts. per pound. When slaughtered the largest proportion of dressed carcass, 47.8 per cent, was noted with the lot fed corn and oil meal, and the smallest, 43.3 per cent, with the lot fed oil meal in addition to coarse fodder.

The principal conclusions follow:

The lot fed field peas harvested the crop, made better gains, and went to market in better condition than the lot fed corn and alfalfa.

"It is possible to fatten lambs without grain on a cheap ration of alfalfa, turnips, and oil meal, and such rations will be further investigated.

"A complete and well-balanced ration of alfalfa, turnips, corn, and oil meal gave the largest gains on the smallest actual amount of nutrients in the food.

"There are probably better and more practical rations for fattening lambs in Wyoming than the alfalfa and corn ration commonly used.

"Combinations of wheat and barley fed alternately in ten-day periods did not give the best results. Fed in this manner, the lambs ate less grain and made smaller gains than on other grain rations.

"Under our conditions it will not pay to feed small, stunted lambs on full grain rations for short periods."

Sheep-feeding experiment, W. BRUCE (*Edinb. and East of Scot. Col. Agr. Bul. 4, pp. 1-17, 33*).—Using 6 lots of 38 sheep each, a test was undertaken to learn the most profitable feeding stuffs to use with a basal ration of cut Swedish turnips ad libitum with hay in the winter feeding of sheep, and to determine whether the use of concentrated feeding stuffs effected any saving in the daily consumption of turnips.

One of the lots was given hay and turnips only, and the others were fed linseed cake, Bombay cotton-seed cake, and grain mixtures containing Bombay cotton-seed cake or decorticated cotton-seed cake. In the 93 days of the test the total gain on turnips and hay alone was 1,040 lbs. and the gross cost per pound of gain 7.32 cts. In the case of the lots fed grain in addition to the basal ration the gain ranged from 1,252 lbs. on wheat, decorticated cotton-seed cake, and cotton seed to 1,461 lbs. on linseed cake and the gross cost of a pound of gain from 6.70 cts. on Bombay cotton-seed cake to 8.22 cts. on a mixture of wheat, decorticated cotton-seed cake, and cotton seed.

When dressed the weight was very uniform, being about 51 per cent of the live weight in every case. Considering the test as a whole the conclusion was drawn that Bombay cotton-seed cake was the most satisfactory of the concentrated feeds tested. An examination of the dressed carcasses showed that the animals fed this material were very superior to the others in appearance. The greatest financial return per acre of turnips was noted with the lots fed the Bombay cotton-seed cake.

On the presence of cotton-seed oil in lards from hogs fed upon cotton-seed meal, A. D. EMMETT and H. S. GRINDLEY (*Jour. Amer. Chem. Soc., 27 (1905), No. 3, pp. 263-270*).—The presence of vegetable oil and cotton-seed oil was shown by several tests with samples of lard from pigs fed cotton-seed meal.

It is evident, according to the authors, "first, that the lards contain a vegetable oil, and second, if we agree with the most recent authorities, they contain 3 distinct constituents of cotton-seed oil. Hence, it seems safe to say that a part at least of the oil existing in cotton-seed meal is absorbed, in the case of hogs fed upon this ration, by the animal body and transmitted in its unaltered condition to the fat cells."

Feeding farm horses, L. A. MERRILL (*Utah Farmers' Inst. Ann. 1904, pp. 43-49*).—Information regarding the feeding and management of horses is presented, some of the data being based on the experience of the Utah Station. The principal points are thus summarized:

"The amount of hay fed to horses on the average Utah farm can be very materially reduced, and if this be done it will result in (a) great financial saving to the State, and (b) the elimination of many digestive disorders to which our horses are subject.

"Horses should receive most of the hay at night, very little in the morning, and none at all for the noon meal. Always water before feeding. Oats make the best grain feed for horses, but these can be replaced by bran and shorts, or supplemented by corn.

"Carrots and sugar-beet pulp have a marked beneficial effect in horse feeding, serving as a laxative and a tonic, as well as enabling the horse to digest the hay and grain more effectively. Horses may eat as much as 40 lbs. of sugar-beet pulp daily."

Poultry culture in Minnesota, C. S. GREENE (*Minnesota Sta. Bul. 91, pp. 239-258, figs. 2*).—On the basis of personal experience, general questions of feeding, raising, and marketing poultry are discussed. One section of the bulletin is devoted to turkeys.

Poultry under confinement, J. WITHYCOMBE (*Oregon Sta. Bul. 84, pp. 8, fig. 1*).—Data are given regarding the financial returns from a flock of 24 White Plymouth Rock pullets, 5 old hens, and a cock, the test covering 1 year. The total number of eggs produced was 3,529.

Seventy-five chickens were raised from a total of 100 eggs set. "The low percentage of hatch of home-produced eggs was evidently due to too many hens to one male." Although the cost of feed was abnormally high, the flock yielded a profit of 180 per cent on the original investment of $15. "This test demonstrates conclusively that a small flock of poultry may be profitably kept under confinement; [and] that early hatched pullets are more profitable than late hatched ones."

Winter egg production, J. DRYDEN (*Utah Farmers' Inst. Ann. 1904, pp. 84-98, fig. 1*).—Feeding, care, and management of hens and construction of poultry houses

are among the subjects treated, the material presented being in part a summary of the poultry work carried on at the Utah Station.

The dry feeding of chickens, E. Brown (*Jour. Bd. Agr.* [*London*], *11* (*1905*), *No. 11, pp. 683, 684*).—The author states that experiments and observations extending over several seasons have led to the conclusion that the high mortality of artificially reared chickens during the first 10 or 20 days was due to want of exercise. Substituting dry feeds for wet feeds insured exercise and reduced the mortality to a minimum. The dry grains were scattered on the floor of the breeder or brooder house among chaff, where the chickens had to scratch to find them. Different grain mixtures which have been used with success at the Reading University College Poultry Farm are given.

The modifications of the respiratory quotient due to age, especially with reference to chickens and ducks, L. Mayer (*Trav. Lab. Physiol. Inst. Solvay, 6* (*1904*), *No. 3; abs. in Zentbl. Physiol., 18* (*1904*), *No. 21, p. 679*).—When expressed in the form of a curve the excretion of carbon dioxid by chickens and ducks in the first month after hatching is very similar to that which the author has reported for mammals. The excretion of carbon dioxid is very large in the first days after hatching, but diminishes rapidly in the first week, and then gradually, reaching its normal value when the birds are fully developed.

DAIRY FARMING—DAIRYING.

Investigations on the influence of irritating substances on the consumption and digestibility of food, and the secretion of milk with rations deprived of these substances and with normal rations, G. Fingerling (*Landw. Vers. Stat., 62* (*1905*), *No. 1-3, pp. 11-180*).—In studying the influence of irritating, stimulating, or condimental substances upon the consumption and digestibility of food and the secretion of milk, 2 series of experiments were conducted, one in which the food was nearly or entirely deprived of irritating substances, and one in which such materials were added to a normal ration. The experiments were made with rabbits, goats, and sheep. Among the substances under investigation were fenugreek, fennel, sugar, anise, hay extract, malt sprouts, and several proprietary preparations.

The addition of irritating substances was found to increase the consumption of food and the secretion of milk, but only when the ration was extremely poor in or entirely free from such substances, which would rarely be the case in practice. With normal rations the addition of condimental substances was entirely without effect. Under certain conditions it is believed that the addition of such substances to normal food may be injurious by causing a chronic catarrhal inflammation of the digestive tract. Contrary to views generally held, the irritating substances tested did not increase the digestibility of the food. This was true whether the food was originally poor or rich in these substances.

As regards the practical application of these results, it is considered clear that only in such cases where the food is deprived of its normal constituents, as, for example, hay which has been subjected to the effects of rain, can these substances be used to advantage. With normal feeding stuffs their addition is not only unprofitable but sometimes injurious. Cases where their use would be profitable are believed to be very rare, and then it is believed to be better to use seeds like fennel, anise, fenugreek, and caraway than proprietary mixtures consisting for the most part of such seeds and neutral substances. The author believes that good aromatic hay with salt is the best stimulating material.

Scant v. ample rations for dairy cows, H. Isaachsen (*Ber. Norges Landbr. Höiskoles Virks., 1903-4, pp. 249-259*).—This is a report of an experiment conducted during a full year with 19 cows, 4 of which were fed a scant ration of 2½ kg. cut straw, 8 to 9 kg. hay, and 1 kg. ground corn per head daily, while the other cows

received rations consisting of hay, straw, and silage, with 2 to 3 kg. of concentrated feed.

On an average 100 lbs. of milk was produced by lot 1 from 103 "food units," and by lot 2 from 84 "food units." The average milk production for the year was for lot 1, 1,765 kg., and for lot 2, 2,303 kg., while the average profit for the year for lot 1 was $11.34 per head, and for lot 2 $15.93. Several factors tended to render direct comparisons of the results of doubtful value, but on the whole the greater economy of the more liberal system of feeding of the second lot is apparent from the larger production of the cows and the larger increase in body weight during the year.—F. W. WOLL.

Feeding sugar to milch cows, E. A. BOGDANOV (*Izv. Moscov. Selsk. Khoz. Inst. (Ann. Inst. Agron. Moscou), 10 (1904), No. 3, pp. 471–504*).—Two cows were used in each of 6 experiments, covering 3 periods of 10 days each. During the middle period sugar was fed in addition to the normal ration or as a substitute for a portion of either the nitrogen-free extract or proteids. The experiments which were conducted in the fall and spring indicated that the sugar was profitably utilized only when fed in rations containing a normal amount of proteids. The experiments conducted in the summer showed that linseed cake was more valuable than sugar.—P. FIREMAN.

Effect of corn silage on the flavor of milk, W. J. FRASER (*Illinois Sta. Bul. 101, pp. 644–646*).—In order to test the effect of corn silage on the flavor of milk, the university dairy herd was divided into 2 lots, one of which was fed 40 lbs. of corn silage per cow per day, while the other lot was fed only clover hay and grain.

The milk from each lot was standardized to 4 per cent and otherwise cared for in exactly the same manner. In all 372 samples from each lot were submitted to ladies, men of the faculty, and men students for an opinion as to any difference in the flavor of the 2 samples, anything objectionable about either, and any preference. The results showed that 60 per cent preferred silage milk, 29 per cent nonsilage milk, and 11 per cent had no choice. When the silage was fed at the time of milking, the percentage in favor of silage milk was much higher than when the silage was fed one hour before milking or after milking.

Five samples of each lot were sent to milk experts in different cities, three of whom preferred silage milk, one nonsilage, and one had no choice. No complaint was received from a hotel to which silage milk was delivered for a period of 1 month. On the whole it was apparent that the greater number of people were able to distinguish between the 2 kinds of milk, but found nothing objectionable about either kind. It is suggested that only good silage should be used for dairy cows and that all feeds of this nature should be fed after milking in order to avoid any unpleasant flavor in the milk.

Influence of feeding sesame cake on the properties of butter fat, J. DENOËL (*Bul. Agr. [Brussels], 21 (1905), No. 2, pp. 182–192*).—In view of the requirements in certain countries that sesame oil shall be added to margarin, the author discusses the reliance that may be placed upon the Baudoin reaction for detecting this oil, and reports experiments to determine whether feeding sesame cake can communicate to butter the reaction of sesame oil.

The experiments included 16 cows and comprised in all 31 tests, in none of which was the least coloration obtained, indicating that none of the sesame oil was transmitted to the milk. Contradictory results which have been obtained by other investigators are noted.

On the different portions of the milking with application to the Hegelund method, H. SVOBODA (*Chem. Ztg., 29 (1905), No. 34, pp. 468–474*).—The literature relating to the composition of milk at different stages in the process of milking is reviewed, and experiments with 5 cows representing 2 breeds are reported in detail.

The yield of milk from the different quarters of the udder was found to vary considerably, the posterior quarters being much more productive than the anterior. Owing to the position of the milker on the right side, and consequently the more intensive manipulation of the right half of the udder this half was found to be more productive than the left half.

The generally held view that the percentages of fat and solids increase from the beginning to the end of milking, while the specific gravity decreases, is not believed to be true. This is, however, the case for a single quarter, for a half of the udder when the 2 quarters are milked simultaneously, or even for all 4 quarters when milked at the same time. In such cases the fat and total solids increase from the beginning to the end of milking, while the proteids, ash, and milk sugar decrease almost uniformly.

While there is practically no difference in the proportion of proteids, ash, and milk sugar from the beginning to the end of milking, such variations as do exist are more marked in the case of proteids and ash than milk sugar. The greater the yield of milk the more marked are the variations mentioned. Where the different quarters of the udder are milked in succession the fat content of the different portions of the mixed milk varies irregularly.

The influence of milking on the composition of milk, M. POPP (*Molk. Ztg., 19 (1905), No. 20, pp. 493, 494*).—This is a discussion of investigations along this line, especially those of Lepoutre (E. S. R., 15, p. 906) and Svoboda (see above). In experiments conducted in Russia it is noted that the yield of milk of cows of 4 different breeds during 10 days when the animals were regularly cleaned was 7 per cent greater than when they were not cleaned.

The chemical composition of milk in Milan, 1902–3, C. BERTOCCHI (*Milchw. Zentbl., 1 (1905), No. 5, pp. 211–215*).—In continuation of the work of Billitz (E. S. R., 16, p. 1013), the author reports the results of analyses of the milk of 24 herds, representing 2,127 cows, in the region of Milan, and of 31 herds, representing 2,304 cows, in the neighborhood of Lokate-Triulzi.

The period covered was from May, 1902, to April, 1903. The average composition of the milk of the 24 herds was as follows: Specific gravity 1.0317, fat 3.61 per cent, solids-not-fat 8.91, and total solids 12.52; and of the 31 herds, specific gravity 1.0316, fat 3.70 per cent, solids-not-fat 8.91, and total solids 12.61. As compared with the earlier analyses the results show a slight improvement in the composition of the milk. Often, however, the total solids fell below 12 per cent and the solids-not-fat below 9 per cent, the standard adopted in Milan.

The milk supply of twenty-nine southern cities, C. F. DOANE (*U. S. Dept. Agr., Bur. Anim. Indus. Bul. 70, pp. 40*).—A detailed account, based upon personal investigation, is given of the milk supplies of Richmond, Norfolk, Portsmouth, Newport News, Lynchburg, Danville, Wilmington, Raleigh, Greensboro, Charleston, Columbia, Spartanburg, Atlanta, Savannah, Augusta, Macon, Jacksonville, Pensacola, Montgomery, Birmingham, Mobile, Vicksburg, Meridian, Natchez, New Orleans, Baton Rouge, Memphis, Chattanooga, and Knoxville.

In addition the author discusses in a general way the dairy situation in the South, the consumption of milk in southern cities, the methods employed in the handling of milk, milk and dairy inspection, and peculiar conditions in the seacoast cities, and makes suggestions for the improvement of existing conditions.

The consumption of milk in southern cities was found to be small. The average daily amount consumed per capita in Richmond was found to be less than $\frac{1}{2}$ pt., while in Mobile it was less than $\frac{1}{10}$ pt. It was also ascertained that the sale of cream was exceedingly light.

Two evils considered by the author as characteristic of the dairy industry of the South are the keeping of cows in small inclosures within the city limits, and the

delivery of warm milk. Many suggestions are made looking toward the improvement of milk supplies in the South.

The production of certified milk on the Biltmore farms, M. N. Ross (*Pure Products, 1* (*1905*), *No. 6, pp. 300–304*).—Notes are given on the dairy herd at Biltmore and on the methods employed in producing and marketing milk.

The sanitary production and sale of milk, Plehn (*Österr. Molk. Ztg., 12* (*1905*), *No. 8, pp. 103, 104; Milch Ztg., 34* (*1905*), *No. 19, pp. 227–229; 20, pp. 241–243*).—This is a brief general discussion of this subject.

Stable hygiene, R. Bissauge (*Indus. Lait.* [*Paris*], *30* (*1905*), *No. 22, pp. 257, 258*).—This is a brief discussion of stable hygiene with special reference to dairy cows.

Variation in the composition of cows' milk, C. Crowther (*Jour. Agr. Sci., 1* (*1905*), *No. 2, pp. 149–175*).—A résumé of experimental work in Great Britain conducted by the agricultural institutions and societies since 1900.

While the greater number of the investigations upon which this article is based have been noted from time to time in the Record, the article also contains additional information secured from private communications. The following factors are discussed as regards their influence upon the composition of milk: Interval between successive milkings, day and night, age, period of lactation, season of the year, food, manner of feeding, weather, pasturing *v.* housing at night in autumn, and sexual excitement.

Data on the composition of milk from different quarters of the udder, on the average composition of milk, and on the limits of variation in composition of mixed milk are also summarized.

Contribution to the bacteriology of milk, S. Severin and L. Budinoff (*Centbl. Bakt.* [*etc.*], *2. Abt., 14* (*1905*), *No. 15–16, pp. 463–472*).—Determinations were made of the number of bacteria in mixed milk and in samples of the same milk taken immediately after separation or clarification, pasteurization, cooling, and bottling.

As compared with the number of bacteria in mixed milk the percentages after separation, pasteurization, cooling, and bottling were respectively 182.8, 0.017, 0.076, and 0.030. In another series of experiments in which the milk was treated in exactly the same manner except that the pasteurizing apparatus was not heated, the percentages after separation and cooling were 232.1 and 246.8 as compared with the number in the mixed milk.

The cause of the large increase in the number of bacteria, due apparently to passing through the separator, was investigated, the results of the experiments showing that this increase could not be attributed to contamination from the air or the apparatus, nor to the multiplication of the bacteria during the brief interval in which the milk was held at 30° C. A further investigation of this subject is contemplated.

Studies were also made of the number and kinds of bacteria in pasteurized and unpasteurized milk. In the pasteurized milk spore-forming and peptonizing bacteria were in the minority, the far greater number consisting of vegetative forms indifferent toward milk. Lactic-acid bacteria were not found in the milk immediately after pasteurization, but were found in the milk at later stages in the process of cooling and bottling. Of the bacteria gaining access to the milk after pasteurization none were spore-forming.

When the pasteurized milk was preserved at 9 to 11° C. for 14 to 27 hours, the spore-forming bacteria played no essential rôle, while the bacteria gaining access to the milk after pasteurization developed with much greater energy. It is considered apparent that the bacteria resisting pasteurization were so reduced in vitality that at least in the interval of 27 hours they were not able to multiply with the rapidity of the bacteria which were not subjected to the unfavorable influence of heat. Similar results were also obtained by means of plate cultures. Colonies on plates prepared immediately after pasteurization developed much more slowly than colonies on plates prepared at later periods.

Gas-producing bacteria and their effect on milk and its products, F. C. Harrison (*Ontario Agr. Col. and Expt. Farm Bul. 141, pp. 7, figs. 6*).—Practical points brought out in connection with a study of 66 varieties of gas-producing bacteria isolated from milk are discussed briefly in this bulletin.

Bacteriological examinations of the milk from a number of farms showed on an average the presence of nearly 15,000,000 bacteria per cubic centimeter, of which over 235,000 were gas producing. The percentage of gas-producing bacteria in 27 examinations made varied from 0.04 to 34.2 per cent. In studying the source of these gas-producing organisms in milk it was ascertained that they were occasionally present in the udders of certain cows, on the hair of the animals, in clean, dry milk cans, in watering troughs, on flies present in the stable, and in manure.

The gas-producing bacteria were found to be readily killed at temperatures of 137 to 146° F. for 10 minutes. While they were destroyed by immersion for 10 minutes in a 2 per cent solution of ammonia or soda washing powders kept at 140°, it is believed that these powders are scarcely more effective than hot water, except as they help to remove the dirt in washing.

It was found that by continued growth in milk the gas-producing bacteria increased their power of fermenting milk sugar. In one instance the increase in gas production noted was from 26 to 62 per cent. In general the development of lactic-acid bacteria tended to check the growth of the gas-producing forms.

The injurious effects of the gas-producing bacteria were shown in butter and cheese making experiments.

A comparative study of sixty-six varieties of gas-producing bacteria found in milk, F. C. Harrison (*Rev. Gén. Lait, 4 (1905), Nos. 12, pp. 265–275; 13, pp. 289–297; 14, pp. 315–328; 15, pp. 337–351; Centbl. Bakt. [etc.], 2. abt., 14 (1905), Nos. 12–13, pp. 359–374; 15–16, pp. 472–480*).—This is a detailed report of the bacteriological investigations upon which the above bulletin is based.

The author proposes a classification of the different varieties which were stated to show every imaginable modification between *Bacillus coli* and *B. lactis aerogenes*, which were taken as extremes. The neutral red test did not appear to be of value in separating members of the coli group, and the agglutination test showed only a limited value in the identification of closely related varieties. A bibliography is appended.

On the preservation of milk with hydrogen peroxid, E. Baumann (*München. Med. Wchnschr., 52 (1905), No. 23, pp. 1083–1088*).—After citing objections which have been raised to the pasteurization and sterilization of milk for infant feeding and reviewing briefly some of the literature relating to the use of formalin and hydrogen peroxid for this purpose, the author reports several series of experiments with the latter substance.

In no instance were all the bacteria in market milk destroyed by hydrogen peroxid added in quantities ranging from 0.35 to 2 parts per thousand, the milk being heated to 45 to 50° C. and kept at that temperature for 2 to 3 hours. The number of bacteria, however, was always greatly reduced and spontaneous curdling of the milk delayed for several days. The reaction for hydrogen peroxid was usually absent at the end of treatment unless the quantity added exceeded 0.54 part per thousand, when a positive reaction was obtained for days.

Market milk treated with hydrogen peroxid in the proportion of 0.42 : 1,000 showed 60, 2,220, and 26,400 bacteria per cubic centimeter at the end of 2, 5, and 7 days, respectively, while milk which had been obtained under rigid aseptic precautions was completely sterilized by the same treatment.

Typhoid, cholera, and dysentery bacilli added to milk sterilized by heating were destroyed in all cases by hydrogen peroxid in the proportion of 0.35 : 1,000, the milk being heated to 45 to 50°. Typhoid bacilli were not all destroyed by hydrogen

peroxid in the proportion of 0.18:1,000 and a temperature of 45° or 0.35:1,000 at room temperature.

Tubercle bacilli were also added to sterilized milk, which was then treated with hydrogen peroxid in the proportion of 0.35:1,000. Inoculation experiments with guinea pigs gave negative results as regards infection. It was concluded as the result of 2 series of experiments that both bacteria and enzyms in milk are capable of decomposing hydrogen peroxid.

Treatment with hydrogen peroxid was found to lengthen materially the time required for coagulation of milk with rennet extract, and also to bring about certain changes in the character of the curd. In artificial digestion experiments the pepsin-hydrochloric-acid solution seemed to act more rapidly and energetically on the samples treated with hydrogen peroxid than on raw milk. The results of the digestion and coagulation experiments are therefore considered as offering no objection to the use of hydrogen peroxid in milk. Aside from its possible use in infant feeding, milk preserved with hydrogen peroxid is believed to be well suited to use in the army and navy and in the Tropics.

In the practical application of hydrogen peroxid to the preservation of milk, it is pointed out that every precaution should be taken to prevent contamination of milk during milking, that milk should be treated immediately after milking before a multiplication of bacteria has taken place, and that the 30 per cent hydrogen-peroxid solution can be used to avoid dilution of milk.

On the question of the preservation of milk with formaldehyde, especially for the purpose of infant feeding, L. Schaps (*Ztschr. Hyg. u. Infectionskrank., 50 (1905), No. 2, pp. 247–264, figs. 7*).—Some of the literature of this subject is briefly reviewed.

Experiments are reported which show the length of time that formalin in the proportions of 1:10,000 and 1:5,000 delays the souring of milk at room and incubator temperatures. The author claims that formalin in the proportion of 1:10,000 renders the milk objectionable on account of taste and that in the proportion of 1:40,000 it is still distinctly recognizable, which is contrary to the statement of Behring that milk treated with formalin in the proportion of 1:4,000 could not be distinguished from untreated milk.

Samples of raw milk and milk preserved with formalin in the proportion of 1:10,000 and 1:5,000 were inoculated with *Staphylococcus pyogenes albus* and kept at room temperature for 12 hours. Plate cultures were then made and examined after remaining 24, 48, and 72 hours in the incubator. When examined at the end of 24 hours many of the plates showed colonies only in the case of milk not treated with formalin, but when examined at a later period it was apparent that formalin had not destroyed the staphylococci.

Formalin checked the development of the lactic-acid bacteria to a much greater extent than that of the staphylococci. As determined by inoculation experiments with guinea pigs, formalin in the amounts above mentioned failed to destroy tubercle bacilli added to raw and sterilized milk.

The history and post-mortem findings in the case of an infant which had been fed milk preserved with formalin in the proportion of 1:10,000 are reported, but the data warranted no positive conclusion as to the influence of formalin. On the evidence so far obtained the author objects to the use of formalin as well as to that of other preservatives in milk.

Milk preserved with formalin and the relation of formalin to certain species of bacteria, P. Sommerfeld (*Ztschr. Hyg. u. Infectionskrank., 50 (1905), No. 1, pp. 153–164*).—The author found that formalin added to fresh milk in the proportion of 1:5,000 or 1:10,000 was capable of hindering to a marked extent the development of bacteria.

The germicidal power of formalin was most marked when the milk was held at temperatures of 10 to 15° C. At 20° and above the number of bacteria in milk preserved with formalin at the end of 24 hours was scarcely less than that in control samples. At 37° formalin showed no appreciable effect in retarding the development of bacteria. On the contrary, when milk was kept at 7 to 8° the addition of formalin in the proportion of 1:10,000 reduced the number of bacteria in 6 days in one instance from 2,160 to 222 bacteria per cubic centimeter. At low temperatures the bactericidal action of formalin was equally marked when the original bacterial content of the milk was high.

While valuable as a means of preserving milk samples for analytical purposes, formalin is believed to be no better suited for preserving milk for human consumption than any other chemical preservative. Cleanliness in milking, immediate cooling, and keeping at a temperature below 10° C. are considered the best means of preserving milk for human use.

In a second series of experiments sterile milk and bouillon preserved with formalin were inoculated with various species of bacteria. The virulence of diphtheria bacilli in milk treated with formalin in the proportion of 1:5,000 and kept at room temperatures for 24 hours and at 37° for a second period of 24 hours was not impaired. Typhoid bacilli added to milk also resisted formalin in the proportion of 1:5,000. In bouillon formalin in the proportion of 1:10,000 showed no inhibitory influence on the development of the coli bacillus. Typhoid bacilli in bouillon were completely destroyed in 24 hours at 21° by formalin in the proportion of 1:5,000 but not the proportion of 1:10,000. *Bacillus pyocyaneus* in milk or bouillon was not destroyed at 37° by formalin in the proportion of 1:10,000 or 1:5,000.

On the passage of antibodies into the milk and their absorption through the digestive tract, DE BLASI (*Centbl. Bakt.* [*etc.*], *1. Abt., Ref., 36* (*1905*), *No. 12–13, pp. 353–355*).—In 2 series of experiments cats and rabbits were immunized passively by means of injections of diphtheria antitoxin and antidysentery serum, and actively by means of cultures of the dysentery bacillus and typhoid bacilli.

The passive immunity of the mother was not sufficient to protect the nursing offspring from the results of inoculation with bacterial cultures. In the cases of active immunity the results showed that the antibodies not only passed over into the milk but were absorbed in the digestive tract in sufficient quantities to neutralize the effect of bacterial injections. A marked difference was, therefore, apparent between the groups actively and passively immunized.

This is published as a preliminary communication, and contains a brief discussion of the literature of the subject.

On the passage of the agglutinins and antitoxins of tuberculosis into milk and their absorption by way of the alimentary tract, F. FIGARI (*Riforma Med., 21* (*1905*), *No. 14; abs. in Jour. Amer. Med. Assoc., 44* (*1905*), *No. 22, p. 1818*).—The author found that the agglutinins and antitoxins pass into the milk of cows and goats actively immunized against tuberculosis, and into the milk of rabbits passively immunized; and furthermore, that the agglutinins and antitoxins in the milk of immunized animals are absorbed in the digestive tract of calves and young goats born of nonimmunized mothers, and are able to excite the formation of other agglutinins and antitoxins.

Outbreak of sore throats due to infected milk (*Jour. Amer. Med. Assoc., 44* (*1905*), *No. 25, p. 1996*).—A brief account is given of an outbreak of septic sore throat involving from 500 to 600 persons, the cause of which was traced to the milk of a cow affected with mastitis.

On the fat content of human milk, P. REYHER (*Jahrb. Kinderheilk., 61* (*1905*), *No. 4, pp. 601–614*).—The author shows that the method of obtaining the samples analyzed has much to do with the marked variations in reported data. In some instances a difference of over 6 per cent was observed in the fat content of the first

and last portions of milk obtained. The method employed by the author is described, some data secured are reported, and a bibliography of the subject is added.

On the fat in human milk, ENGEL (*Ztschr. Physiol. Chem., 44 (1905), No. 3-4, pp. 353-365, figs. 10*).—The literature of this subject is reviewed and determinations of the iodin number of the fat in the milk of 4 women are reported.

The average determinations for each of the 4 subjects were 44, 54, 43.6, and 43.3. The results indicated that in most instances the iodin numbers would lie within the limits reported by Laves and Sauvaitre, namely, 44.5 and 43.37. The conclusion is drawn that the iodin number varies within moderate limits with the different individuals and daily with the same individual.

Productive capacity of the Friesian milch sheep on the moors of Northwest Germany, A. KIRSTEN (*Milchw. Zentbl., 1 (1905), Nos. 4, pp. 145-155; 5, pp. 193-202*).—Detailed data are given showing the yield and composition of the milk of 3 sheep during one lactation period each.

The decrease in the yield of milk was gradual from the beginning to the end of the lactation period. The fat content of the milk remained nearly uniform during the first few months, then increased rapidly and became twice as high in the last month as in the first. The specific gravity decreased in the first month, but increased above that at the beginning toward the close of the lactation period. The highest fat content observed was 14.88 per cent and the highest specific gravity 1.0478. The average percentages of fat in the milk of the 3 sheep for the entire lactation periods were 5.58, 6.81, and 6.97. Marked daily variations were sometimes observed.

Information concerning the milch goats, G. F. THOMPSON (*U. S. Dept. Agr., Bur. Anim. Indus. Bul. 68, pp. 87, pls. 16, figs. 7*).—This is a compilation of available information concerning milch goats, the publication being designed to answer questions received by the Bureau concerning various phases of the industry.

Among the many subjects discussed in this connection are the economy of goat keeping, characteristics and composition of goat's milk, period of lactation, methods of milking, butter and cheese made from goat's milk, care and management of goats, diseases of goats, feeding and breeding of goats, points to be observed in purchasing goats, prices of milch goats, goat's flesh as food, milch goats as brushwood destroyers, and breeds of milch goats. Notes are given on The Milch Goats of Switzerland by F. S. Peer, and on Goats in Norway and Sweden by Caroline Harrison.

The struggle against tuberculosis in Denmark, pasteurization, and the use of pure cultures in Danish dairies, M. BEAU (*Ann. Inst. Nat. Agron., 2. ser., 4 (1905), No. 1, pp. 25-96, figs. 9*).—This is a report upon studies in Denmark relating to the control of bovine tuberculosis, ripening of cream, pasteurization, and the employment of pure cultures in butter making.

On the mechanical splitting-up of the fat globules in cows' milk, C. BARTHEL (*K. Landtbr. Akad. Handl. och Tidskr., 43 (1904), No. 6, pp. 401-408*).—The author furnishes evidence that the fat globules in cows' milk are split up by strong agitation, like that taking place in pasteurizing machines where the milk is stirred at a considerable speed, and also shows that the Adams method of determining fat in milk gives too low results, the percentages of fat found by the Gottlieb method being uniformly higher.—F. W. WOLL.

Various dairy trials, F. FRIIS and H. P. LUNDE (*Ber. K. Vet. og Landbohöjskoles Lab. Landökonom. Forsög [Copenhagen], 57 (1905), pp. 31*).—*Trials with aeration of cream.*—The trials were made with two forms of apparatus for aerating cream. Butter made from aerated and non-aerated cream was judged twice, with an intermission of 14 days. In 34 comparative trials the score for the butter made from aerated cream was higher than that from non-aerated cream in 6 cases, lower in 5 cases, and the same in 23 cases. In the second scoring these figures were changed to 9, 12, and 13, respectively.

The results show that no difference was, in general, found in the quality of the butter from aerated and from non-aerated cream, the trials thus corroborating the results of earlier investigations made with sweet milk (E. S. R., 13, p. 179). The quality of the butter was found to be somewhat impaired by the direct pumping of air into the cream, presumably because oxygen is thus supplied to the aerobic bacteria in the cream which tend to deteriorate the butter.

Trials with Ulander's milk strainer.—The cream separated from milk strained by means of an ordinary strainer and by Ulander's strainer was churned under similar conditions and the butter scored. In the first scoring the butter obtained from the milk strained by Ulander's strainer scored the same as the control lot in 29 cases out of 36, higher in 5 cases, and lower in 2 cases. In the second scoring these figures were changed to 24, 3, and 9, respectively. On the average there was a difference of only 0.1 of a point on either scoring (total score 15), showing that the method of straining the milk did not affect either the grade or the keeping quality of the butter made therefrom.

Trials with the Disbrow churn.—The preliminary report of the comparative trials with the common Danish (Holstein) and the Disbrow combined churn and worker has already been referred to (E. S. R., 16, p. 917). The report here given furnishes a full account of the experimental data, from which the following averages for the Danish and Disbrow churns, respectively, for the 25 different trials are taken:

Churning temperature at the beginning (Danish) 14.2° C., (Disbrow) 14.2°; at the end, 15.4 and 15.3°; length of churning, 25.1 and 35 minutes; revolutions per minute, 131.7 and 28.4; fat in butter milk, 0.43 and 0.45 per cent; water in butter, 13.87 and 14.02 per cent. The score of butter on both first and second scorings was 0.2 point in favor of the Disbrow churn, on a total score of 15. The horsepower required in 3 trials was 1.3 for the Danish churn and 3.3 for the Disbrow churn. The horsepower hours per 1,000 lbs. cream in 2 trials was for the Danish churn 1.35 and for the Disbrow churn 1.25, and in a third trial 2.2 and 1.2, respectively.—F. W. WOLL.

On clean skimming of milk at different temperatures, F. FRIIS and E. HOLM (*Ber. K. Vet. og Landbohöjskoles Lab. Landökonom. Forsög* [*Copenhagen*], *56* (*1905*), *pp. 24–29*).—The general practice in Danish creameries in the early nineties was to skim the milk at 30° C., but since the introduction of the pasteurization method in the creameries high skimming temperatures have been gradually adopted, as the skim milk and the cream are now always pasteurized after separation.

An investigation conducted last winter showed that of 907 creameries 4.7 per cent warmed the milk to 30 to 35° C. before separating, 21.8 per cent to 36 to 40°, 45.8 per cent to 41 to 45°, 21 per cent to 46 to 50°, 5.6 per cent to 51 to 55°, and 1.1 per cent to 56 to 68°, the average skimming temperature for all creameries being 43° C. Analyses of the separator skim milk taken at a number of creameries from different styles of separators showed that the fat content of the milk was lowest at the higher skimming temperatures.

The following average results have been calculated from tables given in the report:

Effect of temperature of skimming on fat content of skim milk.

Skimming temperature (degrees C.)	31	35	40	45	50	55	60	65
Number of analyses	2	7	11	12	8	12	7	2
Average percentage of fat	0.179	0.161	0.137	0.123	0.110	0.101	0.103	0.102

The former of the two series of determinations conducted were made by the extraction method, hence the results are in all probability slightly low, on the average, 0.05 per cent. On basis of the results obtained it is recommended to heat the milk to about 60° C. in the forewarmer, prior to separation.—F. W. WOLL.

A new centrifugal churn, G. RAGONDET and M. HARDY (*Ann. Gembloux, 15* (*1905*), *No. 6, pp. 314–318, fig. 1*).—A centrifugal churn exhibited at the agricultural

exposition in London in June, 1904, is described and results of tests made in France and Belgium are reported. It is believed that this churn will prove of practical value.

The perpetuation of pure cultures for butter starters, E. F. PERNOT (*Oregon Sta. Bul. 83, pp. 8, fig. 1*).—Twelve or more pint milk bottles are thoroughly cleansed, half filled with fresh skim milk, and plugged with cotton. Through the plug in one of the bottles a pipette is inserted, a little cotton placed within the glass tube, and a rubber bulb fitted to the upper end of the pipette.

The bottles are then sterilized and the one fitted with the pipette is inoculated with the commercial culture. In perpetuating this culture the plug is removed from another bottle and the plug with the pipette inserted. Pressure on the bulb forces the material contained in the tip of the pipette into the milk and thus inoculates the second bottle. Suggestions are made concerning the prevention of contaminations.

This method of preparing starters was used in the short dairy course by the students with good success. Scores of the butter made in the work are included in this bulletin.

The proteids of cream, butter, and buttermilk in relation to mottled butter, L. L. VAN SLYKE and E. B. HART (*Jour. Amer. Chem. Soc., 27 (1905), No. 6 pp. 679–690, pl. 1*).—This is a reprint in an abridged form of Bulletin 263 of the New, York State Station (E. S. R., 16, p. 1125).

The Camembert type of soft cheese in the United States, H. W. CONN, C. THOM, ET AL. (*Connecticut Storrs Sta. Bul. 35, pp. 32, figs. 3; U. S. Dept. Agr., Bur. Anim. Indus. Bul. 71, pp. 29, pls. 2*).—This is a preliminary report upon cooperative investigations which are being conducted by the Connecticut Storrs Station and the Dairy Division of the Bureau of Animal Industry of this Department.

Soft and hard cheeses are compared, the market for soft cheeses in the United States is discussed, available literature relating to Camembert cheese is briefly reviewed, and the results of the mycological, bacteriological, and chemical investigations to determine the causes of ripening of Camembert cheese are summarized. A description of practical methods is to be published in a later bulletin. The detailed accounts of the three lines of investigation will also follow in separate papers.

The first change affecting the ripening of Camembert cheese is the souring of the rennet curd, which begins while the curd is allowed to stand in the forms for draining. After about 2 days the curd has become hard and sour and is removed to the ripening cellar where, after a few days, molds begin to grow upon the surface. The acidity of the cheese becomes noticeably less in about 2 weeks and later disappears.

As the ripening progresses the cheese becomes soft and yielding to pressure. In half-ripened cheese the outer layer is soft and the central mass hard. In completely ripened cheese the consistency is that of moderately soft butter. In over-ripened cheese the interior becomes liquefied. The characteristic flavor is developed during ripening, but this sometimes does not appear until late in the process. The final product is a cheese having a firm moldy rind and contents uniformly soft to the center and possessing a characteristic piquant flavor.

In brief the results of the investigations indicate (1) that the acidity of the curd is developed by the lactic-acid bacteria commonly used in the form of a starter and that this prevents further bacterial action, (2) that a species of Penicillium (*P. candidum?*) produces the principal changes in the curd and that *Oïdium lactis* in conjunction with the Penicillium produces the flavor, and (3) that no other organisms than these specific molds and bacteria are absolutely necessary for the production of typical Camembert cheese, though other species of bacteria are always present.

Using pure cultures of the organisms mentioned, soft cheeses have been made at the station which, it is stated, have been pronounced by the investigators, importers, and connoisseurs as practically identical with the best imported goods. The

manufacture of first-class Camembert cheese is, therefore, believed to be perfectly practicable under American conditions. It is also believed to be possible to control the ripening to such an extent as to produce a more uniform product.

Cheese ripening materials, F. REISS (*Milchw. Zentbl., 1 (1905), No. 5, pp. 203–208*).—Analyses of 3 proprietary preparations for hastening the ripening of cheese showed the presence of large quantities of sodium bicarbonate, 2 powders containing, respectively, 48.72 and 57.70 per cent, and 1 liquid 8.40 per cent.

Practical tests were made with each of the 3 preparations, the results seeming to be somewhat favorable to the application of an alkali as a means of hastening the ripening of the sour-milk cheese made. The author believes that the use of such preparations should be tested with various kinds of cheese.

Standards for grading cheese and creamery butter, J. A. RUDDICK (*Canada Dept. Agr., Dairy Div.* [*Circ.*], *May 19, 1905, pp. 3*).—Standards with explanatory notes for use in connection with giving certificates as to the quality of cheese and creamery butter are given.

Fifteenth annual meeting of Missouri State Dairy Association, 1905 (*Mo. Bd. Agr. Mo. Bul., 4 (1905), No. 10, pp. 86*).—This contains the president's address and the following papers: The Business Cow for the Business Dairyman, by R. M. Washburn; The Farmer's Dairy Cow, by A. J. Glover; My Experience with Cows, by T. L. Haecker; and Necessary Conditions for Successful Dairying, by H. B. Gurler.

Dairying as a profession, G. L. MCKAY (*Iowa Agr., 5 (1905), No. 12, pp. 414, 415, fig. 1*).—Brief notes are given on the opportunities in this profession.

VETERINARY MEDICINE.

Proceedings of the American Veterinary Medical Association (*Hartford Press, 1904, pp. 414, pls. 9, figs. 7*).—This volume contains an account of the forty-first annual convention of the American Veterinary Medical Association held in St. Louis, August 16–19, 1904. The papers which were read at this convention have been previously noted (E. S. R., 16, pp. 121–128). The following notes are given on papers which were presented by title, but are included in the proceedings:

The source of mucin in the urine of the horse, H. J. Milks (pp. 305–315).—The study of the origin of mucin is presented in considerable detail. It is concluded that the mucin in horse urine comes chiefly from the mucous glands situated in the pelvis of the kidneys. A small amount may come from the glands in the upper part of the ureters, while none has its origin in the bladder.

The relation of bovine and human tuberculosis, E. Perroncito (pp. 319–327).—Some of the recent literature relating to this subject is briefly reviewed by the author and notes are given on experiments in the transmission of bovine tuberculosis to pigs through the alimentary tract. The disease thus artificially produced differs in several particulars from ordinary spontaneous cases of tuberculosis in pigs. The same author transmitted a paper on The Phosphorescence of Meats (pp. 374–378). In this paper notes are given on the phenomena observed in phosphorescent meat. In certain samples of phosphorescent meat the color was dark red and the surface was covered with a mucous exudation. The literature relating to this subject is briefly reviewed.

Inspection and animal quarantines, J. A. Couture (pp. 349–356).—A historical statement is presented of quarantine regulations which have been established in the United States and Canada. Notes are also given on outbreaks of foot-and-mouth disease and contagious pleuro-pneumonia, in connection with which data are presented on the numbers of different kinds of domesticated animals imported to the United States and Canada.

The volume also contains lists of officers, committees, resident State secretaries, honorary and active members, and also the minutes of the business sessions.

Symptomatology and diagnosis of animal diseases, C. CADÉAC (*Sémiologie et diagnostic des maladies des animaux domestiques. Paris: J. B. Baillière & Sons, 1905, vol. 1, pp. 450, figs. 57; vol. 2, pp. 532, figs. 129*).—These volumes treat in considerable detail of the symptoms and methods of diagnosing various kinds of diseases which affect domesticated animals.

The material discussed in the 2 volumes is arranged according to the parts of the body affected and includes diseases of the digestive organs, respiratory apparatus, circulation, urinogenital organs, nervous system, special senses, and locomotor organs. Special chapters are devoted to a general consideration of animal diseases and means of combating them.

Trypanosomes and trypanosomiases, A. LAVERAN and F. MESNIL (*Trypanosomes et trypanosomiases. Paris: Masson & Co., 1904, pp. XI+418, pl. 1, figs. 61*).—In this volume the authors have brought together a summary of accounts of their own and other authors' investigations regarding the morphology and biology of trypanosomes and the symptoms, distribution, and treatment of diseases caused by these organisms.

In a discussion of these problems numerous references are made to the literature of the subject. The volume contains chapters on the distribution of trypanosomiases, technique for the study of trypanosomes, the morphology of various species of trypanosomes, nagana, surra, mal de caderas, dourine, galziekte, trypanosomiases of man, birds, reptiles, amphibia, and fish. An account is also presented of the tsetse flies, with an analytical table for determining these species.

Diseases due to trypanosomes, L. PANISSET (*Rev. Gén. Méd. Vét., 4 (1904), No. 47, pp. 585–604, figs. 8*).—The general distribution of trypanosomiases is discussed, with notes on the species of animals affected and an outline of the symptoms as observed in different diseases of this group. Particular attention is given to surra, nagana, and dourine. These diseases are believed to be transmitted by various biting insects, such as tsetse fly, species of Tabanus, Stomoxys, Hippobosca, etc.

The cultivation of trypanosomata, R. D. SMEDLEY (*Jour. Hyg. [Cambridge], 5 (1905), No. 1, pp. 24–47, pls. 2*).—A table is given showing the various species of trypanosomata thus far discovered, the names of the discoverers, the host affected, and the common names of the disease.

Particular attention is given by the author to the cultivation of *Trypanosoma lewisi*, and *T. brucei*. The former was cultivated for 9 generations during a period of 9 months without apparent change, while the latter was cultivated through 3 generations for a period slightly exceeding 80 days. From a study of well-stained preparations of the rat trypanosomata it was found that the cultural forms differ considerably from those of the adult parasite found in the blood.

Hemorrhagic septicemiæ of domesticated animals, J. TAUFER (*Fortschr. Vet. Hyg., 2 (1904), Nos. 7, pp. 188–204; 8, pp 209–220; 9, pp. 240–251, figs. 3*).—The author presents a general system of classification for diseases caused by ovoid bacteria and belonging to the group of pasteurelloses. This group of diseases affects fowls, rabbits, dogs, cats, hogs, sheep, goats, cattle, horses, and buffalo.

The more important diseases of this group are hemorrhagic septicemia of cattle, fowl cholera, buffalo plague, swine plague, and hog cholera. These diseases may occur in various forms but possess certain striking features of resemblance. As a result of the author's observations of various forms of septicemia and experiments with the organisms which cause these diseases it was concluded that hemorrhagic septicemia of cattle sometimes occurs in an epizootic form in Germany and is due to an ovoid bacterium.

The organism of this disease must be classified with the group of pasteurella according to its morphological and biological characters. The pasteurella of the disease resembles in its virulence that of hog cholera and fowl cholera. All of these organisms are believed to be closely related. The organism of hemorrhagic septicemia of

cattle in the author's experiments produced no toxins in nutrient media. It was found to be pathogenic for all domesticated mammals. The organism apparently was unable to pass through the uninjured mucous membrane of the alimentary tract of rabbits. Animals which possess an active immunity toward fowl cholera are also immune toward hemorrhagic septicemia of cattle.

Experiments with Spengler's formalin method for making pure cultures of tubercle bacilli from bacterial mixtures, A. DWORETZKY (*Centbl. Bakt.* [*etc.*], *1. Abt.*, *Orig.*, *37* (*1904*), *No. 4*, *pp. 626-631*).—Spengler proposed a method for isolating tubercle bacilli from bacterial mixtures by the addition of small quantities of formalin, which was supposed to destroy all other organisms except the tubercle bacillus. This method was given a thorough test by the author, but in all cases negative results were obtained. Whenever a sufficient quantity of formalin was used to destroy the other organisms in the mixture the tubercle bacilli were also killed.

Histological diagnosis of experimental tuberculosis in domestic mammals, S. ARLOING and J. PAVIOT (*Jour. Méd. Vét. et Zootech.*, *55* (*1904*), *May*, *pp. 257-274*, *figs. 6*).—The literature relating to this subject is critically reviewed.

The authors studied this problem from various points of view, giving particular attention to the histological lesions. As a result of these studies it is concluded that the duality of human and bovine tuberculosis can not be sustained. The disease appears in various animal species under a typical form so far as the histological lesions are concerned. In general the pulmonary lesions are more characteristic of the disease than those which occur in other parts of the body. Exceptionally, however, the pulmonary lesions may be absent. In such cases it is necessary to examine other viscera before reaching a diagnosis concerning the disease. Human and bovine tuberculosis are considered forms of one and the same disease.

The influence of splenectomy on the course of infection with tubercle bacilli in homogeneous cultures, F. ARLOING (*Compt. Rend. Soc. Biol.* [*Paris*], *57* (*1904*), *No. 35*, *pp. 524, 525*).—The author studied lesions of tuberculosis produced by intravenous injection of virulent tubercle bacilli with especial reference to the influence of the spleen in this infection.

Small experimental animals were then used in inoculation tests, during which the spleen was removed. It was found that the removal of the spleen favors extension and the rapidity of the development of tuberculous lesions in various organs. When the spleen was removed before inoculation the development of the tubercles was more pronounced than when this operation was performed after inoculation. The facts observed during this study indicate that the spleen plays an important rôle in protecting the organism against infection with tubercle bacilli.

The behavior of native Japanese cattle toward tuberculosis, S. KITASATO (*Ztschr. Hyg. u. Infectionskrank.*, *48* (*1904*), *No. 3*, *pp. 471-484*, *figs. 2*).—It is a well-known fact that native Japanese cattle, under natural conditions, are free from tuberculosis, while cattle imported into Japan appear to be highly susceptible. The author made a number of tests for the purpose of determining whether the native cattle possess any true immunity to tuberculosis.

Extensive statistics are presented regarding the extent of tuberculosis among men in Japan, and the mortality in this disease as compared with the sanitary condition of cattle in different parts of the island. No tuberculosis among native cattle was found even in localities where human tuberculosis prevailed greatly. Experiments were made during which native cattle were inoculated with virulent tubercle bacilli of bovine and human origin. In these experiments, 52 native cattle and 19 cattle of mixed race were used.

It was found as a result of the experiments and observations that human tuberculosis is as prevalent in Japan as in Europe and America. The occurrence of primary intestinal tuberculosis is about the same in adults and children. There are large areas, however, where, in spite of the frequent occurrence of human tuberculosis,

cattle are entirely free from the disease. In such localities neither the milk nor meat of cattle serve as human food. Under natural conditions, therefore, it appears that human tuberculosis is not dangerous for cattle.

The native Japanese cattle appear to be almost entirely insusceptible to tuberculosis. If large doses of pure cultures are inoculated by the intravenous or intraperitoneal methods, native cattle may become infected to a certain extent. They are not susceptible, however, to hypodermic inoculation. It is concluded, therefore, that human tuberculosis is not transmissible to native cattle or cattle of mixed races.

The bacterial flora of softened tubercles in cattle, K. OESTERN (*Centbl. Bakt. [etc.], 1. Abt., Orig., 37 (1904), Nos. 2, pp. 178–185; 3, pp. 334–344; 4, pp. 498–513*).—The literature relating to pyogenic bacteria in cattle is critically reviewed.

Detailed notes are presented on a number of cases of tuberculosis in cattle in which the tubercles were studied with especial reference to the pyogenic bacteria in association with the tubercle bacilli. The pyogenic bacteria were found to be largely staphylococci of a white, yellowish, or orange color. The staphylococci when tested in inoculation experiments on guinea pigs, rabbits, and mice were all found to possess about the same pathogenic properties. When inoculated hypodermically they produced an abscess at the point of inoculation in which staphylococci were found in pure cultures. Later the abscess healed. In white mice, death was produced after 2 or 3 days after hypodermic inoculation.

Numerous inoculation experiments were made with the tubercle bacilli found in softened tubercles. As a result of the author's study it was concluded that virulent tubercle bacilli are regularly present in softened tubercles in cattle. The organisms associated with the tubercle bacilli in such structures are, for the most part, white and yellow staphylococci. The latter organisms in cattle are not to be distinguished either by their morphological or biological characters from staphylococci in man.

Tuberculosis of the upper jawbone in cattle, LIÉNAUX (*Ann. Méd. Vét., 54 (1905), No. 1, pp. 1–7*).—Brief notes are given on the appearance of tuberculosis in the bones, especially in the superior maxillary bone. A description is given for the purpose of differentiating between tuberculosis and actinomycosis of this bone, with detailed notes on a case which came under the author's observation.

Tuberculosis among veal calves, E. CÉSARI (*Rev. Gén. Méd. Vét., 4 (1904), No. 44, pp. 393–402*).—Tables are presented showing the number of calves slaughtered in France from 1899 to 1903, and the number found to be tuberculous during this period. Statistical data are also presented regarding the relative frequency of tuberculosis in different organs and parts of the body. In 12 cases the author determined the presence of tuberculous lesions in the intestinal mucous membranes. A general discussion is given of the significance of lesions in the mesenteric ganglia, peritoneum, liver, spleen, lungs, pleura, heart, and bones.

Tuberculosis of cold-blooded animals, E. KÜSTER (*München. Med. Wchnschr., 52 (1905), No. 2, pp. 57–59*).—The study of tuberculosis among cold-blooded animals is important, not only on account of the desirability of determining the relationship between tubercle bacilli of different origin, but also from a practical standpoint. The practical value of the knowledge of tuberculosis in cold-blooded animals is apparent from the fact that tubercle bacilli from such sources may be used for conferring immunity in domestic animals.

During the author's study of frogs, it was found that 1½ per cent of these animals are affected with tuberculosis. The most conspicuous alterations due to the disease are observed in the liver. Numerous inoculation experiments were carried out with pure cultures of bacilli obtained from frogs. During these experiments frogs, salamanders, lizards, crayfish, turtles, snakes, carp, and barbel, as well as guinea pigs, rabbits, rats, and mice, were inoculated.

It was found that all cold-blooded animals were susceptible to the action of these bacilli. Some of the warm-blooded experimental animals were killed by inoculation

without, however, showing a typical bacterial infection. Frogs, lizards, and turtles were most susceptible to the disease. When rabbits are inoculated with tubercle bacilli obtained from frogs, small tubercles develop in the body cavity within a period of 6 weeks, and these structures closely resemble those of tuberculosis.

The resistance to bovine tubercle bacilli of two cattle in Marburg which had been treated with tubercle bacilli of different origin, A. EBER (*Berlin. Tierärztl. Wchnschr., 1904, No. 53, pp. 888-891*).—A historical statement is made regarding 2 young cattle which were immunized against bovine tuberculosis. One of the animals was previously treated with intravenous injections of bovine tubercle bacilli which had been attenuated by the addition of iodin trichlorid. The other animal had received intravenous injections of greatly attenuated human tubercle bacilli.

It was found during the experiments which were made on these animals that the intravenous injection of 0.05 gm. of moderately virulent tuberculous virus of bovine origin caused a temporary loss of weight, slight fever after 40 days, a cough, and tuberculin reaction. Subcutaneous injection of 0.5 gm. of similar material in nonimmunized cattle caused the appearance of tuberculous infiltration at the point of inoculation. The 2 immunized cattle, however, withstood subcutaneous injection without any reaction.

Subcutaneous injection of 1 gm. of moderately virulent tuberculous virus of bovine origin caused a large tuberculous infiltration at the point of inoculation, swelling of the corresponding lymph glands, and an elevation of temperature. Experiments were also carried out during which 2 gm of the material were used in inoculating immunized and nonimmunized animals. From this set of experiments it appears that animals which have been treated by the von Behring method are more resistant to artificial infection than untreated animals The resistance is not absolute.

It was found in these experiments that the tuberculin test in case of animals immunized against tuberculosis is not a reliable criterion for determining the presence of tuberculous lesions. The author believes, however, that it is possible to produce considerable resisting power toward tuberculosis by previous treatment with attenuated tubercle bacilli of bovine or human origin.

Antituberculous vaccination according to von Behring, J. B. SCHOFFIÉ (*Rev. Gén. Méd. Vét., 4 (1904), No. 48, pp. 649-655*).—Brief notes are given on the results of experiments by different authors with von Behring's method of vaccination against tuberculosis.

From this discussion and from the author's experiments, it is concluded that young cattle may be successfully vaccinated against tuberculosis by different methods, particularly by the use of intravenous injections of human tubercle bacilli. The practical value of this method can not be established upon a firm basis until results of experiments now in progress in different countries are known. Von Behring's method is considered to be harmless for young animals, but various suggestions are made regarding the improvement of the method.

The transmission of animal tuberculosis to man by means of milk and prophylactic measures, VALLÉE and VILLEJEAN (*Rev. Gén. Méd. Vét., 4 (1904), No. 46, pp. 521-535*).—The authors believe that it has been definitely established that the milk of tuberculous cattle is a dangerous food for man. It remains, therefore, to determine the extent of danger from the ingestion of milk which contains tubercle bacilli.

From the authors' experiments along this line it appears that while bovine tuberculosis is transmissible to man, and the milk of all tuberculous cattle may be virulent, that which comes from cases of mammary tuberculosis is especially so. The only satisfactory method of preventing such transmission through the milk is found in the compulsory pasteurization, boiling, or sterilizing all milk from herds of cattle where tuberculosis has been detected and where the tuberculin test has been given.

The relation between human and animal tuberculosis, DAMMANN (*Deut. Tierärztl. Wchnschr., 12 (1904), No. 53, pp. 541–545*).—Attention is called to the results recently announced by the German Imperial Commission on the investigation of tuberculosis.

The author has been carrying on experiments along this line for a number of years and has found that there are races of human tubercle bacilli which are capable of producing general and fatal tuberculosis in calves and hogs within a comparatively short time. Detailed notes are given on the number of inoculation experiments with such material and on the post-mortem examination of the experimental animals. Material was obtained from a human case of peritoneal tuberculosis, and when inoculated subcutaneously into hogs produced striking cases of pulmonary tuberculosis. The experimental animals died within from 28 to 42 days.

Combating bovine tuberculosis on the basis of the unity of this disease, MOREY (*Rev. Gén. Méd. Vét., 3 (1904), No. 35, pp. 577–592*).—An obligatory system of prevention is recommended, based on the application of the tuberculin test to all cattle in affected herds. The value of the tuberculin test is discussed in connection with a general argument of the necessity of controlling tuberculosis, both from a standpoint of animal production and human health.

Heart water in cattle, F. A. VERNEY (*Natal Agr. Jour. and Min. Rec., 7 (1904), No. 11, pp. 1009–1013, pl. 1*).—Several outbreaks of this disease were observed by the author. The blood from diseased animals when inoculated into healthy animals produces symptoms of the disease after an incubation period of from 5 to 15 days. The micro-organism, which is the cause of this disease, has not been isolated, but experiments have shown that it must be transmitted by the bont tick (*Amblyomma hebræum*).

Rinderpest and the action of Koch's method of bile inoculation, HAEDICKE (*Berlin. Tierärztl. Wchnschr., 1904, No. 50, pp. 823–828*).—A brief historic statement is made concerning the distribution of rinderpest and the losses caused by this disease. Notes are also given on the symptoms and pathology of rinderpest.

The author carried on a number of experiments according to the method of vaccination by means of bile. It is concluded as a result of these studies and observations that rinderpest is enzootic in China, Korea, and Japan. The disease is transmitted by contact. In regions affected with rinderpest, morning temperatures of 38.9° C. or higher, as well as temperatures under 37.1° C., are to be considered as suspicious.

A passive immunity is produced by the use of 10 cc. of bile by the hypodermic method. Such a vaccination influences the course of subsequent infection so that in 66 per cent of the cases the acute form of the disease does not appear, while in the remaining 24 per cent the course of the disease is shortened and much modified. The mortality after such treatment was about 10 per cent.

The immunizing action of the bile of cattle affected with rinderpest, C. ADANI (*Clin. Vet. [Milan], 27 (1904), No. 48, pp. 285–290*).—In order to bring about immunity by the use of bile it is recommended that subcutaneous injections be administered in doses of 10 cc. For this purpose the bile should be collected under antiseptic conditions.

Not all qualities of bile are adapted for use in producing immunity. No blood should be mixed with the bile, since in such cases the active principle of the bile seems to be destroyed. Bile may be desiccated and may thus continue to show an immunizing property for 50 to 80 days. When bile from cattle affected with rinderpest is heated to a temperature of 60° C. it loses its immunizing property entirely.

The Molteno cattle disease, W. H. CHASE (*Agr. Jour. Cape Good Hope, 25 (1904), No. 6, pp. 675–678*).—The symptoms of this disease are briefly described.

As a rule, affected animals are noticed to be sick only 3 or 4 days before death. When examined post-mortem, animals show a pronounced chronic cirrhosis of the liver and this is the most conspicuous lesion of the disease. Inoculation experiments

were tried during which it was shown that the blood and stomach contents of diseased animals were not pathogenic for healthy cattle.

Feeding experiments with *Senecio burchellii* demonstrated that this plant is capable of producing pronounced diarrhea together with the characteristic cirrhosis of the liver. The disease in question, therefore, closely resembles the disease produced in New Zealand and Canada by eating *S. jacobœa.*

The use of serum in the practical treatment of anthrax, A. Carini (*Schweiz. Arch. Tierheilk, 46 (1904), No. 6, pp. 296–304*).—Detailed notes are given on 9 cases in which antianthrax serum was used.

As a result of the author's experience it is concluded that serum therapy may be successfully used in veterinary practice and should be the first choice as a treatment in incipient cases. It may be used in large and repeated doses (150–200 cc. in all). Ten cubic centimeters of the serum is not sufficient to produce a certain immunity in cattle against anthrax. It is better to employ at least as much as 20 cc.

The immunization of sheep for tho purpose of obtaining a polyvalent serum against anthrax and blackleg, V. Galtier (*Jour. Méd. Vét. et Zootech., 55 (1904), Dec., pp. 705–710*).—In the author's experiments, 2 sheep were hyperimmunized by means of repeated inoculations of anthrax and blackleg cultures.

The first inoculations were with anthrax cultures attenuated by means of Lugol's solution. Later, more virulent cultures were given in increasing doses, followed by blackleg cultures and lastly with mixtures of anthrax and blackleg cultures. In all 26 inoculations were given. It was found that the sheep after having received these inoculations at intervals of from 2 to 3 weeks were still in good health.

The serum obtained from these animals was found to be polyvalent. When injected into rabbits and guinea pigs it protected them against an anthrax inoculation 24 hours later and against blackleg inoculation made after a lapse of a similar period.

Disinfection of animals in preventing foot-and-mouth disease, Blume (*Berlin. Tierärztl. Wchnschr., 1904, No. 52, pp. 874, 875*).—The author has found that the hair and skin of living animals may be thoroughly disinfected by the application of a solution of lysoform soap. This material has no injurious effect upon the animal and is, therefore, to be preferred to corrosive sublimate and similar drugs. The hoofs of animals which have been exposed to infection required more thorough treatment than the general integument.

A process of disinfection in the prevention of foot-and-mouth disease should be applied to animals which are affected with the disease, animals which have been directly exposed in stalls or pastures, animals which come from localities in which the disease prevails, and animals which have recently been transported in cars or ships where infection may have existed.

The treatment of milk fever with air and iodid of potash, F. thor Straten (*Maanedskr. Dyrlæger, 16 (1904), No. 6, pp. 165–167*).—During the past 2½ years the author has treated 96 cases of milk fever, of which 72 received iodid of potash, while 24 were treated with air. Of the cases treated with iodid of potash, 6 died, while among the 24 treated with air only 1 case resulted fatally and that was due to improper care.

Necrotic stomatitis, with special reference to its occurrence in calves (calf diphtheria) and pigs (sore mouth), J. R. Mohler and G. B. Morse (*U. S. Dept. Agr., Bur. Anim. Indus. Bul. 67, pp. 48, pls. 5*).—In this country the disease affects calves and young pigs. In calves it has been known as calf diphtheria, but this is a misnomer.

The literature of the subject is discussed in connection with a bibliography, and notes on the distribution, etiology, and pathological anatomy of the disease. Necrotic stomatitis is due to *Bacillus necrophorus* and is an acute contagious inflammation of the mouth characterized by ulcers and necrotic patches. The disease occurs most

frequently in connection with the eruption of the first teeth. The course of the disease is from 5 days to 5 weeks, and untreated animals die in a large percentage of cases.

In treating the disease all affected animals should be isolated, the mouths of exposed calves and pigs should be washed with an antiseptic, and stalls and premises should be disinfected. The mouth and other affected surfaces should be carefully cleansed and disinfected twice daily with a 2 per cent solution of creolin in warm water. Good results may be obtained also from the use of a 1 per cent solution of carbolic acid. Lugol's solution and potassium permanganate also act in an efficient manner.

Bacillus necrophorus has a wide distribution in nature and causes a great variety of lesions in different animals.

Sheep parasite in Australia, F. W. Goding (*Mo. Consular Rpts.* [*U. S.*], *No. 290, pp. 93, 94*).—The sheep maggot fly has gradually been becoming a most serious pest in Australia for the past 10 years. It attacks chiefly breeding ewes and lambs. In destroying these pests most ranchmen use a lime and sulphur dip. Attention has been called to the fact that in Scotland carbolic washes for this purpose have been discarded. Sulphur and oil has been used more extensively, arsenic being added in cases where there are no skin lesions.

The etiology of hog cholera, M. Dorset, B. M. Bolton, and C. N. McBryde (*U. S. Dept. Agr., Bur. Anim. Indus. Bul. 72, pp. 101, pls. 3*).—The Bureau of Animal Industry of this Department has, for many years, been investigating the infectious diseases of swine and methods of producing immunity against these diseases.

The discovery of the hog cholera bacillus in 1885 was considered as a great step in advance in the investigation of hog cholera. The bacillus was at first thought to be the bacterial cause of hog cholera. Recent experiments, however, summarized in the bulletin under discussion indicate that while the hog cholera bacillus is a pathogenic organism capable of causing death in hogs when inoculated intravenously and generally fatal when taken into the alimentary tract, it is nevertheless not the prime cause of the disease. *Bacillus choleræ suis* is found in most cases of spontaneous hog cholera and is very fatal to rabbits and guinea pigs by intravenous or subcutaneous inoculation.

A preliminary announcement of the discovery of the infectiousness of blood serum free from hog cholera bacillus but obtained from an animal suffering from the disease was made in 1903, and the announcement was supplemented by another circular issued by the Bureau of Animal Industry in 1904. The results of the experiments carried out by the authors and Doctor de Schweinitz show that pure cultures of hog cholera bacillus when injected into hogs subcutaneously produce as a rule only slight disturbances. The lesions thus caused may resemble those seen in acute cases of hog cholera, but the disease does not produce the general characteristics of contagiousness.

The most striking facts in connection with these experiments, however, is that hogs which recover from such infection are not immune when subsequently exposed to natural infection. The experiments have shown conclusively that blood serum from hogs affected with hog cholera and known to be free from *Bacillus choleræ suis* produces disease in hogs regularly after subcutaneous injection, and also "that the disease thus produced possesses all of the characteristics of the natural disease, including symptoms, lesions, contagiousness, infectiousness of the blood, and immunity in those animals which recover."

All attempts to isolate the micro-organisms from the filtrates with which the authors experimented were without result. The pathogenic property of the filtered blood, however, is certainly due to the presence of a micro-organism since the disease is produced by the filtered serum and may be transferred to other animals by subcutaneous injections. The hog cholera bacillus was also present almost uniformly in all

cases of the disease studied by the authors. The exact rôle played by this organism, however, is not definitely known.

It appears to be necessary to assume that hogs are subject to a disease caused by the hog cholera bacillus and having no connection with that produced by the filterable virus found in the outbreaks of the hog disease under discussion. Whatever may be the influences which lead to an invasion of healthy hogs by the hog cholera bacillus the authors believe that the filterable virus investigated by them is the direct cause of the high degree of infectiousness characteristic of the disease which was studied.

The virulence of cultures of bacilli of swine erysipelas after the addition of serum or grape sugar, P. Gordan (*Berlin. Tierärztl. Wchnschr., 1904, No. 53, pp. 891, 892*).—A considerable series of culture experiments along this line were carried out by the author. It was not possible to immunize mice against swine erysipelas by inoculation with erysipelas bacilli to which grape sugar had been added. By the addition of 0.1 per cent sheep-blood serum to the nutrient bouillon it was possible to increase the reproductive power of the bacilli. It was noticed that even after 6 weeks such cultures had not lost their virulence as they usually do in ordinary media.

Combating fowl cholera and swine plague, Klett and Braun (*Deut. Tierärztl. Wchnschr., 12 (1904), Nos. 51, pp. 517–521; 52, pp. 529–532; 53, pp. 545–547*).—In the opinion of the authors the toxins in filtrates and the endotoxins of *Bacillus avisepticus* and *B. suisepticus* are identical. The former produces more toxin than the latter. The toxicity of the toxins from both organisms appears to be independent of the virulence.

For the purpose of producing a preventive serum against swine plague, horses were treated, for long periods, with dead cultures and with filtrates. The serum thus obtained was both bactericidal and antitoxic. The passive immunity produced by treatment of gray mice with this serum lasted for 3 or 4 weeks. It was not determined whether an active immunity could be brought about by this serum. Brief notes are also given on hog cholera.

Bacterial pyelonephritis in hogs, E. Wyssmann (*Schweiz. Arch. Tierheilk., 46 (1904), No. 6, pp. 287–290*).—The symptoms and etiology of this disease are briefly discussed. In some cases studied by the author it is believed that the disease was due to a mixed infection which occurred at the time of birth. The lesions caused during the development of this disease are briefly described.

The external parasites of hogs, E. C. Stevenson (*U. S. Dept. Agr., Bur. Anim. Indus. Bul. 69, pp. 44, figs. 29*).—The most important external parasites of the hog are *Hæmatopinus suis*, *Sarcoptes scabiei suis*, and the mite which causes follicular mange. The last named parasite, however, seemed to be of little economic importance.

A historic review is given of the appearance, synonymy, and classification of *H. suis*. This parasite lives on domesticated and wild hogs, but is not known to live as a parasite on any other animal. The insect is described in detail in all of its stages. The eggs are deposited largely on the hair back of the ears and along the shoulders and flanks. The period of incubation appears to be 15 or 16 days at a temperature of 85° F. The parasites cause an irritation of the skin with the formation of scales and inflammation. Certain authors believe that hog lice may carry the infection of hog cholera.

In combating this pest the pens of infested hogs should be thoroughly treated. If they are kept vacant for 2 weeks or more the lice seem to perish. Various remedies have been suggested for the treatment of infested buildings, but whitewash made in the proportion of 1½ lbs. of lime to 1 gal. of water is probably the most convenient method. Experiments with remedies applied directly to hogs, such as kerosene emulsion, kerosene and water, pure kerosene, and benzine emulsion are successful,

cheap, easily prepared, and readily applied. Directions are given for the preparation of the more important of these remedies.

Sarcoptic mange of hogs is described with notes on the symptoms and methods of contagion. In severe cases it ultimately causes the death of young pigs. Dipping combined with scrubbing is the only practical method of eradicating this disease. A second dipping should follow 6 days after the first treatment. Notes are also given on infestation with *Demodex phylloides*, and detailed directions are presented for the preparation of suitable vats and other apparatus to be used in dipping hogs. A bibliography of the subject is appended to the bulletin.

An infectious disease of horses with alterations in the bones, CHARON and THIROUX (*Rec. Méd. Vét., 81 (1904), No. 23, pp. 737–759, figs. 2*).—In Madagascar a certain percentage of horses and mules are affected with a specific disease accompanied with changes in the bone tissue. The symptoms include general debility, uncertain gait, redness of the conjunctiva, occasional hemoglobinuria, etc. Detailed notes are given on the bone affections which accompany the disease. In blood preparations the author found specimens of *Piroplasma equi*. Detailed notes are given on a number of cases of this disease.

Immunization against horse sickness by the method recommended by Professor Koch, C. E. GRAY (*Jour. Compar. Path. and Ther., 17 (1904), No. 4, pp. 344–351*).—A number of experiments in the treatment of this disease were begun by Koch during his sojourn in Bulawayo. These experiments were continued by the author and his associates.

It has been found that unless the process of repeated inoculation is extended over a very long period and unless the doses of virulent blood are increased more gradually than recommended by Koch a point is reached at which the natural resistance of the animal is overcome and an attack of horse sickness occurs.

Apparently no real or lasting immunity is established even after the animal has withstood inoculation with a dose of 5 cc. of virus. Among the 20 horses, the treatment of which was begun by Koch and finished by the veterinary service of Rhodesia, 12 subsequently reacted and died of horse sickness.

Fowl plague, G. MARCONE (*Rev. Gén. Méd. Vét., 3 (1904), Nos. 32, pp. 409–423; 33, pp. 465–481*).—Attention is called to the fact that this disease affects not only the ordinary domestic fowls, but pheasants and a number of wild birds.

Notes are given on outbreaks of the disease. The various forms under which it occurs are described and a brief account is presented of its pathological anatomy. Various micro-organisms have been suspected of causing this disease, but thus far no investigator has been able to demonstrate to a certainty the pathogenic organism. The virus maintains its virulence under ordinary conditions for from 21 to 90 days, depending on the temperature. Chickens are most susceptible, but ducks, geese, and other domestic birds may also be affected. Particular attention is given to a study of this disease among pheasants.

Fowl plague has been particularly destructive to pheasants in the neighborhood of Naples. The spread of the disease among pheasants in parks is believed not to be due to wild birds, but to stray domestic fowls.

Vaccination against fowl cholera by means of toxins, C. BISANTI (*Rev. Gén. Méd. Vét., 4 (1904), No. 45, pp. 457–460*).—According to the author's experiments it is possible to produce immunity against fowl cholera in susceptible animals by means of cultures in vivo in collodion sacs. The presence of cultures in the peritoneum, as interchanges between them and the living organism are very active, confers more lasting immunity than can be obtained by hypodermic vaccination.

Serum inoculation for fowl cholera, T. KITT (*Monatsh. Prakt. Tierheilk., 16 (1904), No. 1, pp. 1–19*).—It was found possible by repeated subcutaneous inoculations with cultures of *Bacillus avisepticus* in horses to obtain a serum which, in doses

of 2 to 5 cc., would protect rabbits, geese, ducks, chickens, and even pigeons against large subcutaneous injections with virulent blood.

These experiments were repeated on a number of horses, and in some cases it was found possible to obtain an exceedingly active serum within a very short time. In all these experiments the control animals died within 12 to 48 hours, while the treated animals were unaffected by virulent cultures. This treatment is considered, therefore, as conferring a passive immunity. The duration of such immunity appears to be about 18 days. Experiments with female hares showed that the immunity produced in this manner may be transmitted from the mother to the offspring.

RURAL ENGINEERING.

Irrigation in Canada (*Jour. Soc. Arts, 53 (1905), No. 2740, pp. 745-747*).—A description of irrigation works and the possibilities of irrigation in the semi-arid region of the South Saskatchewan Valley, 10,000,000 acres of which are estimated to be irrigable. The international complications between the United States and Canada regarding the water supply for irrigation on the two sides of the boundary line are briefly referred to.

Irrigation in the United States, ZIMMERMANN (*Mitt. Deut. Landw. Gesell., 20 (1905), No. 22, pp. 145-150*).—A brief account showing the extent and development of irrigation in this country, and referring to the work of this Department in aid of irrigation.

The irrigation project of the Canadian Pacific Railway (*Engin. News, 53 (1905), No. 17, pp. 429-431, figs. 8*).—A system of canals taking water from Bow River to ultimately irrigate over 1,000,000 acres of land near Calgary is described.

Irrigation in Klamath County, F. L. KENT (*Oregon Sta. Bul. 86, pp. 16, figs. 3*).—This is an account of experiments made in cooperation with this Office to determine losses by seepage and evaporation, the duty of water under different conditions, and the cost of applying water in irrigation. The results and conclusions reached are summarized as follows:

"(1) In the soils of the region considered the losses by seepage and evaporation are comparatively small, ranging between 10.24 per cent and 13.5 per cent in the three cases observed on main ditches.

"(2) The percentage losses in laterals may be considerably greater than in the main ditches.

"(3) The duty of water was rather high, a depth of only 4.92 to 6.27 in. being required to produce the desired moisture conditions for the second irrigation of alfalfa fields.

"(4) The cost of applying water to checked fields, after the land is properly fitted, is less than one-half the cost of application in free flooding.

"(5) During the height of the growing season the evaporation from a water surface may amount to a depth of 11 in. in 31 days.

"(6) Chemical analyses show the waters of this region to be very desirable for irrigation purposes.

"(7) While two irrigations are commonly given alfalfa fields each season, there is a growing tendency toward the use of three."

Water problems of Santa Barbara, California, J. B. LIPPINCOTT (*U. S. Geol. Survey, Water-Supply and Irrig. Paper No. 116, pp. 99, pls. 8, figs. 17*).—This bulletin describes the location and drainage of this district, reviews earlier work by others, and summarizes data relating to the sources of water supply of the city and suburbs of Santa Barbara.

The use of irrigation for different crops, E. J. WICKSON (*For California, 2 (1905), No. 8, pp. 5, 6*).—General information applicable especially to California conditions.

Geology and water resources of a portion of east-central Washington, F. C. CALKINS (*U. S. Geol. Survey, Water-Supply and Irrig. Paper No. 118, pp. 96, pls. 4, figs. 14*).—This paper reports studies of the topography, climate, vegetation, agricultural conditions, geology, and hydrology of an area on the arid Columbia Plains, covering parts of Douglas, Lincoln, Adams, Franklin, Yakima, and Kittitas counties, a large portion of which is said to be almost without surface streams available for the uses of mankind.

"Surface wells capable of supplying perennially even the modest requirements of domestic use can be sunk only in places where conditions are locally favorable. Springs once formed the only source of water for a large area, but they are so widely scattered and often so difficult of access that great labor is sometimes involved in hauling a supply from them. Deep wells, now fairly numerous and rapidly increasing in number, are coming to be considered the most satisfactory sources of water. To determine to what extent the supply from these wells may be increased, and to find whether there is hope of obtaining artesian flows in any portion of the region, were the prime objects of the writer's expedition."

It is stated that abundant water of good quality may be found in the region at depths varying from 40 to 670 feet. Apparently the water is as a rule under pressure and therefore in a broad sense artesian. The success of deep borings for artesian water is questioned.

A general working plan for the irrigation farm of Berlin, A. BACKHAUS (*Allgemeiner Wirtschaftsplan für die Rieselgüter der Stadt Berlin. Berlin: W. & S. Loewenthal, 1905, pp. 80*).—This report discusses the scope and purpose of the Berlin sewage irrigation farm, its organization, operations, equipment, results, etc.

Agricultural experiments on the irrigation farm of Berlin during 1904, A. BACKHAUS (*Landwirtschaftliche Versuche auf den Rieselgütern der Stadt Berlin in Jahre 1904. Berlin: Paul Parey, 1905, pp. 122, figs. 11*).—Plat experiments with a great variety of garden and field crops and forage plants are reported. Pot experiments with sewage sludge and sludge ash and experiments in composting sludge are also reported.

The experiments include tests of varieties, amounts and methods of application of the sewage, fertilizers, methods of soil preparation and culture, tests of special forms of cultural implements (plows, mowing machines, etc.), methods of curing crops, control of weeds and plant diseases, etc., as well as studies of soils and drainage waters.

The experiments were seriously interfered with by drought, but the results obtained indicate a number of ways in which improvements may be made, among which are (1) occasional liming to improve the physical condition of the soil; (2) so arranging the irrigation as to protect against drought; (3) shallow culture in spring and deep culture in summer and fall; (4) avoiding excessive accumulations of sludge on the soil; and (5) raising fish in the drainage water.

Measuring the flow in underground streams (*Irrig. Age, 20 (1905), No. 8, p. 233, figs. 2*).—A brief description of Slichter's method.

River surveys and profiles made during 1903, W. C. HALL and J. C. HOYT (*U. S. Geol. Survey, Water-Supply and Irrig. Paper No. 115, pp. 115, pls. 4, figs. 18*).—This paper contains the results of cooperative river surveys carried on during 1903 between the topographic and hydrographic branches of the Geological Survey. It presents data of special interest to engineers and others interested in power development.

Relation of the law to underground waters, D. W. JOHNSON (*U. S. Geol. Survey, Water-Supply and Irrig. Paper No. 122, pp. 55*).—In this paper an attempt is made to outline the main features of the laws respecting underground waters, with the object of giving to the owner of such waters some idea of his rights and obligations concerning them.

"It is needless to say that the report is in no sense a legal treatise, but rather an endeavor to collect and arrange such legal decisions as will serve to show the relation of the law to problems which are essentially geological in character. In summing up the general features of this law, I have recorded some observations which present themselves to the student of geology." The paper is divided into 2 chapters: (1) common law rules concerning underground waters, and (2) legislative acts affecting underground waters.

Bibliograghic review and index of papers relating to underground waters published by the United States Geological Survey, 1879–1904, M. L. FULLER (*U. S. Geol. Survey, Water-Supply and Irrig. Paper No. 120, pp. 128*).

The lignite of North Dakota and its relation to irrigation, F. A. WILDER (*U. S. Geol. Survey, Water-Supply and Irrig. Paper No. 117, pp. 59, pls. 8, figs. 5*).—"The investigation on which this report was based was carried on under the charge of Mr. N. H. Darton as a part of the general investigation of the underground-water resources of the western portion of the United States."

Index to the hydrographic progress reports of the United States Geological Survey, 1888 to 1903, J. C. HOYT and B. D. WOOD (*U. S. Geol. Survey, Water-Supply and Irrig. Paper No. 119, pp. 253*).

Contributions to the study of drainage, E. RISLER and G. WERY (*Ann. Inst. Nat. Agron., 2. ser., 4 (1905), No. 1, pp. 5–23, dgms. 4*).—The interrelations of precipitation, temperature, evaporation, and drainage are discussed, with detailed data of observations on this subject.

Tile drainage, F. W. TAYLOR (*New Hampshire Sta. Bul. 118, pp. 19–48, figs. 12*).—This bulletin describes the implements and methods used in tile drainage, as well as the classes of lands needing drainage in New Hampshire and the best methods of handling them. A drainage system put in at the New Hampshire Station is described, and a statement of cost is given. "The classes of land in New Hampshire needing drainage are (1) meadow lands, (2) gently rolling tillable lands, (3) lowlands around swamps or lakes, (4) lowlands adjacent to salt water. Thorough drainage on most lands will cost \$35 to \$40 per acre. Many lands can be greatly benefited for \$15 or \$20 per acre."

Notes regarding sewage disposal at Paris and Berlin (*Engin. News, 53 (1905), No. 11, p. 285*).—A brief review is given of the annual reports of the operation of the sewers and sewage disposal systems of Paris and Berlin for the year 1903. It is noted that in neither city at the present time is any untreated sewage discharged into the streams. At Paris the greater part of the irrigated land is under private ownership, taking sewage by agreement, and in general in such quantities as are required by the crops. At Berlin the whole irrigated area is owned by the city. The following comparative data are taken from the reports:

Statistics of sewage disposal in Paris and Berlin.

	Paris.	Berlin.
Population by last census	2,714,068	1,956,010
Drinking water supply, gallons per capita daily	32	21
Unfiltered river water (not used for domestic purposes)	62	....
Total water supply, gallons per capita daily	94	21
Sewage pumped, gallons per capita daily	59	32
Area actually under irrigation, in acres	13,100	17,500
Average quantity of sewage applied, gallons per acre daily	12,300	3,530
Number of persons per acre	207	112

It is stated that of the whole volume of sewage applied to the land at Paris fully one-half reappears in the drains, where it is measured, sampled, and tested regularly as to the degree of purification. It is claimed that these examinations "demonstrate the perfect harmlessness of the waters after their passage through the soil."

The cost of pumping and distributing the sewage, not including interest and sinking fund charges, is $11.30 per million gallons at Paris and about $9 at Berlin. At Berlin the income from the sewage farms exceeds the cost of their operation and has done so for several years past.

Historic highways of America, A. B. HULBERT (*Cleveland, Ohio: Arthur H. Clark Co., 1905, vol. 16, pp. 188*).—An index to volumes 1 to 15.

Data on roads and pavements in Iowa (*Engin. News, 53 (1905), No. 6, pp. 143, 144, figs. 2*).—This article calls attention to a marked revival of paving in Iowa following the enactment of an amended paving law, reports traction tests on brick and asphalt pavements at Iowa State College, and gives a general survey of road conditions in the State. Attention is called especially to the State law creating the Iowa State College a highway commission, and pointing out the fact that although about $2,250,000 of road taxes are annually collected and expended upon the country roads of the State, these roads, like those of the surrounding States, are notoriously bad, especially in bad weather.

Improving the roads (*Country Gent., 70 (1905), No. 2731, pp. 509, 510*).—In this paper, which was read at the good roads conference held at Cornell University, May 17, 1905, it is considered unwise to attempt in general to bring our roads up to the European standard within a few years, or to construct a great State system of macadam or similar roads. The gradual improvement of such roads as we have is advised, reserving in all cases about four-fifths of the available funds for maintenance and repairs.

Miscellaneous implements exhibited at Park Royal, 1904, J. B. DUGDALE (*Jour. Roy. Agr. Soc. England, 65 (1904), pp. 184–211, figs. 18*).—This article describes the implements and appliances to which silver medals were given at this exhibition, besides a number of agricultural engines, dairy appliances, swath turners, plows, drills, root cleaners and graters, potato digger, horse hoe, and miscellaneous articles.

Electric plows in Italy, P. CUNEO (*Mo. Consular Rpts. [U. S.], 1905, No. 292, pp. 111, 112; Amer. Agr., 75 (1905), No. 22, pp. 615, 616, fig. 1*).—A device invented and constructed by the Italian Electrotechnical Society of Turin for applying electric power to plows and other farm machinery is described, and an account is given of successful experiments in plowing by means of electric power.

"The [plowing] device consists of two power cars, which are stationed at each side of the field and between which are stretched cables attached to the plow. The electric current is taken from a trolley line; a current of about 500 volts is said to be needed. Each car is said to communicate 25 horsepower, which can safely be increased to 40 horsepower. The plow is pulled by the cables from one side of the field to the other, and when it reaches the end of the furrow it stops automatically, the current being cut off. It can be run backward or forward with ease. One man manages the plow, and each car is operated by one man. Thus three men do all the work.

"Of course, much depends on the condition of the soil, but it is said that from 7 to 15 acres can be plowed in 12 hours. These power cars are said to be as easily managed as traction engines, and their power can be applied to thrashing machines, corn shellers, pumps, grain drills, etc."

The evolution of the plow (*Maschinen Ztg., 3 (1905), No. 1, pp. 2–4, figs. 13*).—A brief account.

Plowing with a traction engine (*Amer. Threshermann, 8 (1905), No. 1, pp. 3–7, figs. 13*).—The cost and efficiency of this method of plowing are discussed.

On peat gas motors, HUBENDICK (*Svenska Mosskulturför. Tidskr., 19 (1905), No. 1, pp. 46–54*).

RURAL ECONOMICS.

The business side of agriculture, A. G. L. ROGERS (*London: Methuen & Co., 1904, pp. 159*).—This book is a study of the economic problems of the English farmer, with especial reference to the methods of marketing farm products.

The introductory chapter deals with the farmer and his markets. The fact is especially emphasized that the English farmer is a business man, that he "seeks to make money exactly as the manufacturer does." The reasons given for the English farmers being so distinctively commercial agriculturists are that (1) they are practically all tenant farmers and invariably pay cash rent, and (2) they depend more largely upon the market for the articles of every-day consumption than do the farmers of most other countries; the bread supply, for example, is bought ready-baked. These demands for money make it necessary for the farmer to center his thought and energy upon the one problem of putting upon the market those products which will best replenish his bank account.

Chapters II and III are devoted to a discussion of the "traditional methods" of marketing the various products of the farm, including cereals, hops, fruits, vegetables, live stock and live-stock products. Special attention is given to the methods of marketing wheat in America and England. The great variety of weights and measures which still remain in use in the rural districts and the different methods of making the sales are described in considerable detail.

To the English farmer the marketing of live stock and dairy products is more important than the marketing of grain. "Barely one-seventh of the supply of wheat consumed by the nation is grown in these islands, while more than one-half of the meat eaten at home is home-bred." There are two methods commonly used in disposing of live stock. The first is by direct sale; the second by auction. Where the first method is used the custom is for the seller to seek his purchasers by advertising widely in the agricultural and other newspapers. The most common method of selling live stock, however, is by auction, and these auctions take place most commonly at the markets. "Nearly every large town has its market, some more than one, while many quite insignificant villages have their sale yards; and other places are known entirely by the great fairs held there once or more often every autumn or spring. There are about nine hundred such places in Great Britain."

The fourth, which is also the last, chapter is devoted to a discussion of "some of the schemes that have been devised in recent years by persons or organizations interested in the prosperity of the agricultural classes to assist them to dispose of their produce to better advantage." The principal organizations described are the following: The National Poultry Organization Society; the Produce Supply Association; the Agricultural Organization Society; the Irish Agricultural Organization Society; the Irish Agricultural Wholesale Society; and the Irish Beekeepers' Federation.

The influence of farm machinery on production and labor, H. W. QUAINTANCE (*Pubs. Amer. Econ. Assoc., 3. ser., 5 (1904), No. 4, pp. 1-106*).—This monograph contains a discussion of the course of agricultural production as contrasted with the increase in population. It discusses the increase in cultivated area per farm worker and the greater effectiveness of farm workers when aided by machinery, the cost of production by hand and by machine methods, the wages of labor under hand and under machine methods, the influence of machinery upon fluctuations in quantity and quality of product, upon the size of farms, the life and general welfare of the farmer, and upon the length of the working day.

Largely owing to the introduction of new forms of machinery, the area of land devoted to the crops in the production of which machinery has come to be generally used has increased from 23.3 acres in 1880 to 31 acres per male worker in 1900. The general conclusion is reached that the introduction of agricultural machinery during

the 20 years from 1880 to 1900 increased the effectiveness of human labor on the farm about one-third. The increase in the use of machinery has reduced the number of laborers per farm, increased the wages of labor, and shortened the length of the working day on the farm.

The decline of landowning farmers in England, H. C. TAYLOR (*Bul. Univ. Wis., 1904, No. 96, pp. 1-66*).—This monograph shows that more than half of the farmers of England of 200 years ago owned the land which they cultivated, but at the present time the representatives of this class are very few, so few indeed that the word "farmer" means "tenant farmer" in England.

The most important causes of decline were: (1) The introduction of new agricultural methods which made large farms more profitable than small ones; (2) the agricultural depressions which forced those who were heavily in debt to sell their land; (3) the very high price of land due to the presence of a wealthy class of merchants and manufacturers who, because of the social position which is usually attached to the ownership of landed estates in England, were often willing to pay twice as much for the land as the farmers could afford to pay; and (4) the law and custom of progeniture and entail.

The first three conditions and forces made it necessary for the farmers to part with their land, and the fourth condition kept the land locked up in large estates after the farmers had parted with it, so that even if the farmers desired to buy land at the high prices they would find few farms for sale. But as a matter of fact the farmers of England rarely think of buying land, because they find the tenant system more profitable. "The relation between landlord and tenant is very satisfactorily arranged. The farmers are as a rule contented with the present system, and the fields of England prove that landownership on the part of farmers is not essential to good agriculture."

The history of agriculture in Dane County, Wisconsin, B. H. HIBBARD (*Bul. Univ. Wis., 1904, No. 101, pp. 68-214, figs. 3*).—This is an economic study of the agriculture of Dane County, tracing the changes which have taken place in the system of farming.

The movement of settlers to Wisconsin and the character of immigrants, the selection of land, and the precaution against land grabbing are interesting subjects taken up in the introduction. A discussion of the agriculture of the earlier period is centered about the wheat production, whereas that of the later period is centered about the introduction of the dairy industry, of the tobacco industry, and of the rise and fall of the hop industry.

The main object of this monograph is to outline the economic influences which made necessary the transition from the one-crop system, with wheat as the staple, which system prevailed during the early period when a virgin soil and a distant market were the principal factors in molding the farmer's economic life, to the complex farm organization of the present time, with cheese production, butter production, and tobacco culture as locally specialized industries superimposed upon a basis of mixed farming.

The book emphasizes the fact that the welfare of the farmer is closely dependent upon industrial and commercial conditions in the larger world of which he is a part; that in this larger world changes are constantly taking place which affect the prices of the products which the farmer has to sell, and upon which his profits depend; that as a result of these changes, the lines of production which are at one time most profitable, may at another time and under changed conditions as to market relations, prove relatively unprofitable; and that the farmer must ever be alert if he would so adjust the organization of his farm to the demands of the market as to secure the largest profits.

It is shown that the conservatism which leads the farmer to adhere to obsolete customs when it is clearly to his interest to reorganize his farm operations, is one of

the reasons why the necessary economic changes cause so much loss and suffering; but the difficulties which the farmer has to meet in readjusting himself to the changed conditions are also pointed out. It often happens that the necessary reorganization is expensive and he has not the money and can not secure the credit necessary for making the change. And, again, the conditions which influence the prices of farm products are so complex that it is very difficult for the farmer to distinguish between temporary and permanent changes in the prices of his products. This was shown to be especially true in the hop industry.

The book impresses upon the mind of the reader that the farmer must not only be alert in the carrying out of the operations of the farm, but he must be a man well informed on the price-determining forces, and an habitual thinker on the problems of farm economy, if he is to secure from his land and labor the greatest possible profits.

AGRICULTURAL EDUCATION.

The first book of farming, C. L. GOODRICH (*New York: Doubleday, Page & Co., 1905, pp. 259, pl. 1, figs. 86*).—The first part of this book is devoted to the general principles underlying plant culture, including discussions on the plant and the functions of the roots, stems, leaves, and flowers. Several chapters are given on the soil, with reference to the different kinds of soil, their moisture-holding capacity, and soil temperatures, together with the consideration of soil preparation, seed planting, and cultural operations. The second part of the work considers soil fertility as affected by farm operations and farm practices, and is devoted to discussions on soil fertility and its maintenance, methods of controlling the moisture condition of the soil, cultivation and rotation of crops, and the uses and value of farm manure and commercial fertilizers.

General laws relating to agricultural and mechanical land-grant colleges (*Rpt. Comr. Education [U. S.], 1902, Chap. 1, pp. 1–90; 1903, Chap. 2, pp. 39–226*).—A compilation of the laws of the different States concerning the donation of public lands, and the establishment, maintenance, etc., of land-grant colleges.

Farm mechanics in the Nebraska School of Agriculture, J. B. DAVIDSON (*Nebr. Farmer, 37 (1905), No. 27, pp. 653, 654, fig. 1*).—In this article the author discusses the need of general instruction in farm mechanics in all college agricultural courses, and outlines some of the essentials of such instruction. He also urges the necessity of specialized courses to meet the needs of agriculture in different regions.

Prospectus of courses of instruction in poultry keeping (*Univ. Col. Reading and Col. Poultry Farm, Theale, Prospectus, 1905, pp. 26, figs. 7*).—Outlines are given of short courses in poultry keeping, which are supplemented by other courses related to this subject.

Agricultural education as a factor in developing useful men, F. H. RANKIN (*[Urbana, Ill.], 1904, pp. 15*).—An address dealing mainly with agricultural college extension and agriculture in the rural schools.

Agriculture through the laboratory and school garden, C. R. JACKSON and MRS. L. S. DAUGHERTY (*New York: Orange Judd Co., 1905, pp. 403, pl. 1, figs. 150*).—This manual and text-book of elementary agriculture for schools was prepared to meet the need for instruction in a one-year course in agriculture for teachers at the State Normal School of Kirksville, Mo. It comprises chapters on the nature and formation of soils, classification and physical properties of soils, soil moisture and preparation of the soil, the soil as related to plants, leguminous plants, principles of feeding, rotation of crops, milk and its care, propagation of plants, improvement of plants, pruning of plants, enemies of plants, and ornamentation of school and home grounds.

Suggestions for experiments in laboratory exercises and field work are liberally interspersed throughout the book, and nearly every chapter is followed by references

to literature related to the subject under consideration. There are also appended lists of general references to publications, lists of agricultural experiment stations in the United States, and of publishing houses whose books are mentioned in the reference lists, and a glossary.

County normal training classes in Michigan, P. H. KELLEY (*Mich. State Supt. Pub. Instr., County Normal Bul. 1, 1905, pp. 15*).—The act enabling the different counties to maintain normal training classes with State aid is given, together with rules and suggestions relating to the conduct of such classes The teaching of agriculture is required in these classes and the conducting of school gardens is recommended.

Agriculture in Missouri schools (*Mo. Bd. Agr. Mo. Bul., 4 (1905), No. 12, pp. 44, figs. 6*).—This bulletin includes information regarding facilities and methods for teaching agriculture in the first district normal school at Kirksville, the second district normal school at Warrensburg, the third district normal school at Cape Girardeau, the College of Agriculture of the University of Missouri at Columbia, the Columbia High School, and the Columbia Normal Academy. Some of the courses are quite fully outlined, and numerous suggestions for laboratory work are made.

Studies suitable for elementary schools, P. MAGNUS ET AL. (*Rpt. Brit. Assoc. Adv. Sci., 1904, pp. 352–360*).—This report deals mainly with nature study, which the committee regards "as the sound foundation of all scientific training."

Report of Springfield Township Schools, Clark County, Ohio, A. B. GRAHAM (*Rpt. Springfield Township Schools, Clark Co., Ohio, 1904, pp. 47, figs. 36*).—The course of study for the rural schools of the township is given in detail, together with suggestions for supplementary work in nature study and elementary agriculture.

Improvement of school buildings and grounds (*Maine Ed. Dept., 1904, pp. 52, figs. 16, dgms. 6*).—In addition to suggestions for improving the architecture of school buildings, this pamphlet includes a sketch of the school-garden movement, and offers hints for the planting of school grounds and the location and use of school gardens.

School grounds and school gardens, R. A. EMERSON (*Agriculture* [*Nebr.*], *4 (1905), No. 4, pp. 10–26, figs. 2, dgms. 2*).—Detailed suggestions for the planning, planting, and care of school grounds and school gardens are given.

A study of school gardens and elementary agriculture for the schools of Michigan (*Mich. State Supt. Pub. Instr. Bul. 10, pp. 44–57, dgm. 1*).—A brief history of the school-garden movement is given, together with an account of agricultural schools in France and Russia, and suggestions for the care, culture, and management of school gardens.

Children's gardens, D. J. CROSBY (*Amer. Civic Assoc., Dept. Children's Gard. Leaflet 1, pp. 8*).—This is a prospectus of the department of children's gardens, dealing with the educational value of school gardens and the proposed work of the department in furnishing information regarding school gardens, and in conducting an active propaganda for their extension. A bibliography of recent school-garden publications is given.

School gardens and their relation to other school work, W. A. BALDWIN (*Amer. Civic Assoc., Dept. Children's Gard. Pamphlet 2, pp. 15, figs. 6*).—Suggestions are given for correlating school-garden work with arithmetic, language, drawing, and other subjects. Additional references to school-garden publications are given.

Cornell nature study leaflets (*N. Y. Dept. Agr., Nature Study Bul. 1, pp. 607, figs. 382*).—This is a selection, with revision, from the Teachers' Leaflets, Home Nature-Study Lessons, Junior Naturalist monthlies, and other publications from the College of Agriculture of Cornell University, issued between 1896 and 1904. The volume includes 80 of these reprinted leaflets, 50 of which are grouped in part 1 under the title, Teachers' Leaflets, and 30 in part 2, under Children's Leaflets.

MISCELLANEOUS.

A popular review of the work of the experiment station, E. B. Voorhees (*New Jersey Stas. Bul. 182, pp. 42*).—In addition to summaries of the numerous lines of investigation which have been carried on at the station during the last 25 years this bulletin contains a complete list of the officers and publications of the station since its organization to the present time.

Experiment Station Work, XXVIII (*U. S. Dept. Agr., Farmers' Bul. 222, pp. 32, fig. 1*).—This number contains articles on the following subjects: Home mixing fertilizers; sweet corn in the south; Kherson oats; cowpea hay; weight of feeds; grain rations; horse feeding; classification of swine; and silage for dairy cows.

Trade with noncontiguous possessions in farm and forest products, 1901-1903 (*U. S. Dept. Agr., Bur. Statis. Bul. 33, pp. 40*).—This is a compilation of the statistics of exports and imports of farm and forest products in the trade of the United States with Alaska, Hawaii, Porto Rico, Philippine Islands, Guam, and Tutuila during the 3 years ended June 30, 1903.

Crop Reporter (*U. S. Dept. Agr., Bur. Statis. Crop Reporter, vol. 7 (1905), Nos. 1, pp. 1-8; 2, pp. 9-16*).—These contain statements of the condition of crops in the United States on May 1 and June 1, 1905, and the usual statistical information on crops in foreign countries.

Report of the bureau of agriculture for the year ended August 31, 1904, W. C. Welborn (*[Philippine] Bur. Agr. Rpt. 1904, pp. 93, pls. 11*).—This report contains brief statements regarding the work of the bureau and reviewing the agricultural situation of the islands in general.

The introduction of live stock, principally cattle, is reported and work of the Singalong or Manila and Batangas experiment stations, the Government rice farm at Murcia, the San Ramon farm at Zamboanga, and the experimental college and experiment station at Negros is briefly noted. The report further includes a discussion of seed and plant introduction and soil and fiber investigations carried on, as well as of various agricultural industries.

The crops mentioned in the report are cotton, hemp, sisal, coffee, rice, corn, castor bean, cocoanuts, abacá, cacao, sugar cane, tobacco, and various fruits, vegetables, and forage plants. Culture tests of alfalfa and clovers were, in general, not successful, while velvet beans and soy beans made a most satisfactory growth. Sorghum, teosinte, Kafir corn, and similar forage crops produced excellent yields.

Report of the department of agronomy for 1904, J. Wolfbauer (*Ztschr. Landw. Versuchsw. Oesterr., 8 (1905), No. 3, pp. 192-206*).—A general report is given on work conducted by the agricultural chemical experiment station at Vienna. The different experiments in progress are described and some of the results obtained are discussed.

Plowing and subsoiling to a depth of 27 cm. gave profitable returns as compared with plowing 15 cm. deep, but the increase in yield differed considerably with the crops grown and also on different plats. The results are considered due rather to the mechanical improvement of the soil and a better conservation of soil moisture than to a higher nitrification. A discussion is given of the process of nitrification under field conditions and those obtaining in pot experiments.

NOTES.

Arkansas University and Station.—The State legislature has made the following appropriations for the experiment station: $9,000 for an agricultural building; $5,000 for a dairy building; $11,500 for salaries of agriculturist, assistant agriculturist, horticulturist, assistant horticulturist, entomologist, veterinarian, farm foreman, and dairy and live stock husbandman; $5,000 for maintenance of agricultural, horticultural, and veterinary departments; $2,000 for student labor; and $3,000 for substations. Frank P. Hall, Fayetteville, and Dougald McMillan, Arkadelphia, have been appointed members of the governing board, vice J. C. Mitchell and C. C. Hamby, retired. J. L. Hewitt has been appointed assistant horticulturist.

Connecticut State Station.—This station is erecting a two-story laboratory, covering an area of about 1,500 sq. ft., to supplement its present laboratory, which is much overcrowded. It is expected that the building will be ready for occupancy early in 1906. I. A. Andrew resigned from the station staff July 1 to take a position on a farm. E. M. East, formerly assistant in plant breeding at the Illinois Station, has been appointed to the station staff and will devote himself to the study of selection and breeding of corn.

Connecticut Storrs College and Station.—The State legislature has appropriated $40,000 for current expenses for 2 years, $3,600 for investigations in nutrition and dairy bacteriology, and $60,000 for the erection of a brick and stone dormitory to accommodate 66 students. The enrolment in the summer school for teachers and others in nature and country life subjects was 61.

Florida University and Station.—F. M. Stearns has been appointed foreman of gardens and orchards, vice J. H. Jefferies, resigned; B. H. Bridges, assistant chemist, vice R. A. Lichtenthaeler, resigned; and A. H. Chapman, assistant in agriculture, vice S. A. Robert, resigned. Mr. Jefferies goes to the North Carolina Station and Mr. Robert into private business. C. F. Dawson, whose resignation was previously noted (E. S. R., 16, p. 1139), has been elected consulting veterinarian to the station.

Georgia College and Station.—A movement was recently inaugurated looking to the removal of the experiment station to Athens, the site of the State University and the College of Agriculture and Mechanic Arts. This effort has met with decided opposition on the part of the citizens and authorities of Spalding County and the city of Griffin, and a countermovement has been made to move the State College of Agriculture and Mechanic Arts from Athens to Griffin, to be operated in close connection with the experiment station and entirely divorced from the university. Bills have been introduced and are now pending in the general assembly of Georgia looking to the accomplishment of these ends. The title of the dairy department of the station has been changed to that of department of animal industry, C. L. Willoughby remaining in charge. The work of this department will be extended to include experiments in feeding steers, and a barn for this purpose has been provided by altering and adding to an abandoned tobacco-curing building.

Iowa Station.—V. R. Gardner has been added to the station staff in horticulture.

Louisiana Stations.—P. L. Hutchinson, chemist in charge of the analysis of fertilizers and feeding stuffs, has resigned to accept a position in this Department, and his position has been filled by the appointment of J. E. Halligan. J. T. Felt has been appointed assistant chemist.

Maine University and Station.—Sanford C. Dinsmore, assistant chemist of the station, resigned July 1 to accept a similar position at the Nevada Station, and John B. Reed, for two years instructor in chemistry in the university, has been appointed to succeed Mr. Dinsmore.

Maryland Station.—E. P. Walls, assistant in agronomy, has resigned, and will take up the study of medicine at Johns Hopkins University.

Michigan College.—U. P. Hedrick, professor of horticulture, has resigned to accept the position of horticulturist at the New York State Station. Professor Hedrick has been succeeded by S. W. Fletcher of Cornell University.

Mississippi College and Station.—At the beginning of the present college year the dairy department of the college and station will occupy a new barn costing about $6,000. The building is T-shaped, the upright being 40 by 60 ft., 2 stories high, and the cross 240 by 35 ft., 1 story high. The former contains on the first floor a milk room and a bath room with cement floors, an office and several feed rooms with wood floors. The second story is devoted to storage for grain and roughage. The stable contains 100 stalls for milch cows, 6 box stalls for calves, and 6 box stalls for bulls. The stable floors are of cement and the stalls of brick to a height of about 6 ft. The framework and walls above the brick are of wood, mostly native pine. Both feed and manure will be handled by means of trolleys, the latter being carried by gravity to a manure shed some distance from the barn.

The summer school for teachers, held from June 20 to July 15, had an enrolment of more than 200 teachers. The industrial courses included agriculture, horticulture, nature study, school gardening, manual training, and drawing, and this feature of the work was so popular with the teachers that they passed resolutions asking that the school be held again next year.

Nebraska University and Station.—A. Keyser has been appointed assistant in agricultural chemistry. C. W. Melick, former instructor in dairying, has been appointed instructor in dairying at the Kansas Agricultural College. Provision has been made by the regents of the university for improvements costing about $30,000. These will include the erection of a new barn for pig feeding experiments, the rearrangement of cattle feeding barns and sheds, and the construction of a sewer.

Nevada University and Station.—The station staff has recently completed a ten-day tour through the eastern part of the State, where farmers' institutes were held at various places. C. R. Fitzmaurice has resigned as assistant chemist of the station and S. C. Dinsmore of the Maine Station has been appointed to take his place. N. E. Wilson, vice-director and chemist of the station, has been appointed dean of the university and consulting chemist to the station. S. B. Doten, station entomologist, has resigned to become principal of the university high school. J. E. Stubbs, president of the university and director of the station, has been given a year's leave of absence in order that he may rest and regain his health.

New Hampshire College.—Charles Brooks, formerly assistant in botany in the University of Missouri, has been appointed instructor in botany.

New Jersey Stations.—Equipment has been provided for investigations in plant nutrition in which the fertilizer requirements of soils will be studied with cereals and leguminous plants.

North Carolina College.—F. C. Reimer, formerly assistant horticulturist and botanist at the University of Florida and the Florida Station, has been made assistant horticulturist at the college.

Oklahoma College and Station.—W. R. Wright, a graduate of the Michigan Agricultural College, has been appointed assistant in bacteriology in the college and station, succeeding J. F. Nicholson, who, as previously noted (E. S. R., 16, p. 1141), has been made botanist and entomologist. C. E. Quinn, a graduate of the University of Nebraska, has been appointed assistant in soils and crops in the college and station during the leave of absence of L. A. Moorhouse. F. A. Hutto, principal of the school

of agriculture and domestic economy, has resigned. E. H. Riley, formerly assistant in animal husbandry in the college and station, has been appointed principal of the school of agriculture and domestic economy in the college and assistant in agriculture in the station. C. H. Tourgee has been relieved of station work and is no longer assistant in agriculture.

Pennsylvania College and Station.—Thomas I. Mairs, assistant professor of animal industry in the college, has been added to the station staff and placed in charge of the work in animal industry. Robert E. Stallings, assistant in animal nutrition in the station, has resigned to accept a position with the North Dakota Station. F. W. Christensen, of the U. S. Department of Agriculture, who served last year as assistant in connection with the animal nutrition experiments, has been appointed assistant in agronomy and animal industry in the station. A. W. Clark, assistant chemist, resigned July 19 to accept a position in the New York State Station. The division of botany of the station has been discontinued.

Porto Rico Station.—O. W. Barrett, entomologist and botanist of the station, has resigned to accept a position in the Office of Seed and Plant Introduction of the Bureau of Plant Industry of this Department.

Rhode Island Station.—In cooperation with the Bureau of Animal Industry of this Department the station has begun experiments in breeding turkeys with a view to controlling the so-called blackhead disease. George E. Adams, assistant in agronomy at the station, has been made associate agronomist.

South Dakota Station.—The agronomy division of the station has been put under the immediate supervision of the director, James W. Wilson. J. S. Cole, assistant in agronomy in the college, has been made assistant in agriculture in the station. An additional quarter section of land has been purchased recently by the State for the agricultural department, making in all a total of 480 acres for agronomy and live stock investigations. The first annual farmers' excursion to the college in June was very successful.

Tennessee Station.—H. A. Morgan, director and zoologist and entomologist of the station, has been appointed State entomologist and plant pathologist.

Texas College.—David F. Houston, president of the college, has been called to the presidency of the State University, and has accepted.

Utah College and Station.—W. W. McLaughlin has been appointed irrigation engineer; H. J. Frederick, veterinarian; E. G. Peterson, assistant entomologist; and C. W. Porter, assistant chemist. Robert Stewart, assistant chemist of the station, has also been made assistant professor of chemistry in the college. In compliance with a law passed by the last legislature discontinuing the engineering courses in the college, the board has decided to take no more new students in engineering, but provision has been made for those who have already entered to complete their courses.

Virginia College and Station.—The second annual meeting of the Virginia State farmers' institute, held at Roanoke on July 12, 13, and 14, was attended by over 500 farmers. On the last day of the institute an excursion train was run to Blacksburg for the purpose of visiting the college and station. Resolutions were adopted asking the State legislature to appropriate $100,000 for the development of college and station work.

Washington College.—The name of the Washington Agricultural College and School of Science has been changed to State College of Washington. The courses of study will remain the same as heretofore. J. J. Browne and S. G. Cosgrove have been appointed regents.

Wisconsin University and Station.—The following appointments have been made: D. H. Otis, of the Kansas Agricultural College, assistant professor of animal nutrition and assistant to the dean; C. A. Ocock, of the University of Illinois, assistant in agricultural engineering; J. G. Moore, assistant in horticulture; G. H. Benkendorf, assistant in dairying; and E. R. Jones, assistant in soils.

The last legislature passed an act requiring that all stallions used for breeding purposes in the State be registered and licensed by the department of horse breeding of the College of Agriculture, University of Wisconsin. The purport of the act is to necessitate the standing of stallions for what they actually are as regards breeding, and to weed out, so far as possible, sires that are notably unsound. It is expected that the effect of this new law will be to encourage the use of sound, pure-bred, pedigreed sires and lead to the more general recording of eligible colts, while at the same time discouraging the use of unsound, grade, "scrub," and crossbred sires. The act will take effect January 1, 1906. Dr. A. S. Alexander has been placed in charge of this department.

Domestic Science Work in Great Britain.—In Great Britain cookery and other branches of domestic science are attracting a good deal of attention, and work along these lines is encouraged through state and municipal aid, by the county councils, board of education, and in other ways. A large new wing, recently added to the Gloucestershire School of Domestic Science at Gloucester, was formally opened April 8. The board of education holds regular examinations in cookery, the chemistry of food, and the theory and practice of teaching nutrition. The interest in work along these lines is shown by the attention attracted by the sixteenth annual cookery and food exposition, which was opened May 2 by the Duke of Connaught, at the hall of the Royal Agricultural Society, Westminster. This exhibition was largely educational, and courses of lectures and demonstrations of the preparation of foods were given. A collection of ancient culinary implements, old cookery books, etc., was exhibited. The prize list was liberal, and the competitions arranged for army and navy cooks and for school children excited much interest.

Society of American Florists and Ornamental Horticulturists.—The twenty-first annual meeting of this society was held in Washington, August 15 to 17, with about 3,000 delegates and visitors in attendance. Prof. B. T. Galloway, of this Department, gave an illustrated lecture before the association in which he described the work that the Bureau of Plant Industry is doing along the lines of horticulture and agriculture in the introduction of new fruits, trees, and plants, and in the fostering of public interest in these subjects, both from an esthetic and industrial point of view. Miss Susan B. Sipe described the work of the Bureau of Plant Industry in encouraging civic improvement and the teaching of horticulture in the public schools of Washington. Other important papers presented at the meeting were Helps to Floriculture in the South and Southwest, by R. Nicholson, and The Ideal Country Home for the Man with a Long Head and a Short Purse, by Oglesby Paul. A number of essays on the Ideal Employer were submitted in competition for cash prizes. The first prize on this subject was won by S. S. Skidelsky. A committee of five was appointed by the president of the society to investigate the feasibility of preparing a text-book of horticulture for dissemination by florists' clubs and report at the next meeting. Dayton, Ohio, was selected as the place for the next annual meeting. The following officers were elected: President, W. F. Kasting; vice-president, H. L. Altick; secretary, W. J. Stewart. H. B. Beatty was continued as treasurer.

Dunn County School of Agriculture.—A recent bulletin of this school announces several lines of work which the school is prepared to do for the farmers of the country free of charge. This work includes testing of milk and seeds; inoculation of clover and other legumes; treatment of oats for smut and potatoes for scab; grafting of apple trees; planning of roads, barns, silos, poultry and milk houses, water systems, and drainage and sewage systems; selecting of pure-bred stock, and giving information regarding feeds, stock, crops, diseases, insects, spraying, and other farm subjects.

District Agricultural Schools of Alabama.—By recent action of the boards of control of the nine district agricultural schools of Alabama each boy in attendance at these schools will be required henceforth to work at least 2 hours a week at the school

farm, and each girl will be required to do practical work in floriculture and other kindred subjects.

Personal Mention.—General Roy Stone, the first chief of the Office of Road Inquiry of this Department and a distinguished veteran of the Civil War and the Spanish-American War, died at his home in Mendham, near Morristown, N. J., on August 7, and was interred with full military honors at the Arlington National Cemetery on August 10. He was 72 years of age.

General Stone was a pioneer leader in the movement for good roads in the United States. For many years previous to the establishment of the Office of Road Inquiry, General Stone had been agitating the improvement of the country roads, and in his home county he succeeded in perfecting a system of roads which served as a practical object lesson for the State of New Jersey and led to the building of a complete system of improved highways in that State. He was largely instrumental in securing the passage of the bill for the establishment of the Office of Road Inquiry in the Department of Agriculture, and when the law went into effect he was appointed by Secretary Morton as a special agent in charge, organizing and directing the work. With a limited appropriation, he did much to popularize the movement for good roads, and he inaugurated a system of object-lesson roads which greatly stimulated interest in the subject. Many instructive publications were issued under his direction.

Eugene Risler, honorary director of the National Agricultural Institute of France, died August 6 at the age of 77. His early agricultural studies were carried on at Grignon and Versaille in France and at Hohenheim and Regenwald in Germany, following which he traveled extensively, studying the agricultural conditions and practices in various countries. He became a frequent contributor to the French agricultural press, his first articles setting forth his observations on agriculture in the countries he visited. In 1856 he secured an estate of about 200 acres near Nyon in Switzerland and established there at his own expense the first Swiss agricultural experiment station. When the National Agricultural Institute was reestablished at Paris in 1876 Risler was made professor of comparative agriculture, and in 1879 he succeeded Tisserand, who had been appointed director of agriculture in the agricultural ministry, as director of the institute, a position which he held until his retirement in 1901. Among his numerous agricultural publications is his well-known treatise on agricultural geology, consisting of 4 volumes. A quite full account of his life by H. Hitier is given in No. 34 of the current volume of the *Journal d'Agriculture Pratique*, to the columns of which he contributed frequently ever since 1852.

W. H. Beal, of this Office, J. T. Willard, of Kansas, L. H. Smith, of Illinois, and W. L. Jepson, of California, were delegates to the International Congress of Agricultural Education at Liege, Belgium, July 28 and 29. The congress was well attended, about 150 delegates, representing 12 countries, being present. An international committee was appointed to give continuity to the work of the congress, Dr. A. C. True, W. H. Beal and L. H. Smith being the American representatives on this committee.

A. B. Graham, who as superintendent of Springfield Township Schools, Clark County, Ohio, has for a number of years been active in promoting agricultural education in the public schools, has been placed in charge of a newly organized department of agricultural extension in the Ohio State University. One of the features of the extension work to be undertaken will be the publication at regular periods of bulletins relating to the extension of agriculture in the rural schools.

John A. Widtsoe, who recently retired from the directorship of the Utah station, has become director of the agricultural department of Brigham Young University at Provo, Utah. For three or four years past the church schools have been giving attention to the teaching of elementary agriculture, and there is considerable demand for that kind of instruction at Brigham Young University. It is proposed to

strengthen this branch of the work at the university so far as funds at its disposal will permit.

Nature states that among the honors recently conferred by King Edward VII upon the occasion of his birthday was that of C. M. G. (Companion of the Order of St. Michael) upon James W. Robertson, late commissioner of agriculture and dairying of the Dominion of Canada.

William H. Kelley, chief veterinarian of the New York State department of agriculture, was a delegate for the United States to the International Veterinary Congress held at Budapest, Hungary, September 3 to 9.

Miscellaneous.—The first annual meeting of the Indiahoma Farmers' Union, including members from the Indian and Oklahoma Territories, was held at Tishomingo, I. T., July 18–21. The programme included addresses by J. A. Bonsteel and W. J. Spillman, of this Department; J. B. Thoburn, secretary of the Oklahoma Board of Agriculture, and P. G. Holden, professor of agronomy at the Iowa Agricultural College.

The Idaho Industrial Institute at Weiser, Ida., has recently erected and equipped a dairy building to handle the milk from a dairy of 40 cows, and is constructing a reservoir for irrigation purposes which will cost about $5,000.

The last report of the Royal Botanic Gardens at Peradeniya, Ceylon, advocates the establishment of a cotton experiment station in the dry region of north-central Ceylon, to be supplied with water from irrigation tanks. The soil is said to be excellent and the locality well suited to Sea Island cotton. The establishment of such a station is pronounced of primary importance.

Two numbers have been received of the *Kansas Agricultural Review*, a monthly magazine published by the students of the Kansas Agricultural College and devoted to agricultural education, college news, and notes concerning the alumni of the institution.

According to a recent note in *Science*, an agricultural conference was held at Aberystwyth, Wales, the third week in June, to aid in extending and developing the work of the agricultural department of the University College of Wales. The college is now receiving from the board of agriculture $4,000 for its agricultural department, $1,000 for a new farm opened on the day of the conference, and one-sixth of the "residue grant" to the County Councils for the counties connected with it. The County Councils were asked to appoint delegates to another conference to be held in October to consider details of a scheme of organization for the agricultural department of the college.

O

EXPERIMENT STATION RECORD.

VOL. XVII. OCTOBER, 1905. No. 2.

Among the presidential addresses at the South African meeting of the British Association the past summer was one on irrigation, which is especially worthy of note on account of its treatment of the larger irrigation problems of the world. It brought together, furthermore, a large amount of information regarding the prominent features and conditions of irrigation in the principal irrigated countries. The address was delivered before the section for engineering by Sir C. Scott Moncrieff, president of the section. The speaker was competent to discuss the subject from his extended experience in the principal irrigated countries, and the study he has made of it from an economic as well as an engineering standpoint.

The paper served to show anew the enormous proportions which irrigation has attained, and the scientific basis which it has been placed upon in some of the countries of the Old World. It brought out in a rather striking way the similarity between the problems which are occupying special attention in other countries and those which are uppermost in this country, such as the pumping of water, utilization of artesian wells and of small reservoirs, the necessity for drainage as an accompaniment of irrigation, and the basis of payment for water. It also gave some striking illustrations of the colonization in India and elsewhere of vast tracts of country which, previous to the installation of irrigation works, were desert wastes.

The speaker characterized the irrigation in India and Egypt as being on the largest scale, that of Italy as having the most highly finished works and careful water distribution, and that of America as exhibiting rapid progress and bold engineering. "It is in India that irrigation on the largest scale is to be found," the Great Plains of northern India being peculiarly well adapted to it, and the teeming population absolutely dependent upon it for maintenance. As shown by the recent report of an irrigation commission, there are now under irrigation in that country something over forty-four million acres, or ten times the area at present irrigated in this country.

The greatest of its canals, discharging from 3,000 to 10,500 cubic feet of water per second, was built to carry water into a tract entirely desert and unpopulated. It was opened in 1892 and enlarged, and ten

years later was irrigating 1,829,000 acres, supporting a population of eight hundred thousand inhabitants, who were brought there from more congested parts of India. The Ganges Canal, opened in 1854, "at a time when there was not a mile of railway and hardly a steam engine within a thousand miles," has a length of nearly ten thousand miles, including distributing canals. Supplemented by the lower canal, drawn from the same river, it irrigates 1,700,000 acres annually.

A very bold and successful piece of irrigation engineering in southern India, which was completed a few years ago, diverts the waters of the Periyar River through the mountains to the plains on the other side. The river formerly descended to the sea on the west coast, where its waters could not be utilized, and large expenditures were required periodically to control its furious floods. A dam was built across its course and a tunnel made through the mountains, enabling the reservoir to be discharged into a system of canals to the east and applied to the irrigation of a vast area much in need of water.

In the state of Mysore a reservoir is now under construction which closes a valley containing over two thousand square miles by means of a masonry dam 142 feet high. The reservoir thus formed will contain 30,000 million cubic feet of water when filled, which, however, will rarely occur, the reason for the height of the dam being an engineering one rather than the need of ordinarily impounding such an enormous volume of water.

Perhaps there are no more familiar examples of the wonders wrought by irrigation than those furnished by Egypt, but to the layman Mr. Moncrieff's statement that purely agricultural land near Cairo, where the average rainfall is only 1.4 inches, is sold as high as $750 an acre is a revelation of the value which irrigation has placed upon these desert lands.

Here, it will be remembered, is the great Assuan Dam, six hundred miles below Cairo. This dam holds up a depth of sixty-six feet of water, forming a lake of more than one hundred miles in length, extending up the Nile Valley, and containing 38,000 million cubic feet of water. The chief object of this great reservoir is to enable perennial irrigation to be substituted in upper Egypt in place of the basin system of watering the land through the Nile flood only—that is, to enable two crops to be grown every year instead of one, and cotton and sugar cane to take the place of wheat and barley. It is expected that these works on the Nile will be finished in 1908. There will then have been spent on the great dam at Assuan, the minor one at Assuit, and the new canals of distribution in upper Egypt about £6,500,000, or approximately $31,525,000.

Not only will this undertaking have a far-reaching effect upon the agriculture of the country, the methods of cropping, and the handling

of water, but it is calculated that it will increase the land rental by over $13,000,000 and its sale value by upward of $130,000,000.

But in spite of these large enterprises, wells and small reservoirs are employed to a large extent in some countries, and have the advantage of placing the control of the water in the hands of the farmer. It was stated that about thirteen million acres, or 30 per cent of the lands irrigated in India, are watered by wells. Small reservoirs are also very numerous. In the native state of Mysore there are about forty thousand irrigation reservoirs, or practically three to every four square miles, and in southern India no less than ninety thousand of these small reservoirs are recorded.

The large volume of water required to be stored for an acre of land is often a matter of surprise to those who have not given the subject attention. Mr. Moncrieff stated that in India the storage of a million cubic feet of water does not suffice for more than six or eight acres of rice, while about one-third as much would be required for wheat. He speaks of districts so flat that to store water enough to irrigate an acre requires the drowning of more than an equal area; but as the irrigated acre yields eight or ten times as much as the unirrigated one, the idea is not as impractical as would at first appear. After the storage reservoir has been emptied it is often possible to raise a good crop on the saturated bed.

Improvement in the means of raising water is one of the most important of recent developments in irrigation. Measured by value, nearly one-tenth of the irrigated products of this country are now grown with water lifted by pumps. In the rice districts of Louisiana one-fourth of the outlay in growing a crop is for pumping; and manifestly the efficiency of the pumping machinery employed, which has been found in our own investigations to vary all the way from 5 to 82 per cent, has much to do with the profits of farming.

The centrifugal pump is rapidly coming into use in connection with irrigation, and is being extensively installed in this country where pumping is required. It is interesting to learn that these pumps are taking the place of the primitive shadoof, which has been for ages the method employed for raising water along the Nile. As the cotton and sugar cane crops in that country yield from $30 to $40 an acre, or even $50, the well-to-do farmer can afford a centrifugal pump run by steam power. There are now many hundreds of these pumps, fixed or portable, working on the Nile banks of Egypt.

Mr. Moncrieff was very strongly of the opinion that irrigation should be accompanied by drainage, a view which is coming to be widely held in this country. Speaking specifically upon the subject, he said: "In the great irrigation systems which I have been describing, for a long time little or no attention was paid to drainage. It

was taken for granted that the water would be absorbed or evaporated, and get away somehow without doing any harm. This may hold good for high-lying lands, but alongside of these are low-lying lands into which the irrigation water from above will percolate and produce water logging and marsh."

This is exactly what has happened in many places in our own country, rendering land practically useless and often causing it to be abandoned for cultivation. Where the evil has not progressed so far as this, alkali has taken possession of vast tracts of land, greatly restricting its value and the uses to which it can be put, and even rendering it unfit for any crops.

The speaker advised that the drainage canal should be constructed along with the irrigation canal, and he quoted no less an authority than Sir W. Willcocks in support of this. The latter states that the capacity of the drain should be one-third of that of the canal. "The two should be kept carefully apart—the canal following the ridges, the drain following the hollows of the country, and one in no case obstructing the other. This subject of drainage early occupied the attention of the English engineers in Egypt. In the last twenty years many hundred miles of drains have been excavated, some as large as fifty feet width of bed and ten feet deep.'

A survey like the above shows that in this country we are, relatively speaking, only at the beginning of irrigation development. A large proportion of our first efforts have been little more than temporary makeshifts, and have lacked that degree of stability and permanency which characterizes the works of the Old World and which is so important when we consider the dependence of arid agriculture upon irrigation. This dependence is not temporary, as are some conditions of agriculture, but is to be reckoned with as a permanent requirement of farming. Mr. Moncrieff, while mentioning some of our larger and better works, comments upon them as a whole as "often rude and of a temporary nature, the extensive use of timber striking a foreigner from the Old World." He also refers to the lack of a well-devised scheme of water control, such as exists in Italy and elsewhere.

It required time, of course, to convince capital of the possibilities of irrigated agriculture and to bring about a faith which warranted more permanent works; and as the experiments had all to be made by private enterprise the surprise is not at the imperfect character of these works, but at the public spirit and enterprise which have made some of our larger and more difficult works possible. Sir W. Willcocks has said that "if private enterprise can not succeed in irrigation works of magnitude in America, it will surely not succeed in any other country in the world."

Our progress now, both in the development work and the investigation of irrigation problems, is in line with that in other countries,

as judged by the above survey. With the Federal Government supplementing private enterprise in the construction of large projects and carrying on extensive investigations upon the use and economy of water, this important branch of agricultural development is placed upon a rational and intelligent basis which will make for greater permanency and stability.

Elsewhere in this issue a brief account is given of the meeting of the National Association of Agricultural Implement and Vehicle Manufacturers. This association holds annual meetings, and this year met at Niagara Falls the last of September. It represents interests which stand very close to agriculture, and the present development of instruction and experimentation in farm mechanics makes its deliberations a matter of special interest.

The development of agricultural implements and machinery has been very closely connected with our agricultural development and the increasing economy of production. It is calculated that in 1830 over three hours of labor were employed in growing a bushel of wheat, while in 1896 the labor aggregated only ten minutes; in 1850 the labor represented in a bushel of corn was four and one-half hours, while in 1894 it had been reduced to about forty minutes. As compared with the cost of production in 1830–50, modern machinery now grows crops for less than half, although operated by men who receive twice the wages paid formerly. Furthermore, the general quality of the product is better and it is handled in a more cleanly manner.

The American farmer buys annually one hundred million dollars' worth of farm implements and machinery, and the total assessed value of this portion of his equipment is $761,261,000. This is a vast investment, upon which he should realize good returns through being able to select implements which meet all the requirements for which they were purchased, and to secure the highest possible efficiency.

The introduction of power upon the farm is steadily increasing, and among the latest sources of power for this purpose alcohol is commanding wide attention. This material is already coming into use in Europe, where its application to a great variety of purposes in reducing hand labor and eliminating drudgery has been demonstrated. Its convenience, safety, and cleanliness commend it, and especially the possibility of its cheap production upon the farm. Alcohol motors have been perfected and machinery for distilling improved, and the German Government has encouraged the industry by removing the taxes from the product used for technical purposes. It is reported that raw alcohol is produced in that country from potatoes for 13 cents a gallon by processes so simple as to be within the reach of farmers. Already there is demand in this country for the removal of the taxes from alcohol used for technical purposes, the present revenue amounting to nearly fourteen times the cost of manufacture.

There is believed to be a wide field of usefulness open to the agricultural colleges and experiment stations and the National Department of Agriculture in connection with instruction and experimentation upon farm machinery and the application and economy of power. The results will be of substantial aid to both the farmers and the implement manufacturers. The men now employed by the manufacturers in designing and experimentation were often trained for something else, as there have been no schools for training men in agricultural mechanics; hence these men are often lacking in their knowledge of agricultural affairs, and this affects the efficiency of the experimental departments upon which the implement manufacturers have to rely to a large extent.

Already the experiment stations have been able to call attention to defects which manufacturers were glad to remedy, and to make suggestions for needed devices which would render the use of the machinery more efficient. The corn planter, which is still in a developmental state, furnishes illustrations of this, as does also the corn harvester. Resolutions commending the work of the experiment stations and the Department in this line, and indorsing the teaching of farm mechanics at the agricultural colleges, were unanimously adopted by the association, which pledged to these undertakings its cordial cooperation and support.

RECENT WORK IN AGRICULTURAL SCIENCE.

AGRICULTURAL CHEMISTRY.

Formation of oceanic salt deposits, J. H. VAN'T HOFF (*Zur Bildung der ozeanischen Salzablagerungen. Brunswick: Vieweg & Son, 1905, pp. VI+85, figs. 34; rev. in Nature* [*London*], *71* (*1905*), *No. 1848, pp. 508, 509*).—This is the first instalment of a collection into one publication of the results of the well-known investigations of the author and his collaborators on the formation of double salts, the principal object of which was to study the problem of the formation of natural salt beds.

"The experimental basis of the work is the determination of the solubility, at certain temperatures, of the common salts of the sea, in water and in solutions of each other. With the information so obtained, it is possible to follow exactly the crystallization of a solution containing all these salts, as it gradually loses water by evaporation at the temperature of the experiment. The temperature most used is 25° C., which is fairly representative of the temperature of sea water evaporating in salt gardens, such as those of Hyères or Cadiz in summer.

"When average sea water has been evaporated down to the point at which chlorid of sodium begins to crystallize, the liquor contains (in molecular proportions) 100 NaCl, 2.2 KCl, 7.8 $MgCl_2$, 3.8 $MgSO_4$; and this mixture of salts is associated with, roughly, 1,000 molecules H_2O (exactly 1,064). On allowing this liquor to evaporate at 25° C., the crystallization follows a definite route, which can be traced exactly and without difficulty on one of those marvellous charts representing the march of physical and chemical phenomena with which the resourceful inventiveness of van't Hoff has familiarized us.

"The crystallization takes place in four acts corresponding to the regions in the chart.

"(1) Rock salt: Separation of chlorid of sodium in great abundance. Of the 100 NaCl present when crystallization began, only 4.6 NaCl remains dissolved; the remainder, 95.4 NaCl, has been deposited.

"(2) Kieserite region: Separation of chlorid of sodium, sulphate of magnesium, and kainit ($MgSO_4$. KCl. $3H_2O$). The salt separated in this act consists of 4.42 NaCl, 2.02 KCl, and 3.07 $MgSO_4$; or, 4.42 NaCl, 1.05 $MgSO_4$, and 2 02 kainit.

"(3) Carnallite region: Separation of chlorid of sodium, carnallite ($KMgCl_3$. $6H_2O$), and kieserite ($MgSO_4$. H_2O), and the amounts separated are 0.03 NaCl, 0.1 carnallite, and 0.35 kieserite.

"(4) Final liquor: What remains solidifies to 0.15 NaCl. 7.62 $MgCl_2$ (bischofite), 0.08 carnallite, and 0 38 kieserite."

A technical method for the determination of free phosphoric acid in superphosphates, GERHARDT (*Chem. Ztg.*, *29* (*1905*), *No. 14, pp. 178, 179*).—The method proposed is as follows: Shake 20 gm. of the superphosphate mixed with 1 gm. of ferrocyanid of potassium dissolved in a little water for ½ hour in 1 liter of water and filter; add a known weight of calcium carbonate to 100 cc. of the filtered solution and stir for ½ hour; remove the excess of calcium carbonate by means of a quick filter, wash a little, dry, burn, ignite carefully, and weigh. The difference between the calcium carbonate used and that thus obtained furnishes a means of calculating the free phosphoric acid.

Good results may be obtained by determining carbon dioxid by means of a Scheibler apparatus, or by dissolving the unused carbonate in hydrochloric acid and titrating with sodium hydroxid solution, using methyl orange as indicator. The solubility of the carbonate and the presence of iron and aluminum are the chief sources of error in the method.

A technical method for determining free phosphoric acid in superphosphates, R. ZÖCKLER (*Chem. Ztg., 29 (1905), Nos. 17, p. 226; 25, p. 338*).—The author believes Gerhardt's method to be unreliable, and considers the alcohol method simpler and safer.

Tables for reckoning the composition of ammoniated superphosphates, GERHARDT (*Chem. Ztg., 29 (1905), No. 15, p. 194*).—Tables are given which show amounts of ammonium sulphate and superphosphate of different grades which must be used in order to obtain mixtures containing desired percentages of nitrogen and phosphoric acid.

Analysis of compounds containing nitrogen in union with nitrogen by means of Kjeldahl's method, C. FLAMAND and B. PRAGER (*Ber. Deut. Chem. Gesell., 38 (1905), pp. 559, 560; abs. in Jour. Chem. Soc. [London], 88 (1905), No. 509, II, p. 201*).—"Kjeldahl's method is applicable to azo-, azoxy-, and hydrazo-compounds which have been subjected to the following preliminary treatment: 0.15–0.2 gm. of the substance to be analyzed is mixed with 10 cc. of alcohol, 0.5–1 gm. of zinc dust, and 2–5 cc. of concentrated hydrochloric acid of sp. gr. 1.19, and heated until decolorization takes place. Ten cubic centimeters of concentrated sulphuric acid and 0.5 gm. of crystalline copper sulphate are then added and the mixture heated until white fumes are evolved. After addition of 6 gm. of powdered potassium sulphate, the liquid is heated until it becomes clear and light green. This method does not give accurate results with phenylhydrazin, benzylidenephenylhydrazin, and formazyl compounds."

The gravimetric determination of nitric acid by means of nitron according to Busch, A. GUTBIER (*Ztschr. Angew. Chem., 18 (1905), No. 13, pp. 494–499*).—The author reports a series of tests of the accuracy of Busch's method (E. S. R., 16, p. 945) under various conditions, especially solubility of the nitron and the nitron precipitate in water. The form of the method which he recommends and with which he obtained very accurate results is as follows:

Dissolve 0.1 to 0.15 gm. of potassium nitrate, or a corresponding amount of the other material to be tested, in 80 cc. of water in a beaker covered with a watch glass, add 12 to 15 drops of dilute sulphuric acid, and bring to boiling temperature; remove the flame and add to the hot solution 12 to 15 cc. of a 10 per cent solution of nitron in 5 per cent acetic acid; stir the mixture and allow to stand for ½ to ¾ hour, during which time the nitron nitrate will crystallize out. When the solution has attained room temperature place the beaker in ice water and after 1 to 1½ hours collect the precipitate on a weighed Neubauer crucible by decantation of the mother solution, using gentle suction, wash with 10 to 12 cc. of water at 0° C., dry, and weigh.

The qualitative determination of nitric acid by means of the diphenylamin reaction, G. FRERICHS (*Arch. Pharm., 243 (1905), p. 80; abs. in Chem. Centbl., 1905, I, No. 13, p. 957*).—The author calls attention to the fact that this reaction is interfered with by the presence of a number of substances, such as ferric salts, chromates, etc., and he describes a method of treatment with ether and sulphurous acid solution which overcomes some of these difficulties.

On Frerichs' method of determining nitric acid in water, UTZ (*Chem. Ztg., 29 (1905), No. 14, pp. 177, 178*).—This method (E. S. R., 14, p. 940) was compared with favorable results with those of Schulze-Tiemann and Mayrhofer.

A new method for determining ammonia, A. TRILLAT and TURCHET (*Bul. Soc. Chim. Paris, 3. ser., 33 (1905), No. 6, pp. 304–308; Compt. Rend. Acad. Sci. [Paris], 140 (1905), pp. 374–377; abs. in Chem. Centbl., 1905, I, No. 11, p. 832*).—This method,

which is claimed to be superior to the ordinary Nessler method, is based upon the fact that when 3 drops of a 10 per cent potassium iodid solution and 2 drops of a saturated alkali hypochlorite solution are added to 20 to 30 cc. of water containing ammonia, a black coloration is produced which can be easily compared with standard solutions as in the Nessler test.

Application of the nitrogen iodid reaction in determining ammonia in potable waters, A. TRILLAT and TURCHET (*Bul. Soc. Chim. Paris, 3. ser., 33 (1905), No. 6, pp. 308–310*).—A series of tests of the above described method on samples of water from different sources are reported.

On a new method of determining ammonia in ammoniacal salts applicable to the study of potable waters, A. TRILLAT and TURCHET (*Ann. Inst. Pasteur, 19 (1905), No. 4, pp. 259–265*).—A summary of the article by the same authors noted above.

On the physico-chemical analysis of cultivated soils, H. LAGATU (*Compt. Rend. Acad. Sci. [Paris], 140 (1905), No. 10, pp. 669–672, fig. 1*).—A uniform graphic method of representing the results of physico-chemical analysis is described and its applications briefly explained. (See also E. S. R., 16, p. 756.)

Determination of sulphur and phosphoric acid in foods, feces, and urine, W. L. DUBOIS (*Jour. Amer. Chem. Soc., 27 (1905), No. 6, pp. 729–732*).—A note on the calorimetric methods followed at the Bureau of Chemistry of this Department, particularly that of Neumann and Meinertz.[a] For earlier notes on the same subject see E. S. R., 16, p. 539.

The analysis of wheat and flour for commercial purposes, H. SNYDER (*Reprinted from Rpt. 5. Internat. Cong. App. Chem., Berlin, 1903, Sect. 6, vol. 3, pp. 9, pls. 2*).—The moisture content, acidity, total and alcohol-soluble nitrogen, the power to absorb water, microscopical characteristics, and other factors of value in determining the quality of flour are discussed, and methods of carrying out some of the determinations are described.

According to the author, "while no large amount of chemical work has yet been done in the way of testing wheat and flour for commercial purposes, the results which have been secured are sufficient to show that the milling of wheat is as capable of chemical control as is the sugar or any other industry."

The separation of proteids, H. C. HASLAM (*Jour. Physiol., 32 (1905), Nos. 3–4, pp. 267–298*).—On the basis of experimental evidence the author proposes methods, regarded as exact, for the separation of proteids by precipitation, one of which is dependent upon repeated precipitation and constant volume until the organic nitrate in the filtrate is constant in quantity, and another a method of fractional precipitation different from that of Pick.

"The application of these methods to proteids of serum and the digestive mixture shows that the various procedures (crystallization excepted) of previous authors in dealing with these complicated mixtures are quite inadequate to produce pure substances. Albumoses have been completely separated from peptones and other bodies. On this separation is based a method of estimating total mixed albumoses. Primary albumoses are shown to consist of at least three substances: Hetero-albumose, α-proto-albumose, β-proto-albumose."

The author states that "a particular proteid (or group of proteids) being precipitated, carries down with it large quantities of other proteids and also other substances, while large quantities of the proteid desired to be precipitated remain in the filtrate." It is suggested that "the best explanation of the tenacity with which these bodies cling to each other is to be found in the supposition that there is some sort of loose chemical combination among them. This hypothesis would also explain the fact that once a complete separation has been effected, if the products are arti-

[a] Ztschr. Physiol. Chem., 43 (1904), p. 37.

ficially mixed again, a second separation is not so difficult. It is also in harmony with our general knowledge of the chemical condition of the living organism.

"When the chemical equilibrium of such a system of proteids in loose combination is upset by the addition of a precipitant, only a partial separation is effected, some of the soluble proteids going into the precipitate and some of the insoluble remaining in the filtrate, the loose combination in these two cases being maintained. It is only by extensive and exact methods such as I have described that we can hope to effect the isolation of such bodies."

Simple proteids and their cleavage by ferments, A. KOSSEL and DAKIN (*München. Med. Wchnschr., 51 (1904), No. 13, p. 545; abs. in Hyg. Rundschau, 15 (1905), No. 9, pp. 451, 452*).—The simplest known proteid, according to the authors, is salmin, which gives 5 cleavage products, namely, α-pyrrolidin-carbonic acid, serin, amino-valeric acid, urea, and diamino-valeric acid or ornithin. Data are given regarding the cleavage products obtained by the action of erepsin on clupein, and the structure of proteids is discussed.

Investigations on the vegetable proteids, T. B. OSBORNE (*Connecticut State Sta. Rpt. 1904, pt. 5, pp. 457-459*).—This is a brief summary of investigations which have been or are to be published in full in the *American Journal of Physiology*. The subjects investigated are as follows: The alcohol-soluble protein substances of wheat flour, the separation and purification of protein substances, the solubility of globulin in salt solutions, and the protein constituents of the castor-oil bean.

Detection of cotton-seed oil in lard, L. M. TOLMAN (*U. S. Dept. Agr. Yearbook 1904, pp. 359-362, pls. 4*).—The author points out the difficulty of detecting lard adulterants and the failure of ordinary tests for cotton-seed oil, and describes Bömer's test, which has been found successful in detecting cotton-seed oil in lard. This test depends upon the fact that phytosterol is present in vegetable fats but not in animal fats. While lard from hogs fed cotton-seed meal gave the usual color tests that would be given by products containing added cotton-seed oil, no phytosterol was present. Phytosterol may be identified by the form of the crystals or by the melting point of the acetate.

Investigations on the Gottlieb method of determining fat in milk, M. SIEGFELD and W. ROSENBAUM (*Milchw. Zentbl., 1 (1905), No. 6, pp. 244-248*).—Comparative tests of the Adams, Gottlieb, and Gerber methods are reported. The results by the 3 methods agreed closely on skim milk and whey. With buttermilk, however, the results by the Adams method were usually about 0.1 per cent lower than by the Gottlieb method. The substance insoluble in ether obtained in the Gottlieb method while not identical with lecithin is believed to be derived from that substance by oxidation during drying.

Studies on the possible saponification of fat by concentrated ammonia in the Gottlieb-Röse method, A. BURR (*Milchw. Zentbl., 1 (1905), No. 6, pp. 248-250*).—The results of the experiments reported indicate that ammonia does not cause a saponification of the fat in the determination of fat in milk by the Gottlieb-Röse method.

The identification of artificial coloring matter in fat, H. SPRINKMEYER and H. WAGNER (*Ztschr. Untersuch. Nahr. u. Genussmtl, 9 (1905), No. 10, pp. 598, 599*).—In the method described 10 gm. of melted fat is shaken with 10 cc. of petroleum ether. Fifteen cc. of glacial acetic acid is then added and the mixture thoroughly shaken and allowed to stand Added coloring matter is indicated by the yellow or pink color of the lower layer of the liquid.

A new automatic pipette, GREINER and FRIEDRICHS (*Ztschr. Angew. Chem., 18 (1905), No. 12, p. 465, figs. 2*).

Standard methods of sampling: A review with some suggestions, M. L. GRIFFIN (*Jour. Soc. Chem. Indus, 24 (1905), No. 4 pp. 183-185*).—A review.

The sampling of fertilizers, L. GRANDEAU (*Jour. Agr. Prat., n. ser., 9 (1905), Nos. 17, pp. 533, 534*).—A brief discussion of general conditions and precautions to be observed in sampling, with directions for sampling fertilizers of different kinds and physical condition.

METEOROLOGY—WATER.

The Weather Bureau and the homeseeker, E. L. WELLS (*U. S. Dept. Agr. Yearbook 1904, pp. 353–358*).—This article discusses the history and causes of movements of population in the United States and explains how the climate and crop service of the Weather Bureau may aid the homeseeker in determining whether the proposed change will be advantageous and in making plans to meet the new conditions and to turn them to his profit.

Meteorological observations, W. T. ELLIS, R. ROBERTSON, W. S. BLAIR, S. A. BEDFORD, A. MACKAY, and T. A. SHARPE (*Canada Expt. Farms Rpts. 1904, pp. 17, 18, 313–316, 353, 354, 362, 409, 452, 485*).—Summaries are given of observations on temperature, precipitation, etc., during 1904, at Central Experimental Farm, Ottawa; Nappan, Nova Scotia; Brandon, Manitoba; Indian Head, Northwest Territories; and Agassiz, British Columbia.

Weather report, 1904, at the Ontario Agricultural College, Guelph, J. B. REYNOLDS (*Ann. Rpt. Ontario Agr. Col. and Expt. Farm, 30 (1904), pp. 32, 33*).—A monthly summary for 1904 is given of observations at Guelph on temperature and precipitation. A summary is also given of mean temperatures, dates of first and last frosts for the 6 years 1899–1904. The general character of the weather of the year 1904, which was marked by large departures from the normal both in temperature and in precipitation, is briefly discussed.

Semi-annual bulletin of the Colorado College observatory containing the annual meteorological summary for 1904 (*Colo. Col. Studies, 11 (1905), Sci. Ser. Nos. 39–41, pp. 117–190, pl. 1, figs. 2*).—This bulletin contains an article by F. H. Loud on meteorological statistics, including notes on building, equipment, and exposure of instruments, and daily records and monthly summaries of meteorological observations; notes on meteorological topics by F. H. Loud, including discussions of topography, diurnal change of atmospheric conditions, the cold wind of October 24, and tables and charts relative to wind direction and movement, times of sunrise and sunset, etc.; and a paper on The Evolution of the Snow Crystal, by J. C. Shedd.

Meteorological observations, 1903–4, J. G. HANEY and O. H. ELLING (*Kansas Sta. Bul. 128, pp. 286–290*).—A summary is given by 10-day periods of observations at Fort Hays, Kans., on temperature, precipitation, cloudiness, prevailing winds, and general soil and climatic conditions during the period from March 1, 1903, to December 31, 1904.

Meteorological observations, J. E. OSTRANDER, G. W. PATCH, and C. H. CHADWICK (*Massachusetts Sta. Met. Buls. 197, 198, pp. 4 each*).—Summaries of observations at Amherst, Mass., on pressure, temperature, humidity, precipitation, wind, sunshine, cloudiness, and casual phenomena during May and June, 1905. The data are briefly discussed in a general note on the weather of each month.

The weather during the agricultural year, 1903–4, F. J. BRODIE (*Jour. Roy. Agr. Soc. England, 65 (1904), pp. 381–392*).—A general discussion of the weather of Great Britain and Ireland during the winter of 1903–4, and the spring, summer, and autumn of 1904, with tabulated data relating to temperature, rainfall, and sunshine during the period.

Rainfall in southern Rhodesia during December, 1904, and January and February, 1905 (*Rhodesian Agr. Jour., 2 (1905), No. 4, pp. 157–159*).—The rainfall at 43 stations during this period is recorded.

Meteorological observations of Victor and Camille Chandon of Montdidier, H. DUCHAUSSOY (*Mém. Soc. Linn. Nord France, 11 (1903–4), pp. 25–221*).—Continuous

observations during 86 years, 1784–1869, are summarized. Data are recorded for pressure, temperature, rainfall, evaporation, casual phenomena, and phenological observations.

On the organization and conducting of meteorological observations, F. W. TOUSSAINT (*Fühling's Landw. Ztg., 54 (1905), No. 9, pp. 303–312*).—A general discussion of this subject.

Islands for weather forecasting purposes, W. J. S. LOCKYER (*Nature [London], 72 (1905), No. 1857, pp. 111, 112, figs. 2*).—The importance of meteorological stations on islands in the course of the rain-bearing winds of a country is explained, and the desirability of closer cooperation between the meteorological services of different countries is pointed out.

The régime of rainfall and of rain-bearing winds, M. CHASSANT (*Ann. École Nat. Agr. Montpellier, n. ser., 4 (1905), No. 4, pp. 297–326, pls. 7*).—This is a summary of observations at the meteorological station of the National School of Agriculture of Montpellier during the period from 1873 to 1904.

Data are summarized and discussed with reference to the absolute and mean depth of rainfall, the number of rainy days, the intensity of rainfall, the distribution of rain with reference to direction of wind, snowfall, and hailstorms. The maximum annual rainfall for the period was 1,037.5 mm. in 1875, the minimum 450.8 mm. in 1881. The mean annual rainfall for the whole period was 710.1 mm. The months showing the greatest rainfall during the period were October 82.4 mm., April 79.1, January 74.5, and November 72.8. The months showing least rainfall were July 25.9 mm., February 43.8, March 50.2, and August 52.1.

The average rainfall by seasons was as follows: Autumn 218.4 mm., spring 185.5, winter 174.7, and summer 131.4. The average number of rainy days annually during the period was 91. Rains occurred most frequently in spring, but the largest amount of rainfall occurred, as noted above, in autumn, showing more violent downpours during this season. The greatest amount of rainfall occurred with southeast and east winds, especially the first.

An average of 2 snowfalls per year during the period was recorded. The largest of these occurred February 10–13, 1890, and January 6–8, 1901, each being about 50 cm. in depth. Hailstorms occurred very rarely, that of June 28, 1874, however, doing considerable damage.

Measurements of the duration of sunshine at Aas Agricultural College, 1897–1903, J. SEBELIEN (*Ber. Norges Landbr. Höiskoles Virks., 1903–4, pp. 143–167*).—The author discusses the apparatus constructed by various scientists for making sunshine records and gives comparative results with several of these.

The main work was done with a Jordan photochemical apparatus, the registration paper of which was sensitized with an organic ferrisalt, the picture being developed and fixed in a solution of potassium ferricyanid. This apparatus registered sunshine at Aas (59° 40′ N. lat.) during the light season as early as 4.15 a. m., and as late as 9.30 p. m., which is about 1 hour after sunrise and about 10 minutes before sunset, respectively. The average results of the sunshine records for the years given are shown on the following page.

Average sunshine records, Aas Agricultural College, 1897–1903.

	Sun above horizon.	Registered sunshine.	In per cent of hours sun above horizon.	Maximum.	Minimum.
	Hours.	*Hours.*			
January	209.51	51.42	24.5	37.2	13.0
February	243.92	91.03	37.3	45.6	26.4
March	353.41	126.12	35.7	58.0	12.5
April	437.26	175.10	42.3	51.3	29.6
May	530.56	240.90	45.4	57.9	26.4
June	557.36	257.69	46.3	57.6	33.4
July	552.23	274.35	49.7	63.7	38.1
August	478.39	210.73	44.0	67.3	28.3
September	382.49	150.10	39.3	49.9	19.3
October	310.57	92.80	29.9	51.1	14.9
November	223.34	68.33	30.4	40.9	11.3
December	184.11	22.03	12.0	27.9	5.3
Total for year	4,463.14	1,741.17	39.0	49.2	33.5

The results show that the months which are generally considered dark as regards number of hours and days of sunshine are also dark in so far as they have the smallest percentage of theoretically possible sunshine. It is also apparent that the largest monthly variations in the percentage of sunshine occur during the summer months.—F. W. WOLL.

On the distribution of photochemically active light on the northern hemisphere at summer solstice, J. SEBELIEN (*Arch. Math. og Naturvidensk., 26 (1904), No. 9, pp. 13*).—The paper contains a discussion of previous work in this line by Wieler, Langley, Spitaler, Bunsen, and Roscoe, with results obtained by the author.

By means of the formulas of the last two scientists mentioned, the amount of photochemically active light is calculated which falls on midsummer day on a horizontal surface unit from sunrise to sunset for each tenth or fifth degree latitude. According to the calculations of the author the maximum number of light degrees of direct sunshine, 89,060, falls at 30° latitude and the maximum degrees of diffused light, 39,839, at the north pole, the total amount of light being highest at 30° latitude (114,835°). At 82° latitude as much chemical light is received on the longest day of the year through reflection from the sky as by direct insolation, viz, 39,000 light degrees.

The results of the calculations are platted and discussed in detail in the paper.—F. W. WOLL.

Photochemical studies of the ultraviolet part of sunlight, J. SEBELIEN (*K. Norske Vidensk. Selsk. Skr., I, Math. Nat. Kl., 1904, No. 9, pp. 59; Chem. Ztg., 28 (1904), No. 104, pp. 1259–1263*).—The paper is an exhaustive treatise on methods of measuring the intensity of the chemically active rays of sunlight, and of the author's researches on this subject. The latter were made mostly with Eder's reagent (ammonium oxalate and corrosive sublimate)[a] during the years 1898 and 1899. The detailed results are given in the paper.

The precipitates obtained were, on the whole, heaviest in summer and lightest in winter, but considerable daily variations occurred, viz, calculated on a 1 sq. cm. surface, from a few tenths of a milligram in December to several decigrams in June and July, the maximum precipitate ever obtained being 590.4 mg. (July 23, 1899). The relations of the data obtained by the author to cloudiness, northern lights, sun spots, etc., are discussed, and also the amount of photochemical light due to direct radiation and to diffused light.

The two kinds of light were found of equal intensity at an altitude of the sun of 30°, a result that closely corresponds to the determinations of Bunsen and Roscoe.[b]

[a] Sitzber. K. Akad. Wis. [Vienna], Math. Naturw. Kl., 2. Abt., 80 (1879).
[b] Ann. Phys., 108, pp. 254, 255.

The author's results fail to show any definite relation between photochemical intensities and the altitude of the sun.—F. W. WOLL.

On the importance of land drainage for the prevention of frost, A. G. HOGBOM (*Svenska Mosskulturför. Tidskr., 19 (1905), No. 2, pp. 112–119*).—A discussion of the subject with special reference to conditions on moor soils.

Well waters from farm homesteads, F. T. SHUTT (*Canada Expt. Farms Rpts. 1904, pp. 191–193*). Analyses of 66 samples from different sources are reported and briefly discussed.

Ground water, M. RINGELMANN (*Jour. Agr. Prat., n. ser., 8 (1904), Nos. 49, pp. 739–741, figs. 5; 50, pp. 771–773, figs. 7*).—A brief general discussion of the conditions which influence the percolation and level of water in soils and the formation of springs, etc.

The natural hardness of water, E. BASCH (*Chem. Ztg., 29 (1905), No. 14, pp. 176, 177; abs. in Chem. Centbl., 1905, I, No. 13, pp. 956, 957*).—The author points out the importance of making a sharp distinction between temporary and carbonate hardness, as well as between permanent and gypsum hardness.

The purification and sterilization of waters by means of calcium peroxid according to the Freyssinge and Roche method (*Ann. Chim. Analyt., 10 (1905), No. 4, pp. 149, 150*).—A brief description of the method.

Changes in the bacterial content of water in passing through a distributing reservoir, B. G. PHILBRICK (*Abs. in Science, n. ser., 21 (1905), No. 535, p. 493*).—Routine weekly analyses covering a period of 10 years of the influent and effluent streams of Chestnut Hill Reservoir, Boston, are summarized.

Presence and distribution of nitrogen-fixing bacteria in the sea, KEUTNER (*Wiss. Meeresunters. Abt. Kiel, 8; abs. in Jour. Chem. Soc. [London], 88 (1905), No. 509, II, p. 189*).—The author reports that the nitrogen-fixing bacteria *Azotobacter chroococcum* and *Clostridium pasteurianum* are widely distributed in the ocean, occurring on algæ and on plankton organisms. They are also found in many fresh waters. *A. chroococcum* was found to have the power of fixing nitrogen in an 8 per cent solution of sodium chlorid.

SOILS—FERTILIZERS.

Swamp soils, R. HARCOURT (*Ann. Rpt. Ontario Agr. Col. and Expt. Farm, 30 (1904), pp. 60, 61*).—Information regarding this class of soils in Ontario is summarized from replies to a circular of inquiry sent to farmers in different parts of the province, and the general chemical characteristics of the soils based upon analyses of 35 samples are briefly discussed.

"None of the soils could be said to be 'sour' or acid, although a few were rather low in lime. They, however, all contained a low percentage of both potash and phosphoric acid, much lower than the ordinary arable lands, and they were all exceptionally low in 'available' ash constituents. Some good authorities state that soils to be productive should contain as much as 0.03 per cent of potash and phosphoric acid in a form available for plants. Only a few of them reached this minimum limit, and many of them contained as small an amount as 0.005 per cent."

Abitibi soils, R. HARCOURT, *Ann. Rpt. Ontario Agr. Col. and Expt. Farm, 30 (1904), pp. 62, 63*).—Analyses of 7 representative soils from this district are reported.

Soil investigations, F. T. SHUTT (*Canada Expt. Farms Rpts. 1904, pp. 145–151*).—Analyses of soils from British Columbia, Peace River district, and Ontario are reported and discussed.

The architecture of the soil of France, O. BARRÉ (*L'architecture du sol de la France. Paris: Armand Colin, 1903, pp. III+393, figs. 189*).—This book deals with the materials of the soil, its architecture or tectonics and sculpture; and the nature and results of geographic evolution, especially as applied to Central Europe. It

reviews the geological history of the region of France, and describes in detail the general geological formations found in that region.

Study of Belgian soils (*Bul. Agr.* [*Brussels*], *21* (*1905*), *No. 1*, *pp. 85-121*).—This is an account of conferences at which the following features of soil investigation in Belgium were discussed: Pot experiments with plants, physico-chemical analysis of soils, climatological observations, observations on natural flora, and organization of the soil studies.

On the composition of the moor soils of Jönköping County, R. TOLF (*Svenska Mosskulturför. Tidskr.*, *19* (*1905*), *No. 2*, *pp. 145-147*).

An apple orchard survey of Wayne County, New York. II, Geology, W. E. McCOURT (*New York Cornell Sta. Bul. 226*, *pp. 363-410*, *figs. 53*).—A detailed examination was made of the geology of Wayne County, New York; its geological history is given, and a description of the different soil types.

The control of soil moisture, F. T. SHUTT and W. S. BLAIR (*Canada Expt. Farms Rpts. 1904*, *pp. 157-164*, *359-361*).—The experiments here reported were a continuation of those of previous years (E. S. R., 16, p. 240) and were designed to ascertain (1) the effect of cultivation and mulching on soil moisture and (2) the relative amounts of water withdrawn from the soil by crops grown in different ways.

In the first series of experiments the crops made poor growth and the results were somewhat inconclusive; in the second the results "clearly indicate that much moisture may be saved by sowing the crops in drills and cultivating between the rows from time to time throughout the summer months." In a series of experiments at Nappan to determine the effect of different cover crops on the moisture content of orchard soil the results indicate that trees may be injured by exhaustion of the water supply in the soil by a growing crop of grain such as rye.

The absorption of water by clay, J. M. VAN BEMMELEN (*Ztschr. Anorgan. Chem.*, *42* (*1904*), *No. 3*, *pp. 314-324*).—Studies of the amount of water absorbed at 15° C. under varying pressures by soils which had been dried at 100° C. are reported, showing that the process of absorption is reversible, it being possible to repeat hydration and dehydration as often as desired. The rate at which absorbed water was expelled was not essentially different from the rate at which water itself evaporated under similar conditions.

The use of coloring matters in soil investigations, B. SJOLLEMA (*Jour. Landw.*, *53* (*1905*), *No. 1*, *pp. 67-69*).—It is shown how the fact that coloring matters, such as Congo red, alizarin, fuchsin, methyl violet, methyl blue, etc., form colored compounds with the colloidal substances of soils may be utilized in the microscopic examination of soils to distinguish between these substances and the quartz and other mineral constituents which are not colored.

The isolation of colloidal substances in soils, B. SJOLLEMA (*Jour. Landw.*, *53* (*1905*), *No. 1*, *pp. 70-76*).—A further study of the author's centrifugal method (E. S. R., 7, p. 752) with subsequent chemical and microscopic (with methyl violet coloration) examination of the separated products is reported.

Field trials of the Swedish Moor Culture Association, 1904, H. VON FEILITZEN (*Svenska Mosskulturför. Tidskr.*, *20* (*1905*), *No. 3*, *pp. 224-240*).—Reports of experiments at different moor plantations with regard to the best mechanical treatment and system of fertilization of moor soils for culture of small grains, legumes, hay, and root crops.

Some questions relating to soil culture, A. ARNSTADT (*Fühling's Landw. Ztg.*, *54* (*1905*), *No. 6*, *pp. 215-219*).—A general discussion of means of improving the physical condition of soils.

The action of ammoniacal salts on nitrification of sodium nitrite by the nitric ferment, E. BOULLANGER and L. MASSOL (*Compt. Rend. Acad. Sci.* [*Paris*], *140* (*1905*), *No. 10*, *pp. 687-689*).—Studies were made in the Winogradski and Omeli-

anski mineral medium containing varying amounts of sodium carbonate (0.15 to 1 gm. per 1,000).

From the results it is concluded that the amount of sodium carbonate may be reduced to 0.2 gm. per 1,000 without inconvenience, and if it does not exceed 0.25 gm. the transformation of nitrite is not interfered with by the addition of ammonium sulphate to the medium. If, however, larger amounts are present the free ammonia (but not the ammonium carbonate) formed retards the action of the nitric ferment.

Nitrification, L. GRANDEAU (*Jour. Agr. Prat., n. ser., 9 (1905), No. 10, pp. 300, 301*).—A brief history of the discovery of the true nature of this process.

Nitrifying organisms, L. GRANDEAU (*Jour. Agr. Prat., n. ser., 9 (1905), No. 11, pp. 332, 333*).—A brief account of the discovery by Winogradski of the fact that these organisms can develop normally in a purely mineral medium.

Nitrification in the soil.—The nitrous organism, L. GRANDEAU (*Jour. Agr. Prat., n. ser., 9 (1905), No. 12, pp. 369, 370*).—This is a brief discussion of the investigations of Winogradski and others on the transformation of organic nitrogen first into ammonia, then into nitrous acid, and finally into nitric acid.

Nitrogen-fixing bacteria, H. FISCHER (*Jour. Landw., 53 (1905), pp. 61–66; abs. in Jour. Chem. Soc. [London], 88 (1905), No. 509, II, p. 189*).—Of 6 samples of soil from differently manured plats only 2 from plats which had received lime were found to contain Azotobacter. The original soil of the plats was a heavy loam with only 0.145 per cent of lime.

The bacterial flora of the soil, L. GRANDEAU (*Jour. Agr. Prat., n. ser., 9 (1905), No. 9, pp. 269, 270*).—A brief general statement regarding the specific rôle of different classes of soil organisms.

Investigations of the bacterial content of cultivated and uncultivated moor soils at Flahult, O. FABRICIUS and H. VON FEILITZEN (*Svenska Mosskulturför. Tidskr., 19 (1905), No. 2, pp. 84–90*).—Chemical and bacteriological examinations of 6 types of moor soils that were of different origin or had received different mechanical treatment were made at the moor culture station at Flahult, Sweden.

The results show that the white-moor soils in their natural condition contain only few bacteria, on account of the acid reaction of such soils. The bacterial flora is only slightly changed by mere drainage, but is greatly increased by liming, admixture with sand, manuring, and mechanical treatment, since the conditions for bacterial growth then become more favorable, and bacteria are moreover added in the sand and manure. The total number of bacteria in the soil is closely related to the soil temperature, and falls and rises with the latter. The number of bacteria on a well manured and well cared for high-moor plantation appears to be about as high as on a low-moor soil under similar physical conditions.—F. W. WOLL.

Methods of bacteriological investigation of soils, II, F. LÖHNIS (*Centbl. Bakt. [etc.], 2. Abt., 14 (1905), No. 1, pp. 1–9; abs. in Chem. Centbl., 1905, I, No. 10, p. 768*).—In continuation of previous work, the author studied the behavior of soil bacteria under various conditions of medium and methods of culture. The behavior of the organisms under different soil conditions is also discussed.

The assimilation of atmospheric nitrogen by a peat mold, CHARLOTTE TERNETZ (*Ber. Deut. Bot. Gesell., 22 (1904), pp. 267–274; abs. in Centbl. Agr. Chem., 34 (1905), No. 3, pp. 205, 206*).

Mutual action of plant food compounds in the soil on their assimilation by plants, P. KOSSOVICH (*Zhur. Opuitn. Agron. (Russ. Jour. Expt. Landw.), 5 (1904), No. 5, pp. 581–598*).—The hypothesis of Prianishnikov and Shulov (E. S. R., 14, p. 851) attributes the greater availability of phosphoric acid in crude phosphates in the presence of ammonium salts than in presence of nitrates to the fact that the ammonium salts are physiologically acid, and thus aid in the solution of the insoluble phosphates.

To further study this hypothesis the author made a series of experiments with

barley grown in sterilized sand, with various combinations of soluble and insoluble phosphates and with nitrogen in form of sodium nitrate, ammonium nitrate, and ammonium sulphate. Ingenious apparatus used to secure and maintain perfect sterilization, and thus to prevent nitrification, which the author considers the indeterminate factor in the investigations of Prianishnikov and Shulov, is described in detail.

The barley was sown July 25 and normally developed plants were harvested September 10. The author concludes from the results obtained that under the sterile conditions maintained the plant utilized equally well the nitrogen from nitrates and from ammonium salts. The form of combination of nitrogen, however, exerted a decided indirect influence on the growth of the plant and the assimilation of plant food by modifying the culture medium.

Plants receiving only nitrogen in form of nitrates took up relatively more acids than bases, thus causing an alkalinity of the nutritive medium, which may have exerted an injurious influence on the growth of the plant and influenced the ability of its roots to dissolve the needed plant food. When only nitrogen in form of ammonium salts was present, the plant took up relatively more of the bases than of the acids, and thus brought about an acid condition of the medium which was likewise injurious to plant growth, unless sufficient neutralizing material was present in the soil. This acid condition, however, facilitates the solution of other plant food constituents, such as the phosphoric acid in insoluble phosphates.

When nitrogen in form of both ammonium salts and nitrates was present, the plant utilized nitrogen equally from both sources without sensibly affecting the reaction of the medium. The conditions were in this case, therefore, most favorable for normal development.—P. FIREMAN.

On different degrees of availability of plant nutrients, O. LOEW and K. ASO (*Bul. Col. Agr., Tokyo Imp. Univ., 6 (1905), No. 4, pp. 335–346*).—The authors discuss the varying chemical availability of lime and magnesia and of phosphoric acid under different conditions, stating that Loew's hypothesis as to the most favorable ratio of lime to magnesia is predicated upon an equal state of availability of the two bases.

"This ratio changes, however, with the difference in availability, since of the more available form also more of the base will enter into the plant and thus the ratio offered to the roots and that which enters into the plant body will differ. Magnesia in the form of burnt magnesia is more available than in the form of pulverized magnesite and in the form of magnesium sulphate still more available. The amounts in which the easily available forms of lime or magnesia can produce the same result as 100 parts of the natural carbonates in the finest powder it is proposed to call the agronomical equivalent. This [factor] changes with the nature of the soils, and the partial transformation of the applied compounds into other forms in the soil.

"The action of lime and magnesia in physiological respect has to be distinguished from the actions these bases exert on the soil.

"The [reason] why lime in the form of gypsum acts differently from lime in the form of carbonate or slaked lime is the low degree of availability, since dilute acids do not increase the solubility. Even heavy doses of gypsum in the soil do not augment essentially the lime content of the leaves, and an excess of gypsum is not so injurious as an excess of carbonate.

"The decrease in harvest by liming certain soils is not always due to a diminution of the availability of phosphoric acid, but may in many cases be due to the production of a very unfavorable ratio of lime to magnesia. The magnesia content of soils has always to be taken in account when [lime and phosphatic manures are applied]."

The determination of the productiveness and plant food requirements of soils, J. KÖNIG (*Landw. Vers. Stat., 61 (1905), No. 5–6, pp. 371–396*).—A discussion of this subject based upon a critical review of literature relating to it, the subject

being considered from the standpoint of physical properties and chemical properties, including various methods of physical and chemical examination and fertilizer experiments.

Composts and composting, B. W. KILGORE ET AL. (*Bul. N. C. Dept. Agr., 26 (1905), No. 2, pp. 58–60*).—Formulas and general directions for preparing composts, especially those containing cotton seed and cotton-seed meal, are given.

Fertilizers and amendments, F. T. SHUTT (*Canada Expt. Farms Rpts. 1904, pp. 151–157*).—Analyses of wood ashes (leached and unleached), muck ashes, ashes from carbid works and from an incinerator, calcareous deposits from British Columbia, and whalebone are reported and discussed.

Analyses of cotton-seed meals (*South Carolina Sta. Bul. 105, pp. 6*).—Tables are given of analyses of 84 samples of meal collected as far as possible from all mills in the State. "The average ammonia yielded by the 84 meals analyzed was found to be 7.52 per cent. Eleven were found to yield 8 per cent or over of ammonia. Thirty-one were found to yield 7½ to 8 per cent of ammonia. Thirty-five were found to yield 7 to 7½ per cent of ammonia. Five were found to yield 6½ to 7 per cent of ammonia. Two were found to yield 6 to 6½ per cent of ammonia."

Analysis of commercial fertilizers (*South Carolina Sta. Buls. 97, 98, 99, 100, 101, 102, 104, 106, 107, 108, pp. 3 each*).—Tabulated analyses and valuations of fertilizers.

The utilization of ammonia nitrogen, A. SCHÄFER (*Fühling's Landw. Ztg., 54 (1905), No. 4, pp. 142–145*).—Investigations by Sessons on the effect of lime, temperature, and moisture on the loss of ammonia from soils are briefly reviewed, showing in brief that there may be considerable losses of nitrogen when ammonium salts are applied to light sandy soils rich in lime, particularly if the material is not thoroughly incorporated with the soil and the conditions made as favorable as possible for nitrification.

The use of peat for the transformation of calcium cyanamid into ammoniacal compounds, R. PEROTTI (*Atti R. Accad. Lincei, Rend. Cl. Sci. Fis., Mat. e Nat., 5. ser., 14 (1905), I, No. 3, pp. 174–177; abs. in Jour. Chem. Soc. [London], 88 (1905), No. 510, II, p. 278*).—The injury due to the direct application of calcium cyanamid to growing crops is stated to be due to hydrolysis of the cyanamid, resulting in the formation of ammonium compounds. This hydrolysis can be brought about before application to the soil by mixing the cyanamid with peat and water. It is suggested that the hydrolyzed material may be used for the transformation of a fresh quantity of the cyanamid and the process thus repeated until a mixture very rich in nitrogen is obtained.

Nitrate of soda as a means of protection against frost (*Deut. Landw. Presse, 32 (1905), No. 31, p. 269, fig. 1*).—A case of frost resistance due to vigorous growth of flowers, vegetables, etc., resulting from applications of nitrate of soda is reported.

Value of potash to farm crops, J. J. WILLIS (*[Rothamsted], 1905, pp. 14, pl. 1*).—A discussion of this subject based upon Rothamsted experiments.

Is the availability of phosphoric acid in bone dust modified by the presence of gypsum? T. KATAYAMA (*Bul. Col. Agr., Tokyo Imp. Univ., 6 (1905), No. 4, pp. 353–356*).—A series of pot experiments with rice grown in sand to test the relative effect of calcium carbonate and calcium sulphate on the availability of the phosphoric acid of bone meal is reported.

The results show that the availability of the phosphoric acid was not depressed by gypsum, but was reduced to a marked extent by applications of calcium carbonate. It should be borne in mind, however, in connection with this latter fact that the artificial soil experimented with contained no humus. Very different results were obtained by Suzuki with a soil containing 11 per cent of humus, as noted above. Varying amounts of magnesium carbonate were used in connection with the calcium compounds. The results show that the larger amounts of magnesia did not act favorably.

AGRICULTURAL BOTANY.

The relation of plant physiology to the development of agriculture, A. F. WOODS (*U. S. Dept. Agr. Yearbook 1904, pp. 118-132*).—The author discusses the relation of plant physiology to the development of agriculture, paying particular attention to its rôle in plant breeding, the physiological action of plants in securing their nutrition, nature and causes of plant diseases, etc.

Regarding the cause of sap pressure and flow in the maple, K. M. WIEGAND (*Abs. in Science, n. ser., 21 (1905), No. 535, p. 504*).—It is claimed that various investigators have shown that the seat of pressure in the maple during the sugar season is in the aerial parts of the tree, principally in the trunk, and pressure is induced by temperature acting as a stimulus. When the temperature passes 2–4° C. pressure results, but a freezing of the tissue is by no means necessary.

The author reviews the various theories regarding sap pressure, and concludes that the only adequate explanation is that pressure is due to the function of living cells. The pith rays seem to be the only ones in proper position in the wood to allow the production of pressure. In this case pressure would be due to the unequal permeability, in opposite directions, of the membrane at the ends of the cells. This would quite likely be caused by the penetration of the morning temperature. Water would tend to pass from the inner layers to the outer, and the sugar carried in solution would be excreted as a necessary factor in the production of pressure.

Further studies on the starch grain, H. KRAEMER (*Abs. in Science, n. ser., 21 (1905), No. 535, p. 504*).—The author calls attention to the alteration of the compound starch grains in seeds of *Theobroma cacao* on the application of heat. Heat was found to transform the starch of cacao into masses resembling the natural starch grains of corn, wheat, rye, barley, and potato in size and shape, and in some cases even showing the concentric or excentric lamellated structures characteristic of those grains.

Notes are also given on the polariscopic examination of starch grains of different origin, in which it was found that in using a red and green selenite plate the yellow and blue areas of the starch grain did not occupy the same relative position in all of the grains. Different explanations are offered for this phenomenon, it being attributed to differences in shape and structure of the individual grains, difference in composition of the different parts of the same grain, or that there are two distinct kinds of reserve starch grains. This last hypothesis is believed to be the most plausible.

Further observations on the nature of color in plants, H. KRAEMER (*Abs. in Science, n. ser., 21 (1905), No. 535, pp. 499, 500*).—A preliminary account of the author's studies on the nature of color in plants has been given (E. S. R., 16, p. 540).

In the present paper the author summarizes his observations, claiming that plant color substances may be divided into 2 classes: Organized color principles, which are characterized by being an organic part of the plastid body and insoluble in water or dilute alcohol, but soluble in xylol and similar solvents; and unorganized color principles, which are not a fundamental or organic part of the plastid, but occur in the vacuoles in the cells of the higher plants and in the vacuolules of the plastids of the brown and red seaweeds. Unorganized color principles are soluble in water and dilute alcohol and insoluble in xylol and similar solvents.

In the photosynthetic processes of the plants the unorganized color substances may be produced, as in the early spring foliage, autumn foliage, foliage of alpine plants, brown and red marine algæ, and the foliage of certain varieties of roses, beech, nasturtium, etc.

The unorganized color substances are distributed ususally at the terminus of the branch, as in the foliage and flowers, or in the roots; but sometimes they occur in both tops and roots. The wide distribution of so-called flower color substances in other parts of the plant points to the conclusion that they are products of plastid

activity, and are not to be considered when found in the flower as designed primarily for the attraction of insects.

The occurrence of chromoplasts in a reserve organ and of reserve starch in the petals of certain plants suggests that these organs have a function of storing nutrient material.

Mutants and hybrids of the Œnotheras, D. T. MacDougal et al. (*Carnegie Inst. Washington Pub. 24, pp. 57, pls. 22, figs. 2, dgms. 11*).—The authors give the results of investigations carried on to determine the ancestral habitat of *Œnothera lamarckiana*, the relationship of this species to various others and to certain hybrids, the dominance of parental characters in hybrids, and the estimation of the fluctuating variability of some of the characters of different species.

The cultures of the evening primroses made at the New York Botanical Garden show that two or more elementary species are grouped together under some of the specific names as ordinarily accepted. The failure to recognize these elements has resulted in the prevalent opinions as to the wide range of variability exhibited by these plants.

It is evident that in the investigation of native species for possible mutating forms the first task to be completed is the resolution of the forms selected into their elementary constituents, and mutations may be taken as properly authenticated only when appearing in guarded pedigree cultures from seeds produced by a known individual, which should always be preserved for comparison. A study of various known mutants seems to indicate that mutation is induced or at least increased by favorable and not by adverse conditions.

The wild legumes of Maryland and their utilization, J. B. S. Norton and E. P. Walls (*Maryland Sta. Bul. 100, pp. 97-124, figs. 17*).—In this bulletin the authors furnish a list of the leguminous plants known to occur in the wild state in Maryland, showing the localities, kinds of soil, and surroundings where they grow best, and indicating the possible ways in which they may be utilized.

Suggestions are offered as to the possible improvement of some of the more promising species, experiments along this line being in progress at the station. After briefly describing the value of leguminous plants in restoring soil fertility, the authors take up the enumeration and distribution of species throughout the State.

Inoculation for the growth of legumes, F. T. Shutt (*Canada Expt. Farms Rpts. 1904, pp. 164-166*).—The author gives a brief statement as to the work that has been carried on at the Canada experimental farms relating to inoculation for the growth of legumes.

Experiments have been carried on with cultures prepared in Germany as well as those obtained from this Department, and the author states that as a result of his observations the necessity for inoculation is not as great as was once thought to be the case. In the Province of Ontario, at least, the failures to obtain a good catch of clover have been due to a deficiency of moisture, unsuitable mechanical condition of the soil, or insufficient drainage rather than to a lack of nitrogen-assimilating organisms.

A similar condition was found to prevail in British Columbia, and the author concludes that the severity of the winter, lack of moisture, uncongenial conditions of soil, or poor seed will be found to militate more against successful clover growing than any supposed lack of tubercle bacteria.

The proliferation of tobacco flowers, F. W. T. Hunger (*Ann. Jard. Bot. Buitenzorg, 2. ser., 4 (1904), pt. 1, pp. 57-60, pls. 2*).—Descriptions are given of a curious proliferation of tobacco flowers in which the character as a flower in some cases has totally disappeared.

Principles of classification of bacteria, F. D. Chester (*Abs. in Science, n. ser., 21 (1905), No. 535, pp. 485, 486*).—The author claims that as far as possible morphological characters should be the primary basis for the classification of bacteria, and for

generic classification the system of Migula, based upon the character of the flagella, is recommended. The division of genera into groups is based on leading characters, such as spore formation, relation to oxygen, liquefaction of gelatin, fermentation of lactose, dextrose, and saccharose, reduction of nitrates, and chromogenesis.

The effect of freezing on bacteria, E. F. SMITH and D. B. SWINGLE (*Abs. in Science, n. ser., 21 (1905), No. 535, pp. 481–483*).—The results of experiments made in freezing a number of different species of bacteria and other plant and animal pathogenic forms are given. Some of the freezings were made in liquid air with usually one-half hour exposure, while the others were made in salt and ice with an exposure of 2 hours. After freezing, thawings were made in tap water, and inoculations made from the cultures. These were sown on plates and the colonies counted after development.

The authors found that the effect of very low temperatures in destroying bacteria has been greatly overestimated. The results were as destructive with salt and pounded ice as with liquid air. The critical period of bacteria seems to be about 0° C., and if an organism can pass this point in safety it is believed that it would not be injured by any amount of cold that could be applied. In every culture some individuals were found that were unharmed when subjected to the temperature of liquid air (190° C.), although the number was a very small proportion of the whole. Repeated freezings and thawings gradually reduced the number of organisms present, although 10 freezings and thawings in the course of 8 hours did not kill all the individuals of the cabbage black rot organism (*Pseudomonas campestris*).

So far as any general inference can be drawn from the experiments, the authors conclude that bacteria behave very much like the higher plants and animals in respect to injury by freezing.

The metabolism of chromogenic bacteria, M. X. SULLIVAN (*Abs. in Science, n. ser., 21 (1905), No. 535, pp. 489, 490*).—Synthetic culture media are said to be the best for the biochemical study of bacteria.

Some bacteria show little power to grow upon synthetic media, but it is believed probable that the power to grow on such media can be developed and that the medium may be accommodated to the organism or the organism to the medium. Many bacteria grow readily on synthetic culture media with or without pigment formation. Whether producing pigment or not these chromogenic bacteria give the same metabolic products, as far as they have been analyzed.

The metabolic products so far investigated are various acids, ammonia, alcohol, benzol derivatives, and albuminous bodies. The metabolic products of a number of species are listed.

A review of the Bacillus subtilis group of bacteria, F. D. CHESTER (*Centbl. Bakt. [etc.], 2. Abt., 13 (1904), No. 24, pp. 737–752*).—The author gives a review of studies on the *Bacillus subtilis* group of bacteria, which is limited to those species of bacillus which produce spores, liquefy gelatin, and grow under aerobic conditions. The morphology of the bacteria is described, notes being given on the measurement, spore formation, germination, vegetative stage, etc., after which the cultural features, chemical functions, and classification of a number of species are discussed at length.

FIELD CROPS.

Field experiments with farm crops, W. SAUNDERS, J. H. GRISDALE, W. T. MACOUN, F. T. SHUTT, J. FLETCHER, C. E. SAUNDERS, R. ROBERTSON, S. A. BEDFORD, A. MACKAY, and T. A. SHARPE (*Canada Expt. Farms Rpts. 1904, pp. 19–37, 78–103, 128–131, 135, 136, 182–191, 255, 256, 259–281, 316–339, 371–389, 411–435, 453–466, dgm. 1*).—The results of experimental work with field crops at the Canada experimental farms in 1904 are reported. The work was carried on in continuation of experiments generally in progress for a series of years (E. S. R., 16, p. 246).

Wheat.—At the Central Experimental Farm at Ottawa a plat on which clover was plowed under in 1901 gave an increase in 1903 of 1 bu. 20 lbs. of grain and 360 lbs. of straw per acre as apparently due to the treatment. The following results were obtained by the chemist in studying the effect of rust on the straw and grain of wheat:

Analysis of rusted and rust-free wheat.

	Weight of 100 kernels.	Moisture.	Crude protein.	Crude fat.	Carbohydrates.	Fiber.	Ash.
	Grams.	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*
Straw from rust-free wheat		7.92	2.41	1.65	39.00	39.95	9.04
Straw from rusted wheat		7.92	7.69	1.97	38.44	36.78	7.20
Grain from rust-free wheat	3.0504	12.26	10.50	2.56	70.55	2.29	1.84
Grain from rusted wheat	1.4944	10.66	13.69	2.35	68.03	3.03	2.24

The following crossbred varieties produced at this farm are described for the first time: Early Riga, Downey Riga, Riga, Bishop, and Red Preston.

At the Manitoba Experimental Farm at Brandon, seed from the largest heads selected from standing grain yielded 54 lbs. more per acre than unselected seed. Rusty wheat was cut at intervals of one week and the best results were obtained by cutting in the dough or late milk stage. In a series of experiments with barnyard manure, green manure, and fallow, the largest average yields of grain were obtained from the fallow plats. The fresh-manure plats gave larger returns than those treated with rotted manure, and peas were more effective as a green manure than clover. Plowing either 2 in. or 3½ in. deep made no appreciable difference in the results.

Of different spring varieties grown in a field test on the experimental farm for the Northwest Territories at Indian Head, Huron, a variety obtained by crossing White Fife and Ladoga, was earliest in maturing, requiring 118 days to complete its growth. This variety also led in productiveness, with a yield of 42 bu. 47 lbs. per acre. A comparison of 4 early and 2 late varieties showed that Preston, Stanley, and Huron mature in practically the same number of days. For 4 years fallow produced an average of 11 bu. 46 lbs. per acre more than stubble land. A test with commercial fertilizers for spring wheat at this farm resulted in favor of an application consisting of 200 lbs. of superphosphate No. 1, 100 lbs. of muriate of potash, and 100 lbs. of nitrate of soda per acre, half of the nitrate being applied as a top dressing when the grain was 2 in. high.

Spelt and emmer.—Ten varieties of spelt and emmer were under test at Ottawa. The best yield of grain per acre, 3,060 lbs., was obtained from single emmer (*Triticum monococcum*). This grain was only slightly rusted, while the other varieties were more or less seriously injured. At the experimental farm for the maritime provinces at Nappan, spelt gave larger yields than emmer, but a greater proportion of the crop was attacked by rust. These crops are reported as giving satisfactory yields in dry regions and producing a comparatively bright and clean straw.

Oats.—Regarding the influence of previous crops on the yield of grain and straw of Banner oats at Ottawa, it was found that the largest yield, 89 bu. of grain and 5,480 lbs. of straw per acre, was obtained where sand vetch was plowed under twice the preceding season. Of the new varieties added this year, which are briefly described, Garton Abundance ranged fourth in yield, and Daubeney and Gold Rain, a yellow sort, ripened early.

At Brandon an 11-acre field of Banner oats yielded 73 bu. 27 lbs. per acre, and a 5-acre field of American Beauty, 81 bu. 2 lbs., the weight per bushel being 37 and 38 lbs., respectively. In the average results for 4 years with oats grown in field lots at Indian Head, Banner led with a yield of 102 bu. 6 lbs. per acre, being followed by Abundance with 96 bu. 32 lbs.

Barley.—In 1904 Escourgeon, Black Japan, Eclipse, and Bere were added to the list of 6-rowed varieties at Ottawa. Of 30 varieties under test 13 are crossbred sorts produced at the experimental farms. In earliness the 6-rowed varieties have not differed much, but Mensury, Common, Odessa, and Stella were several days earlier than most of the varieties in the list. Champion appeared to be the best variety of the beardless 6-rowed type. Zero winter barley, a 6-rowed variety under experiment one season, partly winterkilled, but yielded at the rate of 41 bu. 32 lbs. per acre.

Of 27 varieties of 2-rowed barley under test, 10 are crossbred sorts originated at the farms. The earliest varieties in this list were Beaver, Jarvis, and Gordon. Yale, a 6-rowed sort obtained by crossing Duckbill and Rennie Improved, gave good results at Brandon, and has also given excellent returns at nearly all the experimental farms. Beardless varieties at this farm have been comparatively low in yield and weight per bushel. The 6-rowed varieties had the strongest straw and withstood lodging on summer fallow land, while the straw of 2-rowed Chevalier varieties has usually been too weak on such land. Among 9 varieties grown in field lots for 4 years at Indian Head, Claude ranked first in yield per acre with 63 bu. 4 lbs. and Royal second with 60 bu. 23 lbs. For 4 years fallow at this farm has produced an average of 21 bu. 6 lbs. more per acre than stubble land.

Rye.—At Ottawa 4 varieties of winter rye ranged in yields from 40 bu. to 70 bu. 40 lbs. per acre, the latest variety being Giant. All varieties remained free from rust. At Indian Head spring rye sown May 16 required 91 days to mature. The yield of grain was 18 bu. and that of straw 1,880 lbs. per acre.

Corn.—The cost of producing a ton of silage in the silo at Ottawa this season was $1.63, and the cost of producing an acre ready to feed from the silo was $21.25. Corn for silage grown in drills yielded 1,074 lbs. per acre more than corn in hills. As in previous years, rows 21 and 24 in. apart for the closest planting gave the best results at Ottawa, Nappan, Brandon, and Indian Head.

Peas.—At Ottawa, Chancellor appeared to be the earliest variety, ripening several days before Golden Vine. Of the 34 varieties tested 17 were crossbred sorts produced at the experimental farms. Laxton Charmer, with a yield of 58 bu. 40 lbs. per acre, was the leading variety of a number of garden peas grown in field lots at Indian Head.

Potatoes.—At Ottawa the average yields for 5 years of the 12 leading varieties ranged from 432 bu. 58 lbs. to 496 bu. 19 lbs. per acre. The 4 best varieties of the 12, mentioned in decreasing order of yield, were Professor Maercker, Late Puritan, Burnaby Mammoth, and Money Maker. The yields of 14 varieties tested in addition to the regular list in 1904 ranged from 308 to 545 bu. 36 lbs. per acre. The 3 leading varieties in this collection—Ashleaf Kidney Heber Rawlings, Dalmeny Beauty, and White Albino—yielded each over 500 bu.

Spraying this season was of much greater benefit to the late than to the early varieties. Where Bug Death and Bordeaux mixture were applied together an increase in crop value of $21.86 per acre was secured, as compared with $17.68 in the test where Paris green was used with the Bordeaux mixture. At Nappan the crop treated with Bordeaux mixture and Paris green gave the largest yield per acre, but Bug Death alone was quite as effective in killing the bugs as either Paris green or poisoned Bordeaux mixture. At the British Columbia Experimental Farm at Agassiz whole, smooth, even-sized seed potatoes, averaging from 2½ to 3½ oz. each, gave better results than large seed with not less than 3 eyes each and weighing on an average 1 oz., and seed cut to 2 eyes each and averaging about ¾ oz. in weight.

Flax.—At Ottawa, Yellow Seed and Novarossick, the most productive varieties for the season, yielded 20 bu. and 19 bu. 10 lbs. per acre, respectively. These varieties were medium early, while Russian and Common were earliest in maturing, requiring only 75 and 76 days, respectively, to ripen. At Brandon, La Plata with 23 bu. 32

lbs. and Novarossick with 22 bu. 8 lbs. per acre were the leading varieties. By sowing flax on new breaking at this farm a yield of 8 bu. 12 lbs. per acre was obtained, but the following wheat crop was reduced by 8⅗ bu. per acre as compared with new land not sown with flax.

On old land wheat after flax gave a yield of 43 bu. 40 lbs. per acre as compared with 37 bu. where it was grown after wheat, and still smaller yields where it followed oats, barley, millet, or summer fallow. The following yields are recorded for the different crops grown after flax: Wheat 43 bu. 40 lbs., oats 68 bu. 8 lbs., barley 52 bu. 44 lbs., and peas 53 bu. 20 lbs. per acre.

At Indian Head sowing 40 lbs. of seed gave the best results, while the yields obtained from plats sown at the rate of 20, 30, and 50 lbs. per acre were practically the same. Flax on flax stubble at this farm yielded only 9 bu. 33 lbs. per acre, while on 3 fallow plats from 12 bu. 24 lbs. to 19 bu. 18 lbs. per acre were obtained.

Buckwheat.—Five varieties of buckwheat were sown June 11 at Nappan, and harvested September 5. Siberian or Tartarian ranked first in yield, with 29 bu. 8 lbs. per acre, Silverhull with 22 bu. 24 lbs. standing next.

Root crops.—Turnips, mangels, carrots, and sugar beets were sown at Ottawa on May 17 and 31 and harvested October 14 and 28. In every instance the first sowing produced much the better yields. At Brandon, where similar tests are in progress the results were also in favor of the earlier sowing, while at Indian Head the second seeding gave better yields.

Grasses and other forage crops.—Of 5 different grass mixtures at Ottawa only 1 gave a larger yield than the usual mixture of 10 lbs. of timothy and 8 lbs. of red clover. A plat of 13.75 acres seeded to this common mixture yielded pasturage during the season valued at $10.41 per acre. Notes are given on different grasses and grass mixtures grown for hay. The best yield on the permanent pasture experiment plats, 6 tons 1,398 lbs., was secured from sainfoin sown at the rate of 40 lbs. per acre, while Awnless brome grass gave the lowest yield. The mixtures containing several grasses and clovers stood next to sainfoin this season.

Alfalfa, without a nurse crop, produced a more satisfactory growth at Nappan than when sown with wheat at the rate of 2 bu. per acre. At this farm Moha Green California millet yielded over 4 tons of green feed more per acre than Italian or Indian, and gave more than double the yield of Pearl, or Cat Tail, White Round French, Algerian, and Moha Hungarian. A mixture of 7 lbs. each of Western rye grass and Awnless brome grass gave good results at Brandon.

In a series of tests the highest yield of hay per acre, 2.7 tons, was obtained from a mixture of alsike clover and timothy, being followed by Mammoth red clover with 2.15 tons. The yields of millet at this farm were below the average, with the exception of Moha Hungarian, which yielded 6 tons of hay per acre. At Indian Head one-half acre of brome grass, plowed 2 in. deep in May, 1903, disked and rolled flat, gave this year 1 ton of hay without reseeding. Alfalfa sown in 1902 was almost entirely killed by the spring frosts, and this season Common, Utah, and Turkestan alfalfa and red clover sown in May gave very good results. Soy beans have generally given better results at Agassiz than horse beans, and the results with clover and corn for silage showed a difference of nearly 6 tons per acre in favor of clover.

Miscellaneous.—The average results of fertilizer experiments with wheat, barley, oats, carrots, mangels, and turnips, in progress since 1888 and previously described, were as heretofore in favor of the use of 12 tons of barnyard manure per acre, and indicated that fresh manure is of equal value with rotted material. The season's results at Ottawa with different fertilizer applications show that 800 lbs. of Thomas phosphate produced the largest yield of oats, 400 lbs. per acre of the same fertilizer produced the largest yield of clover, and 400 lbs. per acre of superphosphate the largest yield of Awnless brome grass. Clover as a green manure gave good increases

in the yield of a large number of cereal and forage crops. The results of a mixed crop experiment indicate that in general pure grains may be expected to give greater yields than mixtures.

In an experimental silo at Ottawa corn lost 15 per cent of its gross weight; a mixture of corn and rape, 33 per cent; and rape alone, 54 per cent. This material was put into the silo in September and taken out in March.

Of different methods of fall cultivation, shallow plowing in August, cultivating 3 times, harrowing 3 times, ridging the surface soil for the winter, cultivating once in the spring, and harrowing once at the time of sowing with the seeder produced the best results.

An experiment with 12 different crop rotations at Ottawa is described and the results thus far obtained are noted and given in tables. The results of similar tests at some of the other farms are reported without comment. Notes on summer fallow, deep and shallow breaking, backsetting, and working land after the first crop has been produced are given in the report from the Northwest Territories Experimental Farm. The cost of producing one ton and one acre of different kinds of hay at Ottawa is also given.

Experiments at Fort Hays Branch Station, 1902-1904, J. G. HANEY and O. H. ELLING (*Kansas Sta. Bul. 128, pp. 262-278, 291-302*).—A trial of seeding alfalfa on sod was begun in 1902, the field after breaking being disked both ways, harrowed twice, and worked with a subsurface packer. About 2 weeks later, May 6, it was harrowed again and after a shower on May 19, and as soon as dry enough the clod masher was run over the field and followed by another harrowing. A few days later a heavy rain fell which was all absorbed by the surface soil.

After the field had become dry alfalfa seed at the rate of 15 lbs. per acre was drilled in with a disk drill provided with press wheels. This work was finished on May 29, and on July 23, 57 days later, the alfalfa had begun to bloom and was mown. In 1903, 3 crops of hay were cut on this field, the first on June 12, the second July 23, and the last September 25. The total yield of hay was about 2½ tons per acre.

In 1902 wheat stubble was plowed and packed during July, and alfalfa seeded September 4 with disk drill and press wheels. A little over 10 lbs. of seed per acre was used. A good stand and a fair growth during the fall was obtained, and the fall seeding gave good results.

Bromus inermis was sown on sod which had received nearly the same treatment as the sod of the alfalfa field. Broadcasting the seed by hand was found preferable to using the drill. The field was sown May 29, but owing to heavy rains, only a thin stand was secured. On a higher piece of ground sown June 12 and harrowed before and after sowing, a very fine stand was obtained. Fall seeding of *Bromus inermis* did not give as good results. The following year, which was exceptionally wet, these fields of *Bromus inermis* made a very favorable growth.

In an experiment with fodder beets Golden Tankard yielded 9.1 tons and mangels 15.6 tons per acre. With irrigation the mangels yielded 21.1 tons. Notes are also given on Pearl millet, rape, melons, turnips, and a number of garden crops.

In a variety test with barley the yields ranged from 8.40 to 33.24 bu. per acre, the leading varieties being Telli, Black, and Six-rowed, all yielding over 30 bu. per acre. Harrowing and disking, or packing the land after plowing, were apparently the best methods of soil treatment.

Among the different macaroni wheats under test Yellow Gharnovka gave the best general results. Texas Red oats led all other varieties tested. The best yielding varieties of winter wheat were Theiss, Kharkov, Crimean, and Weissenberg, the yields being 40.97, 40.90, 40.61, and 39.53 bu. per acre, respectively. The best yield of wheat was obtained where the land was plowed, packed, and harrowed.

Where winter wheat was sown on sod, double disking gave better results than single disking or no disking, and sod broken in June or July produced a much better yield per acre than sod broken in April. Winter wheat on soy-bean stubble yielded 15.78 bu. per acre, and on corn stubble 12.33 bu. Notes are given on the culture and value of Kafir corn, sorghum, and grasses. Of the grasses grown *Panicum bulbosum* and *P. texanum* made a promising growth.

In 1904 the work begun in 1903 was continued. Among the varieties of winter wheat tested were a number of hybrids, and the plants secured showed great variations. In 1902, 150 varieties were planted and by selection in 1903 and 1904 these were increased in number to 350. Owing to attacks of rust the yields of winter wheat were low and the varieties of macaroni wheat were practically ruined. Barley and rye also proved a failure.

Of 6 varieties of oats Kherson gave much the best results, yielding 45.3 bu. per acre. The best yield from seeding Texas Red oats at different rates was obtained when 2 bu. of seed per acre was used. As in the previous season, harrowing and packing after plowing proved the best treatment for winter wheat. The cultivation of wheat by means of the harrow or the weeder was not profitable.

In 1904 surface-planted corn made a much more rapid growth and tasseled nearly a week earlier than the listed corn, and also ripened about a week sooner. The listed corn yielded 32.3 bu. and the surface-planted, 33.8 bu. per acre. Disking and harrowing before plowing did not have a marked effect on the yield.

The alfalfa sown on sod in 1902 gave favorable results in 1904, while the growth of *Bromus inermis* on the fields seeded the same year was too small to make a hay crop. *Panicum bulbosum* this season gave a very good yield.

A rotation experiment is in progress for determining the influence of fallowing, Kafir corn, oats, leguminous crops, and barley on the succeeding wheat crop. The best yields of wheat were obtained in 1904 after fallow and after soy beans.

Report on cultural tests in 1903-4, A. DAMSEAUX (*Bul. Agr.* [*Brussels*], *21* (*1905*), *No. 1*, *pp. 50-59*).—Among a number of varieties of different cereals Abundance wheat, Saxon rye, Hessian spelt, Hunsruck oats, and Groningen barley led in yield.

Schlitte sugar beet, the best of 4 varieties, gave a yield of 46,800 kg. per hectare, with 15.70 per cent of sugar in the beet and a purity of 87.20. The application of commercial fertilizers in the drill, as compared with applying the fertilizers broadcast, retarded the beets in their early growth, but they regained the time lost later in the season. The results from applications of barnyard manure and commercial fertilizers showed only slight differences in the yield and value of sugar beets, but they indicated the importance of working the manure into the soil as early as possible.

Fertilizer tests with potatoes proved inconclusive. An application of 2,500 kg. lime per hectare increased the yield of Campine and Bohemian clover by 1,200 kg. and of Lokeren clover by only 600 kg. Of a list of forage crops, excluding sacchaline, crimson clover produced the largest yield of green substance.

Results of fertilizer experiments in progress for ten years, C. VON SEELHORST (*Jour. Landw.*, *53* (*1905*), *No. 1*, *pp. 29-60*).—The results of fertilizer tests with rye, spring wheat, winter wheat, oats, barley, fodder beets, peas, beans, and potatoes are discussed.

The cereal crops were benefited only by nitrogen, potash and phosphoric acid producing little or no effect. The yield of peas and beans was largely increased by the use of potash, while nitrogen was also beneficial, but to a lesser degree. Nitrogen followed by potash caused the greatest increase in the yield of fodder beets. With potatoes the best results were secured where nitrogen and potash were given together. The data obtained did not warrant drawing definite conclusions with regard to the influence of the season on the action of the fertilizer.

A preceding leguminous crop largely increased the yield of rye. The use of nitrogen did not influence the proportion of grain to straw, but where rye followed potatoes the grain constituted 32.5 per cent of the plant where nitrogen was applied, and 30 per cent where no nitrogen was given. Winter wheat after peas lodged on the nitrogen plats, but when following rape and flax nitrogen in the fertilizer application was beneficial.

Where potatoes were grown after beans potash was more effective than nitrogen, but the highest yields were secured where both elements were applied together, while after cereals the use of nitrogen gave a greater increase in yield than the use of potash.

Tests of the vitality of seed grain and other seeds, W. T. ELLIS (*Canada Expt. Farms Rpts. 1904, pp. 15-17*).—This class of work, carried on at the Central Experimental Farm at Ottawa, is briefly described. During the season 2,285 samples of seeds were tested, and tables are given summarizing the results as a whole, as well as the results with wheat, barley, and oats for each province.

Trials of varieties of barleys (*County Northumb. Ed. Com., Ann. Rpt. 1904, pp. 39-44*).—Of 6 varieties Chevalier, Goldthorpe, and Golden Melon gave the highest yields of grain and straw. Chevalier also stood first in the percentage of germination. Sowing in drills 12 in. apart showed a slight advantage in yield of grain and straw, and in weight per bushel, over sowing in drills 6 in. apart, but the narrower drilling gave a little more good grain than the other.

The castor oil industry, C. M. DAUGHERTY (*U. S. Dept. Agr. Yearbook 1904, pp. 287-291*).—This article discusses the manufacture and uses of castor oil, the sources of supply of castor beans, and the distribution of the crop. The production of castor beans in the United States since the Civil War is reviewed.

Improved methods of corn growing and intense cultivation, J. B. ARMSTRONG (*Shenandoah, Iowa: Author [1905], pp. 156, pl. 1, figs. 13*).—A popular book treating of subjects of general interest to the farmer, and discussing more in detail and at greater length the culture of corn and potatoes.

Cotton cultivation (*Buenos Ayres: Argentina Dept. Agr., 1904, pp. 7*).—A brief discussion of cotton culture in Argentina. Sea Island cotton as well as a number of upland varieties, including Peerless, Peterkin, and Russell Big Boll, are reported to have been introduced from the United States.

Relation of weather conditions to growth and development of cotton, J. B. MARBURY (*U. S. Dept. Agr. Yearbook 1904, pp. 141-150, dgms. 6*).—This article discusses the influence of moisture and of sunshine on the yield of cotton, and reviews the weather conditions throughout the cotton belt for the years of greatest and of smallest yields in the decade beginning with 1893. Diagrams are given comparing the precipitation for the months of June, July, August, and September, and the yields of cotton for the years 1893 to 1903, inclusive. The climatic conditions of each year are considered with relation to the yield, but no general deductions are drawn.

Cotton culture in Guatemala, O. F. COOK (*U. S. Dept. Agr. Yearbook 1904, pp. 475-488, pls. 3, fig. 1*).—The native agriculture of Guatemala and cotton culture as practiced by the Kekchi Indians is described and the kelep in its relation to cotton growing is discussed. The introduction of the kelep into the United States with a view to demonstrating the possibility of keeping the cotton boll weevil in check is also briefly noted.

In discussing the American origin of upland cotton the author concludes that "the upland cotton which Linnæus correctly recognized as distinct from the Old World *herbaceum*, and to which he gave the Latin name *Gossypium hirsutum*, is a native of tropical America Both the upland and the Sea Island cottons were originally described from the West Indies"

Report of experiments with forage crops at the coast land experiment station, 1904, J. S. NEWMAN and W. D. GARRISON (*South Carolina Sta. Bul. 103,*

pp. 8).—The yields of 11 varieties of cowpeas, teosinte, barley, soy beans, oats, Canada field peas, cat-tail millet, Egyptian and crimson clover, Florida beggar weed, 6 varieties of wheat, alfalfa from 5 different sources, and hairy vetch and oats, are recorded without comment. The varieties of cucumbers and cantaloupes grown at the station are also given.

Forage crops. The silo, C. M. CONNER (*Florida Sta. Bul. 78, pp. 285-311, figs. 8*).—Brief discussions on the culture and uses of sorghum, rape, teosinte, rye, and Para grass (*Panicum molle*), and directions for the construction of a silo are given.

A bisexual hop vine, C. BRUNOTTE (*Bul. Soc. Sci. Nancy, 3. ser., 5 (1904), No. 4, pp. 173-179, pl. 1*).—The structure of the hop vine is described in detail, and an instance of a vine producing both male and female flowers is reported and discussed. Opinions of different authorities on the occurrence and significance of hermaphrodism in the hop are briefly noted.

The influence of soil moisture on the content of total and proteid nitrogen of oat straw, C. VON SEELHORST and FRESENIUS (*Jour. Landw., 53 (1905), No. 1, pp. 27, 28*).—It is known that an increase in soil moisture, other conditions being equal, causes a decrease in the nitrogen content of oat straw, and that this decrease is the more marked as the nitrogen supply of the soil diminishes. The work here reported has reference to the decrease in proteid and digestible proteid nitrogen.

Three varieties of oats were grown in 3 series of pots containing 55, 70, and 85 per cent of moisture in the soil, respectively. The results show that the rate of decrease is smaller in proteid nitrogen than in total nitrogen. The average percentage of proteid nitrogen in total nitrogen was 61.4 on the soil with 55 per cent of moisture and 86.5 on the soil with 85 per cent of moisture. The digestible proteid nitrogen decreased more rapidly with the increase of soil moisture than the total proteid nitrogen, as is shown by the fact that on the dry soil it constituted an average of 54.2 per cent of the total proteid nitrogen and on the moist soil only 44.3 per cent. The average percentage of digestible proteid nitrogen in the total nitrogen increased from 33.3 on the low moisture soil to 38.4 on the high moisture soil.

Canadian field peas, T. SHAW (*U. S. Dept. Agr., Farmers' Bul. 224, pp. 16, figs. 4*).—This bulletin contains a popular discussion of the Canadian field pea, with directions for its culture for different purposes. A similar article has been previously noted (E. S. R., 8, p. 781).

A description is also given of how this crop is grown in the San Luis Valley, Colorado, at an altitude of 7,000 ft., where it is used for fattening sheep and lambs by pasturing them on the crop. In the author's opinion this system of grazing may be very largely extended in the mountain States. Directions are also given for growing the crop for the purpose of fattening swine in localities where this crop can profitably take the place of corn.

The potato, S. FRASER (*New York: Orange Judd Co., 1905, pp. 185, pl. 1, figs. 51*).—This book devotes a chapter to each of the following subjects pertaining to potato culture: History and botany, some conditions influencing growth and development, soils, rotation, manuring and fertilizing, considerations of seed, varieties, planting, management of the growing crop, obstructions to growth and development, sprays and spraying, harvesting, storing, production, transportation and markets, chemical composition and feeding value, and breeding and selection. A spray calendar and methods of seed treatment, briefly stated, are given in an appendix.

The book of the potato, edited by T. W. SANDERS (*London: W. H. & L. Collingridge, 1905, pp. 222, illus.; rev. in Lancet [London], 168 (1905), No. 4264, p. 1346*).—This work treats of the history and botany of the potato plant, the soil and its cultural and manurial treatment, the propagation by seed, cuttings, eyes, and grafting, the preparation of the seed and systems of planting, forcing potatoes, harvesting, storing and marketing the crop, originating new varieties, and methods of combating

insects and diseases. A descriptive catalogue of 270 varieties is included in the volume.

Potato growing in New York, J. L. STONE (*New York Cornell Sta. Bul. 228, pp. 429–455, figs. 2*).—This bulletin summarizes the data on potato culture published by the station in previous bulletins, and presents other data accumulated since those publications were issued. The different operations and practices in connection with potato growing are discussed.

In 1903 a comparison of barn-stored wilted and sprouted seed and of solid slightly started cold-storage seed showed a gain of 159 per cent in yield in favor of the solid nearly dormant seed. In 1904 the seed tubers stored from November to May in crates in a cool cellar and with no sprouts started May 1, were divided into 4 lots, placed in trays, and stored in different ways from May 2 to June 7, and then planted. The first lot was kept in a dark cellar at a temperature of from 50 to 60°; the second, in a cold frame open above and with the bottom at 80°; the third, in a barn near a window where the temperature was about the same as out of doors; and the fourth, in a greenhouse at from 80 to 90°.

The second, third, and fourth lots gave a gain in yield of 35.1, 28.5, and 13.4 per cent, respectively, over the first. The sprouts on the tubers exposed to light were strong, dark green, and not over ½ to ¾ in. long, while on those stored in the dark cellar they were 3 to 4 in. long, whitish and brittle, and subject to injury in planting, especially if done by machinery.

A test was made of seed pieces of 2 different sizes, the one being as large again as the other. The smaller pieces were as large as those frequently planted by farmers. As compared with the larger pieces, the small pieces gave a yield reduced by 21.7 per cent on one plat and by 41.5 per cent on another. The effect of dusting the cut tubers with plaster one or two days before planting was studied by the station in 1903; in 3 out of 5 tests the increase in yield ranged from 13.31 to 26.18 bu. per acre on the plat planted with the treated seed. In the 2 other cases the results were inconclusive.

The culture tests carried on from 1894 to 1900 resulted in the best yields from 7 to 9 cultivations. Another series of tests showed that level culture is to be preferred to hilling. Spraying with Bordeaux mixture generally gave increased yields, although in some seasons when no blight appeared little effect was observed.

The results of cooperative variety tests made in 1903 and 1904 are given in tables. In one series of experiments Doe Pride stood first, in another Bovee gave better returns than Irish Cobbler, and in the third Gold Coin and Wilson 1st Choice stood about equal. The work of potato diggers and planters is discussed, and an outline of cooperative demonstrations to be made in 1905, comprising different phases of farm work, is given.

Potato culture near Greeley, Colorado, J. M. CLARK (*U. S. Dept. Agr. Yearbook 1904, pp. 311–322, figs. 6, pl. 1*).—The extent of the potato area near Greeley, the markets, irrigation, and alfalfa culture as factors of success in potato growing, crop rotation, and sheep feeding in the potato belt, the preparation of seed potatoes, and the methods of growing the crop, including the application of water, are discussed.

Observations on the influence of nodules on the roots upon the composition of soy beans and cowpeas, C. D. SMITH and F. W. ROBISON (*Michigan Sta. Bul. 224, pp. 125–132*).—The yield and composition were determined of roots, stems, and leaves of Medium Green soy beans grown in 1903 on two areas, the roots in one case being practically free from nodules and in the other nearly covered with them. The leaves and stems from an 8-ft. row bearing nodules weighed 5,125 lbs., and from a similar area without nodules 5,562 lbs. The roots with nodules weighed 0.438 lb., and those without 0.625 lb., the nodules themselves weighing only 0.16 lb.

In 1904 this work was repeated on two plats, each containing a square rod, the one being inoculated with soil from a soy-bean field, and the other being left with-

out inoculation. During the season the roots of the plants on the inoculated plat were well covered with nodules, while those on the uninoculated plat remained free from them. No difference was apparent in the growth on the two plats or in the color of the foliage. A row 8 ft. long on the inoculated plat contained 52 plants, weighing 4 lbs. 5 oz., and on the uninoculated plat 49 plants, weighing 3 lbs. 12 oz. The roots weighed 9 and 6 oz., respectively.

As a mean of the two years, the leaves and stems of the plants bearing nodules contained 2.78 per cent of nitrogen, and the others 1.77 per cent in dry matter. The roots bearing nodules (latter removed) averaged 1.01 per cent of nitrogen in dry matter, and those having no nodules 1.43 per cent. "Inoculation does not seem to notably affect the phosphoric acid nor the potash." In each year the percentage of protein was higher in the inoculated plants, the protein content for the two years taken together being 56.86 per cent greater in the plants from the inoculated plats.

A similar experiment with cowpeas, made in 1904, showed a corresponding predominance of nitrogen in the leaves and stems where nodules were produced, and a decrease in the roots. The cowpeas with nodules on the roots contained 47 per cent more protein than those without nodules.

Analyses of the nodules showed the following composition: Soy-bean nodules—protein 26.19, nitrogen 4.19, potash 2.05 per cent; cowpea nodules—protein 24.39, nitrogen 3.90, phosphoric acid 0.96 per cent. In all except one case the roots without nodules contained a greater percentage of nitrogen than the roots provided with them.

An estimate based on the composition of dry matter of the leaves, stems, and roots of the two crops and the yields of plats 0 8 and 1.29 acres in size shows that the inoculated soy beans contained 113.55 lbs. of nitrogen per acre, as compared with 75.98 lbs. from the uninoculated, and the inoculated cowpeas 139.21 lbs, as compared with 118.45 lbs. in the uninoculated crop. The figure for the cowpeas does not include the nitrogen in the abundant nodules.

In a study of the influence of nodules upon the composition of the seed of soy beans it was found that the ripened seeds of the inoculated soy beans were fully 16 per cent richer in protein than the product of the uninoculated areas. The authors conclude that the nodules on the roots on fairly fertile soil may not notably increase the yield, but that they do increase the relative and absolute amount of nitrogen in the plants.

Tests of different varieties of sugar beets, R. HARCOURT (*Ann. Rpt. Ontario Agr. Col. and Expt. Farm, 30 (1904), pp. 51-54*).—Four years' results with different varieties of sugar beets are reported.

The tests comprised 32 varieties, of which 20 were grown for 4 years, 8 for 3 years, and 4 for 2 years. The beets were grown in level culture in rows 21 in. apart and at 8 in. apart in the row. In 1904 Mangel Sugar Beet, Rimpau Rubensamen, Jaensch Victrix, and Improved Imperial ranked first in quality. The sugar content in these varieties ranged from 17.4 to 18.5 per cent and the coefficients of purity from 83.8 to 90.3.

In the list of varieties tested for 4 years Kleinwanzlebener, Improved Imperial, and Pitzscheker Elite ranked first in average quality. Kleinwanzlebener showed an average sugar content of 16.9 per cent and a purity of 88.1. Among the varieties grown for 2 years Rimpau Rubensamen stood first in average results, with a sugar content of 17.6 per cent and a purity of 89.5.

A study of the influence of the distance between rows on the quality indicated that the best quality of beets is obtained in rows 18 or 20 in. apart, and that wider planting reduces the quality and produces a marked decrease in yield. A brief report on the beet-sugar industry in Ontario is given.

Sugar-beet seed breeding, J. E. W. TRACY (*U. S. Dept. Agr. Yearbook 1904, pp. 341-352, pls. 3*).—The effect of good seed on the quality of the beet, and the advan-

tages of growing sugar-beet seed at home are pointed out. Methods for the production of high-grade commercial seed are outlined, the different steps in scientific growing of sugar-beet seed are summarized, and the work of this Department in this line is briefly reviewed.

Field experiments with sugar cane, C. F. ECKART (*Hawaiian Sugar Planters' Sta., Div. Agr. and Chem. Bul. 13, pp. 17, plans 3*).—This bulletin considers briefly a few of the more important points in connection with practical tests with sugar cane in the field, and indicates some of the sources of error which may occasionally arise.

In considering the modifying influences which may tend to impair the results obtained during short periods a simple plat irrigation experiment is taken as an example, and the nature of plats, preparation of land for planting and the seed cane used, and the treatment of plats with special reference to irrigation are described. The actual difference in weights of cane and sugar per acre which may arise from apparently trifling variations in the growth of the individual cane plants is pointed out, the figures used being based on an increase in diameter of the cane by $\frac{1}{1000}$, $\frac{1}{100}$, and $\frac{1}{32}$ of an inch. Diagrams are presented to illustrate the manner in which small experiment fields, either with or without irrigation, could be laid out to best advantage.

The improvement of tobacco by breeding and selection, A. D. SHAMEL (*U. S. Dept. Agr. Yearbook 1904, pp. 435-452, pls. 7, fig. 1*).—This article points out the need for the improvement of tobacco and its adaptation to soil and climatic conditions, discusses the value of large and heavy seed, including the description of a method for the separation of the light from the heavy seed, and gives general directions for improvement by selection. Record outlines for noting the characteristics of individual seed plants and the development of the progeny are given.

The results of experiments in selection, showing the influence of plant individuality, are reported. Ten separate and distinct types were observed in a field of Sumatra tobacco and seed was selected from the typical plants in each type. In the young plants produced from this seed the characteristics of each type were quite apparent and became more prominent as maturity approached. It was further observed that the progeny produced about the same number of leaves as the parent plants, in which the number had ranged from 4 to 40. An increase in the number of leaves was not associated with an increase in the height of the plants, but the length of the internodes was reduced as the number of leaves increased.

The shape of the leaf in the parent plant was reproduced in the progeny, and in this connection the value of wide leaves with rounded tips and bases is pointed out. "It has been conclusively proven that any shape of leaf desired, which is produced in a given locality, may be fixed and transmitted uninterruptedly to the succeeding crops by selection of the parents having the desired shape of leaf and saving the seed of such plants under bag." It was also found that the size of the leaf can be controlled by selection. Seed from plants free from suckers produced proportionately few suckers, while seed from freely suckering individuals produced plants with large numbers of suckers.

In 1903 the author selected plants apparently resistant to a root disease attacking Sumatra tobacco. "The progeny from these plants were resistant to the disease and produced a profitable crop of tobacco while the plants grown from other selected seed were as seriously injured as in the previous year." These results are believed to suggest the possibility of breeding types resistant to many of the common tobacco diseases.

The improvement of tobacco by crossing varieties is also briefly noted. The progeny of crosses made in 1903 with native and imported variety of cigar tobacco showed a great improvement in quality, vigor of growth, and yield over the native types. The shape of the leaf was materially modified, especially in hybrids of Havana seed and Cuban and Havana seed and Sumatra, the leaves, very round, with regular and uniformly fine veins from the tip to the base, were of finer and

more elastic texture than Havana seed and made better wrappers. The results were even more striking in the crosses in which Broadleaf was used as the mother parent.

The selection of tobacco seed plants, A. D. SHAMEL (*Connecticut State Sta. Bul. 150, pp. 18, pls. 5*).—A somewhat fuller discussion of this subject by the author has been noted from another source (see above). This bulletin treats of the possibility of improving the quality of tobacco, the lack of uniformity of plants in the average tobacco crop, self-fertilization and cross-fertilization in the plant, advantages of using seed from self-fertilized flowers, and methods of selecting plants and securing self-fertilization.

In all the crops grown from imported seed a large proportion of abnormal plants, in type as well as maturity, were observed. This was especially true of the crops from freshly imported Cuban seed, in a field of which the author found about 33 per cent of the plants to be of freak type. The variation in type of the Broadleaf Havana seed and of so-called native varieties was less marked, but the individual variation in the number, shape, and size of seeds, the number of suckers, the number of seed pods, and other characters was nearly as great as among plants grown from imported seed.

It was observed that some plants had nearly double the number of leaves found on average plants, and many individuals produced rounded leaves, while others bore long, narrow, and pointed leaves. Some plants suckered profusely, while in others this tendency was comparatively weak. Again, plants were observed with from 150 to 200 seed pods, while others bore only from 25 to 100. In maturity of leaf a difference of 2 weeks was noted between individual plants, and it was found that the leaves of plants in the same field varied in body, stretch or elasticity, color or appearance, and other characteristics.

In the discussion of self-fertilization and cross-fertilization of tobacco the flowers of the plant are described and the natural method of fertilization is pointed out. For 2 years experiments were made with Connecticut Havana, Broadleaf, Sumatra, and Cuban types grown under cloth and in the open, and on a commercial scale, to determine the relative value of seed produced by exclusive self-fertilization and of seed produced by natural cross-fertilization. The results show that the plants from self-fertilized seed produced exactly the character of the mother plant. The individual character, such as shape and color of leaves, number of leaves and suckers, body or texture, size of veins, time of maturity, and all other observed characters were uniformly transmitted.

In a field of Connecticut Sumatra several hundred plants of different types were selected and seed exclusively from self-fertilization was secured. From this seed a type was produced with leaves which would not burn, and with it another type tested in the same way which had the most perfect burn of any kind of tobacco. In one instance imported seed produced plants which were attacked by a fungus root disease and destroyed, together with certain individuals which were resistant or immune and produced ripe tobacco of excellent quality. Some of the plants were only partially resistant, and seeds saved from these and compared with the seed obtained from the resistant or immune plants when sown resulted in poor plants, showing the characteristics of the diseased ones in root, stalk, and leaves, while the plants from the other seed, although sown on the seed beds where the disease had occurred, produced perfectly resistant individuals.

These cases are cited by the author to show the transmitting power of the seed of tobacco from self-fertilized flowers and to point out its practical importance.

Experiments in growing Cuban seed tobacco in Texas, G. T. McNESS and W. M. HINSON (*U. S. Dept. Agr., Bur. Soils Bul. 27, pp. 44*).—The history of experiments in growing Cuban seed tobacco in Texas is given, the relation of climate and

soil to this industry is discussed, and the results of experiments during 1902, 1903, and 1904 are reported.

The temperature and precipitation for 6 months of the growing season in eastern Texas and Havana, Cuba, are compared, the averages showing a close correspondence for Palestine and Nacogdoches, Texas, with those for Havana. The monthly differences show greater variations, the temperature at Havana varying only about 8° F., while in Texas the variation is 15°. The rainfall at Havana was much heavier during the first 2 months of the period and very much less the third month than in Texas, while for the remainder of the period the differences were not so great. The mean range of humidity is about the same in both regions, but at Havana the relative humidity appears higher for a longer period during the 24 hours than at Palestine, Texas.

The soils used in these experiments were the Orangeburg fine sandy loam and the Orangeburg clay. The Orangeburg fine sandy loam is described as a compact red sandy loam containing considerable silt, with an average depth of about 12 in., and the subsoil a heavy sandy clay reaching a depth of 3 ft. or more. Both the soil and subsoil contain rounded iron concretions about one-quarter of an inch in diameter. The Orangeburg clay, which differs from the fine sandy loam in having a much lighter soil over the red clay subsoil, is described as being from 5 to 9 in. deep, of a dark-red color, and ranging in texture from a heavy sandy loam to a clay loam, with a subsoil of stiff dark-red clay, generally reaching to considerable depths.

Mechanical analyses of both soils and the content of soluble salts in the soil and subsoil are given in tables. It is stated that both soils contain enough potash salts to make them desirable for tobacco, and that the chemical analyses of the two compare favorably with those of the tobacco soils of Cuba, especially with the red soils in the Partidos district.

In 1903 work was conducted on 4 different fields representing the 2 Orangeburg soils. The lighter soils received about 15 loads of well-rotted manure and the heavier soils 20 loads per acre, the manure being plowed under and allowed to decay some time before planting. The plants were set 12 and 14 in. apart in 3 ft. rows. The crops obtained showed a very wide range in yield, believed to be due to differences in the local weather conditions, in the type of soil, and in the amount of fertilizer used.

The tobacco after being thoroughly fermented was examined and graded early in January, 1904, but at this time from 72 to 84 per cent of the crop classified as of good aroma was insufficiently aged, while only 10 to 11 per cent was judged a filler of good aroma with sufficient age. This tobacco was packed and baled and put on the market to determine its commercial value. The firms purchasing it seemed to regard it as satisfactory, although some considered it lacking in aroma and smoothness as compared with the Cuban leaf. Nearly all agreed that the leaf was the best domestic filler they had ever tested, but in the opinion of one firm the quality of the leaf was not as good as the tobacco now being grown in Pennsylvania. The prices received ranged from 28 to 40 cts. a pound.

These experiments were continued in 1904 on 4 different fields, the methods of culture, curing, etc., being quite fully described. The cost of production on the fields varied from 19.3 cts. to 26.4 cts. per pound. As in the previous year, a wide range in the rates of yield was shown. The total yield from the entire area, 8¾ acres, was 5,461 lbs., or 624.1 lbs. per acre, with an average cost of production of 21.6 cts. per pound. "It is believed that the farmer having all the facilities on his plantation can grow this tobacco at a cost not exceeding 10 cts. a pound."

In 1905 this type of tobacco was planted on about 150 acres of Orangeburg soils in three counties, and a tobacco firm has agreed to purchase the barn-cured product at a remunerative price. "It therefore appears that in the course of a few years, if the

industry be conducted on a conservative basis, the growing and packing of tobacco can become an important industry of east Texas."

Experiments in breeding tobacco, E. H. Jenkins (*Connecticut State Sta. Rpt. 1904, pt. 5, pp. 449–456, pl. 1*).—In 1903, 12 different types or strains of tobacco, including 7 of the Sumatra type, 2 of the Cuban, and 1 each of Connecticut Broadleaf, Connecticut Havana, and White Burley were grown, and small quantities of seed from individual plants were selected as being the very best in the plats and exclusively self-fertilized. From this set 4 strains of the Sumatra type, 1 of the Cuban, and 1 each of the Connecticut Broadleaf, Connecticut Havana, and White Burley were obtained and are here briefly described. As in the previous year, seed from selected and exclusively self-fertilized plants was secured for future work.

The general result of the season's work indicates that the characters of the particularly selected mother plant were transmitted to each one of the offspring with a remarkable degree of uniformity. The author reports that this was the first time since the experiments with Sumatra were begun, in 1900, that plats were secured in which the plants were uniform in size and in the number and shape of the leaves. The effect of cross-fertilization and self-fertilization in tobacco is discussed and an article giving one of the very earliest descriptions and pictures of the tobacco plant, written soon after its introduction into the Old World from the West Indies, is reproduced.

A new and valuable cover crop for tobacco fields, A. D. Shamel (*Connecticut State Sta. Bul. 149, pp. 7, fig. 1*).—The need of a suitable cover crop for tobacco fields is pointed out, and hairy vetch, sand vetch, or Russian vetch (*Vicia villosa*) is described with special reference to its use for this purpose. Directions for planting the crop are given, and its value for forage or green manure is also briefly noted.

In October of 1904 several tobacco fields were sown to Russian vetch either with rye or alone. In some instances the soil preparation consisted of plowing and harrowing, while in others the seed was sown on the unprepared ground and disked in with an ordinary disk or wheel harrow. Both inoculated and uninoculated seed was used.

Although the seeding was thinner than desirable, a good stand was obtained and the crop wintered better than the rye which was sown with it, the vetch surviving in spots where the rye completely winterkilled The roots of plants from inoculated seed bore many tubercles, while on the plants from the uninoculated seed they were less numerous and the plants much less vigorous. When the crop was plowed under in May the plants were from 4 to 8 in. high

Universal nomenclature of wheat, N. A. Cobb (*Dept. Agr. N. S. Wales, Misc. Pub. 539, pp. 75, pls. 15, figs. 74*).—This publication includes a series of papers published in the Agricultural Gazette of New South Wales and previously noted (E. S. R., 15, p. 246).

A further study of the volume, microscopic structure, and strength of the aleuron layer in wheat is reported. In this study the distribution of gluten in the ripe endosperm of typical Australian wheat was determined, and observations made on the structure of the flour cell. Directions are given for the selection of average samples, the preparation of sections of a ripe wheat grain, the demonstration of the distribution of gluten in the flour cells, and the collection of all the gluten from a single flour cell.

Spraying to kill weeds, T. D. Jarvis (*Ann. Rpt. Ontario Agr. Col. and Expt. Farm, 30 (1904), pp. 39, 40*).—Early in July weed patches in which 28 species and 12 botanical families of plants were represented were sprayed with a solution of 9 lbs. of bluestone to 45 gal. of water. It was observed that 24 hours after spraying the effects were the same as 6 hours after the treatment. It is concluded that wild mustard is the only weed that can be destroyed by spraying with this solution. The flowers of field bindweed and white cockle, and the leaves of blue weed, bull thistle, Canada thistle, and sow thistle proved very sensitive to the spray.

HORTICULTURE.

Opportunities in agriculture (*U. S. Dept. Agr. Yearbook 1904, pp. 161–190, pls. 3*).—This subject is popularly considered from 3 different standpoints: (1) Growing Crops under Glass, by B. T. Galloway; (2) Fruit Growing, by M. B. Waite; and (3) General Farming, by W. J. Spillman.

On the subject of growing crops under glass such phases are considered as general plant growing, vegetable growing, cut-flower growing, and the growing of bedding and ornamental plants as a specialty. The business and training qualifications necessary for each of these industries, capital involved, and the profits which may reasonably be expected are considered.

Under fruit growing, special attention is called to intensive methods and the desirability of thorough cultivation and care of relatively small areas as compared with more extensive plantings. The various details of orchard management, cost of establishing an orchard, and the opportunities in intensive fruit growing are discussed. The average cost of establishing an orchard and its care for the first 5 years is placed at $100 per acre.

Under general farming special attention is called to possibilities in the milk and fancy butter trade, poultry, vegetable gardening, cheese making and live stock in the South, and seed production.

Horticultural work at the Canadian Experiment Stations, W. T. Macoun, W. S. Blair, S. A. Bedford, A. Mackay, and T. A. Sharpe (*Canada Expt. Farms Rpts. 1904, pp. 105–122, 125–128, 134, 135, 353–359, 364–370, 395–409, 435–446, 466–485, pls. 2*).—A report on the character, culture, and behavior of a large number of fruits, vegetables, and flowering plants grown at the different experimental farms in Canada from Nova Scotia to the Northwest Territories. The reports are similar in character to those of previous years (E. S. R., 16, p. 261).

The severe winter of 1903–4 killed large numbers of fruit trees in the orchards of Ontario and Quebec, which for many years previously had proved hardy. At the Central Experimental Farm 306 apple trees, including 164 varieties, were killed, all above the snow line. During the preceding 6 years 90 varieties of apples were top grafted on hardy stocks to determine whether varieties which would not succeed when grown in the ordinary way would prove satisfactory when top grafted on stocks having heavy trunks. Practically all of the varieties thus used for top grafting were killed back to the stocks.

One instance is cited in which Milwaukee and Martha were top grafted on Wealthy, each variety occupying about half the top of the tree. As a result of the severe cold Martha was entirely killed, while the Milwaukee remained alive and bore a good crop of fruit. Trees which have proved tender when tried as standards are thus shown to be also tender when grown on hardy stocks. Hardy stocks do not appear to make grafts noticeably hardier. A revised list of the winter varieties of apples recommended for the district is as follows: Scott Winter, Milwaukee, Northwestern Greening, Canada Baldwin, and Golden Russet in the more favored localities.

A further account is given by Mr. Macoun of the close-planted (10 by 10 ft. apart) Wealthy orchard set out at the Central Experimental Farm in 1896. The average profit per year per acre from this orchard from 1896 to 1904 has been $54.13, while the average profit per year per acre since the trees have been bearing well, from 1899 to 1904, has been $106.19. This system of close planting is not recommended for general adoption, but is believed worthy of trial by specialists. The 2 varieties Wealthy and Wagener are believed to be the most suitable for this close planting on account of their early bearing habits.

Experimental shipments of apples from this station to points in Ireland and Scotland were made in 1904. All the shipments were made in bushel boxes and all graded XXX. Some of the fruit was sent in cold storage, but the most of it was

not. The fruit was placed in the boxes in regular rows and tiers, with a sheet of cardboard above and below and a very little excelsior between the cardboard and the sides of the box. Apples were shipped as a rule when well colored but still hard. The varieties were Duchess, Charlamoff, Antonovka, Anis, Dudley, Winter Stripe, McMahon White, Wealthy, and Patten Greening. The varieties Charlamoff, Anis, and Winter Stripe in some shipments were wrapped in tissue paper.

In every instance the apples arrived at their destination in good condition, but owing to the unusual abundance of apples in both Ireland and England the results were not as profitable as heretofore. The apples shipped to Belfast, the agent stated, were not good enough for dessert purposes, and hence brought a low price, scarcely sufficient to pay the freight. That market, also, preferred apples in barrels instead of in boxes. Wealthy apples shipped to Dublin sold from 84 cts. to $1.08 per box. The shipment of Patten Greening and Wealthy to Glasgow brought about 68 cts. a box net.

The severe winter killed most varieties of European and Japanese plums at the station down to the snow line. Two seedlings, however, of the Red June plum originated at the experimental farm proved hardy in flower and bud and have been given the names of Togo and Oyama. Three American seedlings originated at the Central Experimental Farm have been named Gloria, Swift, and Fitzroy. All of these varieties are described, as well as some of the newer Americana varieties.

Horse beans have proved a very satisfactory cover crop in the orchards. These beans stand up during the winter and hold the snow well and in the spring are easily broken up by a disk harrow. It is believed that English horse beans and rape grown together will prove an ideal cover crop for that region. The beans furnish nitrogen and humus and hold the snow well, while the rape will cover the ground and thus protect the roots.

One of the disadvantages of hairy vetch, otherwise an excellent cover crop, is the difficulty of plowing under where it lives over the winter. The crop lived over the winter at the Central Experimental Farm and the plan was tried of cutting it and letting it lie on the ground as mulch in the same way as red clover is sometimes used. The vetch, however, was killed by the first cutting.

Further experiments were made during the summer in growing vegetables in a cheese-cloth inclosure. Radishes and cauliflowers grown inside the inclosure were again free of maggots except where the plants had been affected in the hotbed before setting out in the inclosure Both these vegetables developed satisfactorily in the inclosure. The radishes were 2 days later than those grown outside, but remained fit for use nearly a week longer inside than outside. Outside the inclosure the cauliflower was practically a failure, while inside the crop was quite satisfactory.

Lettuce was ready for use 2 days earlier inside the inclosure than outside. Beans were ready for use 1 to 2 days later inside than outside the inclosure. The yield inside the inclosure was 58 qts. and outside 53 qts. on like areas of ground. There was no apparent difference between onions grown outside and inside. The same cheese-cloth cover which was used in 1903 was again used in 1904 but tore considerably and gave trouble. The life of a cheese-cloth tent, therefore, will not exceed 2 years. The cost was 5 cts. per yard.

Nolte Earliest tomato yielded heavier than Spark Earliana, but it is not quite so smooth. Spark Earliana has proved one of the earliest ripening and most satisfactory varieties grown at the station for 5 years. A method of pruning tomatoes tried during the year has been previously noted from another source (E. S. R., 17, p. 36).

At the Nova Scotia station crimson clover has proved one of the best cover crops for use in orchards. It is sown at the rate of 20 lbs per acre. An increase of 44 bu. of green peas per acre was secured by the use of 500 lbs. of a complete commercial fertilizer at a net profit of $5.70 per acre. The Australian Brown onion is considered the best variety for the average grower.

Mr. S. A. Bedford, of the Manitoba Station, gives a list of varieties of standard apples root-grafted on *Pyrus baccata* which have been planted at the station and the effect of the winter on them. Most of the varieties were killed back more or less, but many varieties made a strong growth during the season. Plums were a heavy crop at the station. Three native varieties which fruited for the first time proved superior to anything tested as regards earliness and flavor. The fruit ripened early in August, which was fully 2 weeks sooner than fruit of any other varieties found on the farm. The plums are comparatively large, deep red in color when ripe, skin sweet and juicy with no sign of astringency, and the stone was not out of proportion to the flesh. The fruit from all 3 trees is very similar and has been given the name of Major.

Fall-sown seed of *Caragana arborescens* has given much stronger plants than spring-sown seed. Various tender species of Philadelphus have been successfully grown at the station when bent to the ground and sufficient soil thrown over the tips to hold them there during the winter. Gradus has proved the earliest large pea yet tested.

Report of the professor of horticulture, H. L. HUTT (*Ann. Rpt. Ontario Agr. Col. and Expt. Farm, 30 (1904), pp. 102–116, figs. 5*).—This report gives an outline of the horticultural work at the Ontario Agricultural College during the year, with notes on various cover crops, orchards, small fruits, vegetables, and ornamental shrubs.

The severe winter killed 10 per cent of the trees in the apple orchard, 20 per cent of those in the plum orchard, 35 per cent in the pear orchard, and 44 per cent in the cherry orchard. Twenty peach and 20 quince trees which had survived several winters were also killed.

How to make a vegetable garden, EDITH L. FULLERTON, illus. by H. B. FULLERTON (*New York: Doubleday, Page & Co., 1905, pp. XIX + 347, figs. 253*).—Popular directions for making a garden and the culture of all the usual vegetables and small fruits. The illustrations form a prominent feature of the work. A table is given showing when to plant each of 74 different vegetables, depth to plant them, distance apart, the period when the crop matures, and other information as to cultural methods.

Test of the vitality of vegetable seeds, E. H. JENKINS (*Connecticut State Sta. Rpt. 1904, pt. 5, pp. 438–443*).—A table is given showing the results of germination tests of 415 samples of seeds representing 34 different vegetables.

The age of the samples varied from 1 to 12 years, most of them being 1 to 2 years old. They were sent in by the seedsmen or growers themselves with the understanding that the results of the test were not to be published as representing the character of their goods. Sweet corn and onion seed are grown in large amounts in the State and more tests of these varieties are annually made at the station than of all other kinds of seeds.

California-grown onion seed showed a higher percentage germination than Connecticut-grown seed, and seed less than 1 year old germinated better than older seed. The vitality of crops of onion seed for 1880 and each of the years 1894 to 1904 is tabulated and another table given showing the sprouting ability of different varieties of onion seeds and sweet corn.

Mushroom growing for amateurs, G. F. ATKINSON and R. SHORE (*New York Cornell Sta. Bul. 227, pp. 415–424, figs. 4*).—Experiments were undertaken in the culture of mushrooms to learn what success might be expected by amateur growers where no elaborate preparations were made as to special houses.

Cellars or basement rooms may be used for mushroom culture in winter provided the temperature does not go below 55° F. or rise above 65° F. They should not be grown in cellars under the living part of a house, as the fumes of manure will fill the house. They can be grown in stables which are not too cold.

In the station experiments they were grown in part in boxes under benches in the greenhouse, where the temperature during the winter was about 55° F. at night and

60 to 65° F. during the day, and in part under a bench in a basement. The boxes used were 3x3.5 ft. wide and 1 ft. deep. The bed under the bench in the basement was made by placing a plank against the legs of the bench and filling the space between that and the wall with well-packed manure. The boxes and bed together contained about 90 sq. ft. of surface and yielded at the rate of about 2 lbs. of mushrooms per square foot. The manure for the boxes and bed was composted October 31 and was ready for putting in the beds November 9.

The beds were spawned November 23 and covered over with dirt December 1 and 2. The first mushrooms were picked January 1, or about 5 weeks from the time the beds were spawned. The regular picking began a week later. The spawn in a small part of the bed did not produce mushrooms until about 2 months after spawning. When the crop was at its best 4 to 8 lbs. of mushrooms were collected at each picking.

Detailed directions are given for the making of mushroom beds in cellars, for the preparation of the manure and packing into the beds, and for the buying and insertion of the spawn in the prepared beds, with general notes on the growth of mushrooms, picking mushrooms, and the enemies affecting mushrooms. Illustrations are given of the varieties Alaska, Columbia, and Bohemia, as grown under the different conditions in the experiment.

The orchard and fruit garden, E. P. POWELL (*New York: McClure, Phillips & Co., 1905, pp. XV+322, pls. 24*).—Popular directions are given for the culture of orchard and small fruits, including citrus fruits, figs, dates, olives, pineapples, bananas and other tropical fruits, and nuts. In the concluding part of the work chapters are given on wind-breaks, drainage, irrigation, pruning, mulching, fertilizing, cover crops, spraying, the animal friends and foes of the garden, harvesting and marketing of fruit, and plant breeding. The book is written for the practical fruit grower, and appears to be well adapted for that purpose.

Promising new fruits, W. A. TAYLOR (*U. S. Dept. Agr. Yearbook 1904, pp. 399–416, pls. 8*).—Descriptions with colored illustrations are given of a number of promising fruits and nuts. Among these are the Bloomfield and Doctor apple, Rossney pear, Millennial grape, Perfection currant, Delmas persimmon, and the following 10 varieties of pecans: Centennial, Frotscher, Jewett, Pabst, Post, Rome, Russell, San Saba, Stuart, and Van Deman.

New citrus creations of the Department of Agriculture, H. J. WEBBER and W. T. SWINGLE (*U. S. Dept. Agr. Yearbook 1904, pp. 221–240, pls. 13, figs. 2*).—In the work of the Department with citrus fruits the primary objects sought have been "(1) hardier varieties which would endure the occasional severe freezes which visit the orange sections, and, if possible, varieties sufficiently hardy to be grown farther north than the present citrus belt; (2) new fruits having the loose, easily removable rind of the mandarin and tangerine combined with the quality, flavor, and size of the ordinary sweet orange; (3) new fruits having the sprightly acid flavor of the pomelo with the bitterness reduced, and the loose, easily separable rind of the mandarin and tangerine; and (4) new fruits intermediate between the pomelo and the orange which would possess desirable market qualities."

A hardier fruit has been obtained by crossing the trifoliate orange (*Citrus trifoliata*) with the sweet orange. Considerable difficulty was experienced in crossing these 2 varieties and only about 2 per cent of the flowers operated upon set fruit. Owing to the polyembryonic character of the seeds of citrus fruits considerable care was necessary in selecting the true hybrids. Of 40 hybrids of the trifoliate orange crossed with the pollen of the sweet orange, 29 resembled the former in habit and foliage characters while 11 were intermediate in these characters. From these crosses 2 fruits have been developed which are of considerable promise.

These fruits are about midway in character between the 2 parents and are neither sweet oranges, trifoliate oranges, nor lemons, and have therefore been grouped under

the class name of "citranges." They have been given the variety names of Rusk and Willits. They are described in detail and illustrated with colored drawings.

The Rusk is from $1\frac{1}{2}$ to 2 in. in diameter and $1\frac{1}{4}$ to $1\frac{5}{8}$ in. high. It is considered too sour to be eaten out of hand but is very palatable with sugar. It has a bitter flavor and is considered valuable for making "citrangeade," similar to lemonade, or for use as a breakfast fruit. It may also be used for pies, preserves, marmalades, and general culinary purposes. The Willits, while similar in general appearance, possesses a distinct flavor from that of the Rusk, having more nearly the character and flavor of the lemon.

These fruits have withstood a temperature of from 15 to 18° F. above zero and in one instance a minimum temperature of 6° without injury. It is believed that they may be grown without protection throughout South Carolina, Georgia, Alabama, Mississippi, Louisiana, Arkansas, parts of Tennessee and Texas, also parts of Washington, Oregon, northern California, Arizona, and possibly New Mexico, and will prove of value mainly as a home fruit for cultivation throughout the Southern States where the sweet orange, the lemon, and lime can not be grown.

The tangelo is a name given to a new class of loose-skinned citrus fruits obtained by crossing tangerines with the pomelo. A variety originated in this group, called the Sampson, is described and illustrated. The tangelo is about midway in size between its 2 parents. It has a sprightly acid flavor but is rather sweeter than the pomelo with a slightly bitter taste. "Its most pronounced characters, however, are the looseness of the rind and the ease with which the segments can be separated." The flavor is considered excellent, and it is believed it will become very popular as a breakfast fruit.

Two new tangerine oranges have been obtained by crossing the Dancey tangerine with pollen of the Parson Brown orange. The fruits obtained from these crosses differ from other varieties of tangerines primarily in being larger, earlier, and more highly flavored. The variety given the name of Weshart uniformly colored up and ripened about 2 weeks earlier than the Dancey tangerine. The fruit of the variety given the name of Trimble is slightly larger than the Weshart tangerine but not quite equal to it in flavor. The rough, bumpy appearance of the Trimble serves to distinguish it from other tangerines.

It is believed that these 2 tangerines will prove superior to the Dancey in nearly every respect. They are recommended for culture wherever tangerines are now grown. Neither these tangerines nor the tangelo previously described are more hardy than the ordinary pomelo and tangerine and therefore can be grown only in the districts where such fruits succeed. Detailed descriptions are given of the fruit and trees of both these new varieties of tangerines.

An apple orchard survey of Wayne County, New York. I, The apple industry, G. F. WARREN (*New York Cornell Sta. Bul. 226, pp. 239-362, pl. 1, figs. 62*).—This survey was undertaken under the direction of John Craig. In the survey every orchard in Walworth Township as large as 1 acre in extent was personally inspected. In the remaining townships of the county only orchards of 5 acres in extent or over were visited. Wayne County is one of the leading counties in fruit production in the State.

The data secured in this survey cover such matters as methods of tillage, the use of fertilizers, pruning, spraying, number of trees per acre, distance apart, age of the orchards, soils, drainage, elevations and exposures, whether the orchard was rented or managed by the owner, varieties of apples grown, most prevalent diseases and insect enemies, yields, markets, and prices.

In all, 574 orchards containing 3,761 acres were examined in Wayne County during the summer of 1903. The total apple area in the county is about 21,000 acres or [illegible] per cent of the improved farm land. The most prominent varieties grown are Bald-

win and Greening followed by Roxbury Russet, King, Northern Spy, and Twenty Ounce. From 20 to 25 per cent of the orchards are rented. The average yield of rented orchards for 4 years was 174 bu. per acre and from orchards managed by the owner 210 bu. More attention is paid to orchard culture than formerly, 14 per cent having been distinctly renovated during the past 10 years.

Relative to tillage and yield, 44 per cent of the orchards have been in sod at least 5 years, 20 per cent have been tilled 5 years or more, and 36 per cent have been tilled part of the time. In 1903, 30 per cent of the orchards were tilled. The average yields for 4 years in the orchards thus differently managed were as follows: Tilled for preceding 5 years or more, 266 bu. per acre; tilled most years, 229 bu.; in sod most years, 202 bu.; in sod at least 5 years, 148 bu. It is thus seen that the tilled orchards have given an average yield 80 per cent higher than orchards regularly in sod.

Not all this difference, however, is due to tillage, since the men who till the orchards usually also give better attention to manuring, spraying, and pruning. Taking these factors into account it was found that the increase in yield, due to tillage alone, was about 35 per cent. A large number of the orchards in sod were pastured with various kinds of stock. Orchards pastured with hogs or sheep gave better results than those pastured with cattle or horses. A few orchards in sod were found which were among the best producers.

About one-third of the orchards examined received no fertilizers whatever. The other two-thirds received more or less manure. Commercial fertilizers were used in only about 12 per cent of the orchards. The average yield for 2 years in fertilized orchards was 257 bu. per acre and in unfertilized 202 bu.

Buckwheat is the cover crop most commonly grown. Bad pruning was frequently observed. In 16 per cent of the orchards stubs from 2 to 12 in. long were found. Thirty-three per cent of the orchards was seldom or never sprayed. Forty-one per cent was sprayed in 1903. The sprayed orchards in 1903 averaged 27 bu. more per acre than the unsprayed orchards. Damage from insects and fungus diseases was small during the year, and in some instances only one spraying was given.

In 43 per cent of the mature orchards the trees were 30 by 30 or less ft. apart. The average yield for 4 years where the trees were 30 by 30 ft. apart was 186 bu. When 31 by 31 ft. to 35 by 35 ft. apart the average yield was 222 bu., and when 36 by 36 ft. to 40 by 40 ft. apart the average yield was 229 bu. per acre. Trees were found to reach their maximum yield in Wayne County 44 years after planting.

Eight per cent of the orchards examined needed drainage throughout, 30 per cent needed drainage in part. Fifty-four orchards in Walworth Township which needed drainage yielded 42 bu. per acre less fruit than the average of the township. Good crops of apples were found on many different types of soils, but loam soils are considered best. The kind of treatment the orchard receives is believed to be of far more importance than the kind of soil. Elevation above the surrounding country did not appear to have any marked effect on the yield. Easterly slopes gave considerably better yields than westerly slopes, which it is thought may be due to the strong west winds. Scab fungus and the codling moth are the most serious enemies.

About 75 per cent of the apple crop in Wayne County is used for evaporating. In this work some growers pick off the best apples to barrel, but generally all the apples are shaken from the tree. The average yields per acre for mature orchards in 1900 was 252 bu.; 1901, 34 bu.; and 1902, 222 bu. The gross average incomes for these same orchards were $37.80 in 1900, $14.28 in 1901, and $48.18 in 1902. Mr. Christian Bues gives a detailed account of the cost of renovating an apple orchard in Western New York during the years 1896-1904, with an account of the returns received. It was about 5 years after the work of renovation commenced before the orchard began to produce paying crops.

Besides the statistical matter given the bulletin contains a large amount of useful information relative to the best methods of cultivation, pruning, spraying, etc.

The breeding of crossbred apples for the Canadian Northwest, W. SAUNDERS (*Canada Expt. Farms Rpts. 1904, pp. 6–11, pls. 2*).—All of the improved American varieties of apples have failed or have been killed by cold when grown in the Canadian Northwest, more especially at the experiment stations at Brandon, Manitoba, and Indian Head, Northwest Territories.

The Siberian crab (*Pyrus baccata*) has proved entirely hardy at both these stations during a trial of 14 or 15 years, and has fruited abundantly. Its fruit is very small and suited only for jelly. The flowers have been cross-fertilized with pollen from many of the hardiest and best sorts of apples grown in Ontario, and from the seed thus obtained a number of seedlings have been grown, which have produced fruit much larger than the crab and greatly improved in quality. Many of these seedlings fruited the fourth year from seed.

Root grafts of some of the more promising sorts have been made and have shown no indications of tenderness even when planted in exposed situations. Some partial failures have occurred in grafting on *P. baccata*. Budding gives better results and forms a better union with the stock, and also admits of the trees being multiplied more rapidly.

Other crabs which are being used are *P. prunifolia* and the wild apple of Europe (*P. malus*). These are likewise crossed with pollen from the hardiest of our improved sorts, and a number of promising seedlings have been obtained. Both of these species have proved hardy for several winters at Brandon and Indian Head.

Some of the best crosses produced on *P. baccata* and *P. prunifolia* have been recrossed, thus introducing a second quota of the blood of the larger and better apples, with the hope of improving the size and quality of the fruit.

About 20 of the most promising seedlings obtained by crossbreeding are described. A considerable amount of stock of these sorts has been distributed in different districts of the Northwest for further testing.

Apple culture, H. L. HUTT (*Ontario Agr. Col. and Expt. Farm Bul. 144, pp. 37, figs. 7*).—Popular directions for the planting and management of apple orchards, including a paper by W. Lochhead on insects injurious to the apple.

Observations on the fertilization of peach orchards, E. H. JENKINS (*Connecticut State Sta. Rpt. 1904, pt. 5, pp. 444–447*).—An experiment on the fertilization of peach orchards, which was begun at the station in 1896 and has been continued each year since (E. S. R., 16, p. 52).

Plat A has received annually 65 lbs. of muriate of potash and 160 lbs. of acid phosphate; plat B these same fertilizers and in addition 170 lbs. of cotton-seed meal; plat C, 65 lbs. of muriate of potash and 160 lbs. of acid phosphate; plat D, 130 lbs. muriate of potash and 160 lbs. of acid phosphate; plat E, 260 lbs. of muriate of potash and 160 lbs. of acid phosphate; and plat F, 260 lbs. of high-grade sulphate of potash and 160 lbs. of acid phosphate.

The number of trees that have died during each year since the orchard was set out and the crops produced in each of the years 1899 to 1904 are given, but conclusions relative to results obtained are reserved until further data have been accumulated.

The shipping of fruit to Winnipeg by freight, J. B. REYNOLDS (*Ann. Rpt. Ontario Agr. Col. and Expt. Farm, 30 (1904), pp. 25–30*).—Much of the data given in this article has been abstracted from another source (E. S. R., 16, p. 876).

Some notes are given on the dimensions of fruit packages in relation to cooling. Fruits which ripen quickly must be cooled to a temperature of 40° or lower soon after picking if they are to be preserved in storage for any length of time. A few hours' delay in cooling down to this temperature greatly decreases their length of life.

In the experiment reported 4 packages were filled with apples and long thermometers inserted so that the bulb would come in the center of the package. The packages

were then headed and kept in a room for a week, until they attained a uniform temperature of 64° F. They were then transferred to a room in the warehouse which was kept at a temperature of 32 to 34°. The packages were an ordinary large apple barrel, a bushel box 10 by 11 by 20 in. with close joints practically air-tight, a Georgia peach carrier 10 by 11 by 20 in. with open spaces at sides and the fruit then packed in 6 baskets with air spaces between the baskets, and a half-bushel box 5 by 11 by 20 in. with open spaces at sides, bottom, and top.

Within 9½ hours after the packages had been placed in the cold-storage house the half-bushel crate registered 40°. The Georgia crate with open sides and open packing had cooled to 43° within the same time. Within 22 hours the half-bushel had cooled to 35°, the Georgia crate to 35°, the bushel to 39°, and the box to 47°. It was 2 days after the commencement of the observation before the barrel had reached a temperature of 38°.

As a result of this investigation, the author states that winter apples and winter pears, so far as temperature and ripening are concerned, may be packed in barrels. For summer and early apples the bushel box should be used. For early and quickly ripening pears the bushel box is too large unless in the form of the Georgia carrier with open sides. The half-bushel box is recommended. All tender fruits should be quickly cooled after picking.

Some uses of the grapevine and its fruit, G. C. HUSMANN (*U. S. Dept. Agr. Yearbook 1904, pp. 363–380, pls. 6, figs. 5*).—This is a popular account of the grape industry with reference to the use of the fruit for food, wine, raisins, unfermented grape juice, brandy, vinegar, preserves, tartaric acid, oil, etc., and of the vine for ornamental purposes.

The average annual production of wine in the United States during the past 10 years has been 25,500,000 gal. and of raisins 89,500,000 lbs. The average annual shipment of California-grown grapes to States farther east is placed at 25,156,000 lbs. About 50 per cent of the grape crop in California is made into wine, 35 per cent into raisins, and 15 per cent shipped as fresh grapes.

California is the State of largest production, having over 90,000,000 vines. New York stands second with a little over 29,000,000, and Ohio third with nearly 14,000,000 vines. New York State leads in the production of grapes of American varieties, since practically the whole of the California output is of European sorts. In the Chautauqua grape district of New York more unfermented grape juice is produced than in all the rest of the country combined, the product in 1904 reaching 605,000 gal. New York leads all the States in the production of sparkling wine.

Methods of making red and white wines are discussed, and methods of manufacture of the various by-products mentioned above briefly noted, including a number of household recipes for canning grapes, making grape pickles, jelly, spiced grapes, marmalade, grape butter, junket, etc.

Grapes cultivated in tropical countries, O. LABROY (*Jour. Agr. Trop., 5 (1905), No. 46, pp. 101–106*).—An account of varieties of grapes which succeed best in several different tropical countries.

A chemical study of the tea industry in South Carolina, I, F. S. SHIVER (*South Carolina Sta. Bul. 96, pp. 32, figs. 6*).—In this bulletin a historical review is given of tea culture with statistics as regards production and consumption. The botanical characteristics of tea are considered, together with the soil and climate best suited for tea culture and methods of cultivation.

From the statistics given it appears that about 89,160,411 lbs. of tea, valued at $12,720,310, are imported each year. Ninety-two per cent of the tea imported is furnished by China and Japan. Analyses are given of the soils at Pinehurst, S. C., where about 100 acres are now planted to tea, and of the rice soils on Cooper River, S. C., where it is proposed to establish a tea plantation.

As the result of experiments at Pinehurst in tea culture on different soils, it is recommended that "level lands, thoroughly drained, porous to as great depth as possible and free from all acidity, be used for tea." Based on the analyses of the soils made it is believed that they are well adapted to tea culture as they contain considerable quantities of organic matter, nitrogen, phosphoric acid, and potash. Suggestions are given on the starting of tea plants, setting out the plantation, pruning, and care.

Report on the cocoanut industry, W. S. LYON (*Philippine Bur. Agr., 1904, pp. 88-93*).—An account of the cultural and manufacturing methods observed in the cocoanut industry in the 2 largest cocoanut-growing districts of the Philippines. Considerable space is devoted to the production of cocoanut oil and of copra.

Contribution to our knowledge of the use of the betel-nut in Dutch East India (*Bul. Kolon. Mus. Haarlem, 1905, No. 32, pp. 173, pls. 13, figs. 8*).—A series of 7 prize essays on this subject.

Propagating trailing arbutus, H. J. KOEHLER (*Amer. Florist, 24 (1905), No. 872, pp. 150, 151*).—It is stated that trailing arbutus can be easily rooted from cuttings in the greenhouse in winter. The cuttings are treated in a manner somewhat similar to that of a coniferous evergreen. They are taken preferably in November before they are severely frozen. They are put in boxes of sand and watered twice daily, and the night temperature kept about 50° F. Shade is given during the middle of the day. In about 6 weeks 75 per cent of them will be rooted and ready to pot off.

FORESTRY.

Forest planting and farm management, G. L. CLOTHIER (*U. S. Dept. Agr. Yearbook 1904, pp. 255-270, pl. 1, plans 3*).—A discussion of the relationship of forest planting to general farm management, with concrete examples taken from forest plans devised for an Ohio farm and for prairie farms in the northern and southern sections of the middle western States.

The central thought brought out in the paper is that forestry is a branch of agriculture and can be made to contribute to the welfare of the farmer when wisely planned. The plans suggested take into consideration the cropping system of the farm, protection of the farm buildings, the location of the woodland strips, the kinds of trees to be used, and the best methods of planting and arranging them.

Horticulture and forestry, J. G. HANEY and O. H. ELLING (*Kansas Sta. Bul. 128, pp. 278, 279, 303*).—An account of the horticulture and forestry work carried on at the Fort Hays Branch Station in 1903-4.

Observations in the vicinity of the station indicate that the honey locust is the most hardy and desirable tree in that section for planting. Of 4,000 evergreens planted in 1903, 32 per cent were alive in 1904 and made a good growth. The rather small percentage that lived is thought to be due to unfavorable conditions at planting time. The Austrian pine has proved the most hardy of the different evergreens planted. About 9 acres have been planted to oak and walnut seed.

Forest belts, W. T. MACOUN (*Canada Expt. Farms Rpts. 1904, pp. 136-139*).—The forest belt on the western boundary of the Central Experimental Farm is 165 ft. wide and that on the northern boundary 65 ft. wide. Their total length is nearly 1.75 miles. The number of trees in these belts is 23,100. The trees have been planted 5 by 5 ft., 5 by 10 ft., and 10 by 10 ft. apart, and the first plantings made in 1887.

From the standpoint of forestry, trees planted 5 by 5 ft. apart are giving the most satisfactory results. At this distance the trees are more protected from storms than those farther apart, the tops are less injured, and they are a little taller and do not have to be cultivated so long as those planted farther apart.

Until within 3 years the trees in the mixed plantation made the most satisfactory growth, and are still making better growth than some clumps composed of single

species. The rapid-growing kinds, however, in the mixed plantations are growing so fast as to overshadow some of the more valuable trees, and those which can not endure shade are being killed. Such trees as ash, butternut, black walnut, and elm, which have thin foliage, do not kill the sod underneath. It is believed the results would have been much better if other heavy-foliaged kinds, such as larch, spruce, pine, or box elder had been mixed with them.

Since 1899 other plantations with trees and shrubs have been made in which the spacing has been 2.5 ft. apart. It is too early to report upon these plantings as yet, but it is believed that 3 ft. apart would be as satisfactory or even more so than 2.5 ft. A table is given showing the growth of 20 different species of trees in the forest belt. Black walnut and butternut are making a very slow, unsatisfactory growth where planted on low sandy soil. White spruce is not doing very well on light sandy soil, nor white elm on sandy loam. All these trees have made a much better growth on other soils.

Forestry in Indiana, S. J. RECORD (*Forestry and Irrig., 11 (1905), No. 3, pp. 107-112, figs. 4*).—It appears that 13,000,000 acres, or more than one-half the State of Indiana, consists of broken waste land suitable for tree growth but worthless for agriculture.

Less than 2 per cent of the total area of the State is now covered with good timber and about 85 per cent of the lumber now used for manufacturing is brought in from other States. The large amount of nonagricultural land is well distributed over the entire State in comparatively small areas. Of the several ways in which it is possible for the State to influence matters in forestry it is believed the only method at present available is that of education and persuasion, by which the farmers can be awakened to the possibilities and advantages of forest planting for posts, fuel, and lumber.

A brief review is given of the forest legislation of Indiana. In 1903 a law was enacted which provides for the purchase by the State board of forestry of 2,000 acres of land at a cost not to exceed $8 per acre, and $1.50 is to be allowed annually to defray the expenses of management and labor. This land was purchased in Clarke County, and various experiments are under way to demonstrate methods of sylviculture, tree planting, and forest management. A nursery has been established in which seedlings will be raised for free distribution to the farmers of the State.

The Gila River Forest Reserve (*Forestry and Irrig., 11 (1905), No. 4, pp. 178, 179*).—About 3,640 sq. miles of this reserve has been examined. Of this area 71.25 per cent is covered with merchantable timber of extra quality, while 26.25 per cent is naturally timberless. The estimated amount of timber on the reserve is placed at 5,867,169,750 ft. B. M., giving an average stand of 3,532 ft. B. M. per acre over the entire timbered belt. About 57.75 per cent of the merchantable timber is yellow pine and 28.37 per cent red fir.

Progress report of forest administration in the province of Assam, E. S. CARR (*Rpt. Forest Admin. Assam, 1903-4, pp. 64, map 1*).—A detailed review of the work of the year, including an account of the timber cut, receipts, and expenses, etc.

In the work with rubber trees on the Kulsi plantation, 88 acres containing 2,361 trees yielded 2,708 lbs. of tree rubber and 1,294 lbs. of mat rubber, or an average of 45.5 lbs. per acre and 1.7 lbs. per tree. The cost of tapping was 1,264 rupees and the product brought 11,026 rupees. In the Charduar plantation of 255 acres the average yield per acre in 1903 was 21.7 lbs. or 1.4 lbs. per tree. In 1904 it was 21.79 lbs. per acre or 1.8 lbs. per tree.

Administration report of the forest department of the Madras Presidency (*Admin. Rpt. Forest Dept. Madras, 1903-4, pp. 36 + CXVIII*).—An account of the administration and management of the state forests during the year, revenue and expenditures, etc.

During the year 2,981,880 cu. ft. of timber, including sandalwood, was cut; also 17,422,741 cu. ft. of fuel and a little over 37,000,000 bamboos, while the miscellaneous receipts from grass and grazing was placed at about $500,000. The appendix is made up of tables showing the particulars regarding forests in each of the different districts of the Presidency.

Report of forest administration in the Andamans for 1903-4, B. B. OSMASTON (*Rpt. Forest Admin. Andamans, 1903-4, pp. 31*).—A report on the conditions of the public forests in the Andamans as regards improvements, plantings, and cuttings made during the year, administration, etc.

Natural reproductions of Padouk were searched for, but practically no seedlings nor saplings of this species could be found. Mangrove sowings have proved cheap as well as successful. The average cost to completely restock swampy areas, including the cost of collection of seed, etc., was about $2 per acre. The mangroves are spaced 4 by 4 ft. apart.

The determination of timber values, E. A. BRANIFF (*U. S. Dept. Agr. Yearbook 1904, pp. 453-460*).—Experiments were made to determine exactly how much more valuable a particular kind of a tree of a certain size is than another tree of the same kind but of smaller size.

The special purpose of the investigation was to secure data on the rate at which the timber value of the tree increases with its diameter growth, in consequence of the higher quality of lumber which it will yield. In order to determine this matter trees of different sizes were cut and sawed up into lumber. The exact amount of lumber of the different grades which each tree of each size made was recorded and the value of the lumber thus obtained found by using current market prices for the different grades. Tables containing these data in detail are given for yellow birch timber from trees varying in size from 13 to 31 in. in diameter. Similar data were also collected for sugar maple and beech from Adirondack hard woods and of long-leaf pine.

From the tables given it is shown that lumber from a 24-in. birch tree is worth $5.63 per 1,000 ft. more than lumber from a 13-in. tree. From a tree 31 in. in diameter the lumber is worth $8.43 per 1,000 ft. more than from a birch tree 13 in. in diameter. With the sugar maple and beech, lumber from a 24-in. tree is worth $3.13 and $1.39, respectively, more than from a tree 13 in. in diameter. With long-leaf pine there was a difference of $1.72 per 1,000 ft. in favor of a pine 24 in. in diameter as compared with a pine 14 in. in diameter. It is believed that Adirondack lumbermen may be able to figure out fairly accurately the values of their hard woods if they know the expense of stumpage, logging, and manufacture.

In the working plan for a tract at McKeever, N. Y., the average number of trees of birch, sugar maple, and beech of 17 in. in diameter, etc., was determined. Placing the cost of stumpage, logging, and manufacture as low as $10.50 on 17-in. trees, it was estimated that there would be a profit of 42 cts. per 1,000 ft. on birch and 21 cts. on maple. If all the birch and maple above 17 in. in diameter were cut out the profits would be $11.32 per acre and the average profit per 1,000 ft. would be $4.15 from birch and $1.49 from maple. It was found that when the smaller trees were taken the profits per acre were increased but the profits per 1,000 ft. decreased.

The profits per acre when the expenses of lumbering were $10.50, $10.75, etc., up to $12.75 per 1,000 ft. were calculated for tracts in the Adirondacks, the results of which do not encourage indiscriminate cutting of hard woods in the Adirondacks, but on the other hand furnish strong arguments against careless lumbering. It is believed that the expenses of lumbering in the Adirondacks are so high that it will not pay to cut any but the larger trees. The figures obtained "prove that the lumberman who would make the highest profits out of the Adirondack hard woods must cut within certain diameter limits and leave, in most cases, a considerable stand of timber uncut."

The red gum, A. K. CHITTENDEN (*U. S. Dept. Agr., Bur. Forestry Bul. 58, pp. 9-39, 55, 56, pls. 6, map 1*).—The increased price of cottonwood and yellow poplar has gradually brought the red gum into the market.

Many of the heretofore objectionable features of this wood have been overcome by improved methods of handling, and the gum now occupies a recognized rank as a commercial wood. The red gum (*Liquidambar styraciflua*) grows in the hard wood bottom lands of the South in mixtures with ash, cottonwood, oak, etc. Other important gums which grow in the same region are the tupelo or bay poplar (*Nyssa aquatica*), and the black gum (*N. sylvatica*). The latter is not cut as mill timber.

The author made a study of the red gum as it is found in the Mississippi Valley and along the Atlantic coast. The characteristics of the tree as regards form, tolerance of shade, soil and moisture requirements, reproduction, second growth, rate of growth, etc., were investigated, together with stumpage value, lumbering methods, milling, market and uses of timber, properties of the wood, prices of lumber, methods of seasoning, and of forest management. Some attention was also paid to the lumber manufacture and uses of tupelo gum.

The red gum is intolerant of shade. It reproduces from both seeds and sprouts. Seed crops are borne when the trees reach 25 to 30 years of age and they may continue in bearing up to the age of 150 years. Trees over 50 years old seldom sprout. The stumpage value of young timber ranges from 50 cts. to $1.50 per 1,000 ft. B. M. Logs delivered at the mill bring $5 to $7 per 1,000 ft. B. M. The green logs will not float and since the waterways form the cheapest method of transportation, the method of lumbering now generally followed in the South is to cut the trees without girdling in the fall, from September to January or February, when high water sets in. They are then floated down on rafts with cypress, ash, or cottonwood, to keep them from sinking. The work is simplified where railway logging can be practiced.

Red gum is now used for practically all purposes for which poplar and cottonwood have been used heretofore. The best grade heartwood is largely exported, though some is used for inside finish in this country. Of that exported 75 per cent goes to England, France, and Germany for the manufacture of furniture and for inside finishing, etc. Common and clear sapwood goes into cheap furniture, desks, boxes, etc. The poorer stock goes into boxes, barrels, and the like.

About 60 per cent of the stock from the tree is of sap grade. This is largely used for boxes. From 40,000,000 to 60,000,000 ft. B. M. red gum is now used in this country annually for the manufacture of furniture. About 18,000,000 ft. was used in 1903 for flooring. Large amounts are used in the manufacture of slack barrels. For this purpose it must be steamed more than cottonwood or elm to prevent breakage. Other uses are for wagon-box boards, paving blocks, handles for tools, etc.

The wood is not strong enough for construction purposes. The chief objection to it is its strong tendency to warp and twist. This is largely overcome by proper methods of seasoning, which involve piling it in the yards so as to permit a free circulation of air under and through the piles. Gum boards may be successfully kiln-dried. Boards over 2 in. thick, however, are apt to caseharden.

A number of tables are given showing the rate of growth of red gum in Missouri and South Carolina, and the average stand in native and second growth forests. The rate of growth is slower in the Mississippi Valley but the trees reach there their greatest development The more rapid growth of the trees along the Atlantic results in a larger proportion of sapwood.

Tupelo gum is at present of great commercial importance only in Alabama. With this gum there is no distinction in color between heartwood and sapwood. It is generally sold in the market as bay poplar. It possesses about the same weight and strength as red gum, but is tougher and more perishable when exposed. The wood is used for furniture drawers and backs, panelwork, inside finish, and especially for

boxes. It is also largely used for moldings, wagon boxes, etc., but is not durable enough for flooring.

"Like red gum, tupelo is easily glued, painted or varnished, and absorbs little of the material. In this respect it is better than yellow poplar and much better than cottonwood." Detailed directions are given for the management of gum forests in the South, and a map given showing the distribution of red gum.

The mechanical properties of red gum wood, W. K. Hatt (*U. S. Dept. Agr., Bur. Forestry Bul. 58, pp. 5, 40–56, figs. 7*).—Tests to determine the strength of red gum timber were made at the timber-testing station of the Bureau of Forestry at Purdue University, the results of which are given in detail in tables and discussed. The tables show the comparative strength of green wood of red gum and loblolly pine, of gum from Alabama and Missouri, of heartwood and sapwood, etc.

As a stock for carriages, the tests show that red gum can be bent into shape without difficulty, that it will take a fine finish, and when properly selected will hold its shape after being bent. The best grades of red gum, however, appear to be inferior in strength to even the poorer grades of wood, such as hickory. Its use, therefore, as carriage stock should be confined to those parts of the vehicles that do not have to stand heavy loads and shocks.

The average weight of the green wood from Alabama was 49.2 lbs. per cubic foot, the maximum being 66 lbs. and the minimum 38.8 lbs. With 15 per cent of moisture the weight is about 32.4 lbs. per cubic foot and this may be taken as the weight of the wood when thoroughly air dried. The article includes an illustrated account, by H. D. Tiemann, of the microscopic structure of red gum wood.

A new species of juniper for Texas, G. B. Sudworth (*Forestry and Irrig., 11 (1905), No. 5, pp. 203–206, figs. 4*).—A new species of juniper has been discovered in Texas. The tree is 10 to 20 ft. high and has numerous stems 3 to 5 in. in diameter, which form a more or less dense clump. It has been named *Juniperus pinchoti*.

The wood has distinct narrow rings. The sapwood is nearly white and the heartwood light brown with a pale reddish tinge. It is only moderately durable in contact with the soil. One of its valuable characteristics is its persistent sprouting after fires. The wood is used locally for fuel and fence posts.

Attitude of lumbermen toward forest fires, E. A. Sterling (*U. S. Dept. Agr. Yearbook 1904, pp. 133–140, pls. 3*).—Some estimates are given on losses from fire and conditions which affect them, with some suggestions in regard to the control of fires.

The average annual loss from forest fires is stated to be about $25,000,000. In the Washington and Oregon fires of 1902 there was a loss of $12,000,000 worth of forest property in 9 days. In New York State in the spring of 1903 the direct loss from fires in the Adirondacks was $3,500,000 in addition to a known expense for fire fighting of $175,000.

While these losses are large, there are certain secondary losses of equal importance which are not generally considered by the public. These are the effect of fires on forest reproduction and water conservation. The greatest losses from fire occur on the Pacific Coast and the least in the southern hard woods.

Investigations by the Bureau of Forestry in one instance showed that in a turpentine orchard of Florida longleaf pine, which had been abandoned for 5 years, 33 per cent of the trees above 1 in. in diameter were dead or down, mainly as a result of fire. Practically all the boxed trees were burned, while of the unboxed trees 82 per cent were standing and sound. The "long butting" necessitated by the burns in the base logs of one firm operating in the Sierra forests amounted to 4.5 per cent of the total cut, which was a direct loss.

The general attitude of lumbermen toward forest fires is stated to be one of hopelessness, coupled in a measure with indifference. Forest fires are regarded as inevitable, and heretofore organized effort to prevent and control fires has not been practicable from a financial standpoint.

Practical results of the cup and gutter system of turpentining, C. H. Herty (*U. S. Dept. Agr., Bur. Forestry Circ. 34, pp. 7, figs. 5*).—The cup and gutter system of collecting crude turpentine was described at length in an earlier publication of the Bureau (E. S. R., 15, p. 46).

Since the publication of that bulletin further practical experiments in the use of this system have been carried out, and the present circular covers this work, together with improvements which have been made and an account of the defects in the system which have been discovered during the past 3 years.

The plat of timber described in the bulletin previously referred to as a "first-year crop" has been worked 2 more years as a "second-year crop" and as a "third-year crop." The results show that where the cup and gutter system was used the trees yielded $1,284.04 per crop, or over 30 per cent more than trees boxed in the usual manner.

A study has also been made of the relative condition of the trees on the cupped and boxed areas. During the period of 3 years 78 trees on the boxed area have blown down and 217 died. On the cupped area 44 trees have blown down and 150 died. Only 8 of the 44 cupped trees were blown down because of being turpentined, while the fall of 59 of the 78 trees blown down on the boxed half was due to boxing.

The productive surface lost from all causes averaged from 30 to 50 per cent more on boxed trees than on cupped trees. Much the greater part of this loss in both cases was due to "dry face" and the rate of increase in dry face after the first year was greater in the cupped than in the boxed trees and was thought to be due to the higher number of faces per tree on the cupped half.

Improvements have been made in the cups used for catching the resin. They are now made by machinery, with a stiffer, much drier clay, which prevents the seepage of resin. With experience dippers are able to collect more gum per day from the cups than from boxes. Another improvement is the use of the broadax for facing. For this purpose the usual setting of the broadax on the handle is reversed, so that in hewing the beveled side is next to the tree.

Another improvement is to have one man make both incisions for the gutters instead of employing right-handed and left-handed axmen for making the two. An instance is cited in which one laborer prepared 1,700 faces in one day and the work was well done. Zinc nails have been substituted for iron nails for hanging the cups. These are much softer than the iron nails and do not injure the saws when the trees are afterwards made into lumber.

Experimental tapping of para rubber trees at the botanic gardens, Singapore, R. Derry (*Agr. Bul. Straits and Fed. Malay States, 3 (1904), Nos. 9, pp. 339-379; 11, pp. 442-463*).—Tabular data are given on the results secured in an extensive series of experiments in tapping para rubber trees, which were planted in 1886 to 1888 and which have an average girth of 2.5 to 4.5 ft. at 3 ft. from the ground.

Better results have been secured from morning tapping than from evening tapping, although the evening work commenced as late in the day as possible. It is believed that the flow of latex depends entirely upon the pressure of water within the tree and this is affected to some extent by the contraction and expansion of the tree. It has been noted that a tree 3 ft. in girth at 3 ft. from the ground which measured exactly 3 ft. at 6 a. m. would by afternoon on bright days contract a maximum of 0.5 in. and by 6 p. m. or soon afterwards expand to the early morning measurement.

On wet days also there was considerable expansion in the tree and the flow of the latex was considerably increased, but contained an unusually high percentage of water. In wet weather it seems best to tap some hours after a storm. It has been found that latex from a big tree produces a much thicker biscuit of prepared rubber than the same amount of latex from a small tree, irrespective of age.

Experiments in tapping by the herring-bone method confirm in general the opinion as to the advantage of alternate over daily tapping.

Federal and State forest laws, G. W. WOODRUFF (*U. S. Dept. Agr., Bur. Forestry Bul. 57, pp. 259*).—This is a compilation of the various Federal and State forest laws, which has been prepared to supply the needs of the Bureau of Forestry in various matters relating to the management of forest reserves, etc., and also to supply information to private individuals. The laws are for the most part printed verbatim, except where they have been amended by later acts, or where the law is an unimportant one or but slightly connected with forest questions. In addition some important court decisions are cited, although no attempt is made to include any considerable portion of the court rulings under the laws.

The compilation is arranged according to topics, chapters being devoted to constitutional provisions, in which it is shown that Colorado, Nebraska, New York, and Utah have constitutional provisions relating to forestry; the administration and use of timberland and forest reserves; forest trespass; forest fires; bounties, tax rebates, and tax exemptions; and statutes relating to investigation, education, and public observance.

In appendixes data are given relative to the location, extent, and date of establishment of Federal forest reserves, national parks, military wood and timber reservations, and the various dates observed as Arbor Day in the several States and Territories.

Forest legislation in the Northwest (*Forestry and Irrig., 11 (1905), No. 5, pp. 231–234*).—An account of the forest legislation in Washington, Oregon, and Idaho in 1905, the greater portion of which relates to the protection of forests from fire.

Arboretum and botanic garden, W. T. MACOUN (*Canada Expt. Farms Rpts. 1904, pp. 140, 141*).—A list is given of the genera of trees and shrubs in the arboretum, with the number of species of each genus alive in the autumn of 1904.

DISEASES OF PLANTS.

Notes on fungus diseases for 1904, G. P. CLINTON (*Connecticut State Sta. Rpt. 1904, pt. 4, pp. 311–328, pls. 11*).—In a previous report (E. S. R., 16, p. 62) the author gave notes on all the fungus and bacterial diseases and physiological troubles which had been observed on cultivated plants in Connecticut. In the present report notes are given on those which were prominent during the year or which were observed for the first time. The arrangement is alphabetical by host plants.

Among the diseases and fungi which are reported upon for the first time, the occurrence of the æcidial stage of the asparagus rust is noted. The presence of the rust parasite, *Darluca filum*, is mentioned, and the same fungus is said to attack the carnation rust and the blue-grass rust. The occurrence of the downy mildew, *Peronospora parasitica*, on cabbage is noted; and in a discussion of the brown rot of cherries, caused by *Sclerotinia fructigena*, the author states that from his observations the fungus apparently spreads each spring either from the mummied fruit or infected branches, and does not travel down the diseased pedicles and from these infest the fruit spurs.

The powdery mildew of grapes is said to have been exceedingly troublesome, particularly to thin-skinned and white varieties. Notes are given on a bacterial disease of mulberry, which is reported for the first time in the State, causing more or less injury to young trees in the nursery. This disease, which is due to *Bacillus cubonianus*, destroys the twigs, and frequently the whole tree becomes stunted and yellowish in appearance. Thorough pruning of the trees in the winter time is recommended as probably the best treatment. The effect of frost injury on peaches is described.

An account is given of a disease of potatoes, which is probably of bacterial origin, and the possible relationship between this disease and the soft rot of the tubers is discussed. Mention is made of the black spot, or canker, of tobacco, and the must, which is of fungus or bacterial nature, both diseases occurring in the curing house.

Insects and fungus diseases, W. LOCHHEAD (*Ann. Rpt. Ontario Agr. Col. and Expt. Farm, 30 (1904), pp. 40-49, figs. 5*).—After discussing fungi as a cause of plant diseases, their methods of growth, infection, and control, the author gives keys for the recognition of the diseases of apples, peaches, raspberries, gooseberries, currants, grapes, etc.

Report of the department of bacteriology, F. C. HARRISON (*Ann. Rpt. Ontario Agr. Col. and Expt. Farm, 30 (1904), pp. 117-128, figs. 6*).—A report is given of the work carried on in the bacteriological laboratory during the season, particular attention being given to the preparation of nitrogen cultures for different leguminous plants, and investigations on the bacterial diseases of cucumbers, cabbage, and beans, and fire blight.

In discussing the cucumber wilt, the author describes the appearance of the plants affected by *Bacillus tracheiphilus*, and gives popular directions for the recognition of the disease. Where the disease is suspected it is suggested that a wilted vine be broken and if the juice is slimy it is safe to conclude that the wilt disease is present. If this test is not satisfactory, the transfer into young fruits of juice from wilted vines is suggested, after which the inoculated fruits are placed in a vessel and kept slightly moist for 4 or 5 days. If the bacillus is present at the end of this time there will appear a white, viscid, bead-like drop of bacterial growth exuding from the punctures made by the transfer needle.

If symptoms of disease develop in the inoculated fruit it is recommended that all wilted vines be pulled up and burned; and to prevent further spread, measures should be taken to combat the squash bug and the striped cucumber beetles, as it has been found that these insects carry the organisms from diseased to healthy plants.

Notes are given on the black rot of cabbage due to *Pseudomonas campestris*, which has caused considerable injury to cabbage and cauliflower and is also reported as attacking Swedish turnips. More extended notes have been given of the other bacterial diseases mentioned in Bulletins 136 and 137 of the agricultural college (E. S. R., 16, pp. 477, 480).

A review is given of the experimental work that has been carried on in the bacteriological department from 1895 to 1903, with a list of publications.

Annual report of botanist, C. A. BARBER (*Rpt. Dept. Agr. Madras, 1903-4, pp. 10-13*).—A detailed report is made of the various lines of work carried on by the botanist during the year 1903-4.

Among the more important investigations from an economic standpoint are notes on a red spot disease of sorghum leaves, which has been identified as due to the fungus *Colletotrichum lineola*.

Various diseases of other economic plants are briefly noted, particular attention being given to diseases of the black pepper, the most of which are of fungus nature. One disease in particular is proving very destructive, and it has been attributed to attacks of *Nectria* sp. as well as the root fungus *Rosellinia necatrix*. A careful investigation has led the author to the conclusion that the Nectria is saprophytic and not the cause of the disease, and in no case was he able to determine the presence of the Rosellinia in badly infected specimens in the plantation.

Notes are given of a number of economic plants which are under investigation, and a brief account is presented of the extension of the herbarium work.

Sclerotium diseases of plants (*Bd. Agr. and Fisheries [London], Leaflet 127, pp. 3, figs. 4*).—A description is given of diseases of potatoes, turnips, carrots, peas, beans, and cucumbers, as well as of a number of decorative plants propagated by bulbs.

These diseases are caused by attacks of species of Sclerotinia, which in addition to growing as parasites on living plants, can grow on decaying vegetable matter. The effect of the fungus on the different plants is briefly described, and as a preventive treatment it is suggested that all infested stems, leaves, and bulbs should be col-

lected and burned and either gas lime or quicklime applied to the land where the disease has existed.

Rusts of grain crops, J. FLETCHER (*Canada Expt. Farms Rpts. 1904, pp. 252–255*).—Popular notes are given describing the cause of the wheat rusts, and the relation of the organism to wheat and other host plants, and suggestions for preventing loss. The principal suggestion is plant breeding along the line of rust resistance.

New studies of the vegetative life of yellow grain rusts, J. ERIKSSON (*K. Landtbr. Akad. Handl. och Tidskr., 43 (1904), No. 3, pp. 234–246*).—An account of recent investigations conducted by the author on this subject. These further corroborate the views previously set forth, that the yellow grain rusts at least can live within the wheat plant from the time of germination in the fall until June the next year in the form of a mycoplasma, finally producing a protomycelium, and that from this form contagion may spread, as well as later on from uredospores. The efforts toward eradication of grain rusts must, therefore, be directed against the germ of disease in the form of mycoplasma in the plant itself, rather than against the contagion from without through spores carried about by wind and weather. Breeding experiments to secure rust-resistant varieties must therefore receive still more attention than has heretofore been the case.—F. W. WOLL.

The formalin treatment of grain smut and its application by means of Dehne's disinfection machine, S. RHODIN (*K. Landtbr. Akad. Handl. och Tidskr., 43 (1904), No. 5, pp. 368–372*).—Experiments were conducted with wheat and barley treated in the Dehne disinfection machine.

The treatment only slightly decreased the germination and the germinative energy of the seed grain, and the treated grain was free from smut in every case. The capacity of the machine is 1,000 kg. of grain per 30 minutes. In the experiments conducted by the author, 200 cc. of 40 per cent formaldehyde was dissolved in 70 liters of water for oats, and in 50 liters for other kinds of small grains.—F. W. WOLL.

Burrill's bacterial disease of broom corn, E. F. SMITH and FLORENCE HEDGES (*Abs. in Science, n. ser., 21 (1905), No. 535, pp. 502, 503*).—The occurrence of a bacterial disease of broom corn in Washington, D. C., in 1904 is noted.

The affected plants exhibited the characteristic elongating red-brown spots, followed by the death of the leaves. The disease began on the lower leaves, but by the end of September had reached the top of the plants and had destroyed all the lower leaves and badly spotted the remainder. A microscopic examination of the spots showed a bacterial focus to be present in each one. The infection was found to take place by way of the stomata and was favored by rainfall or dew.

The authors separated the organism and describe its action in various media, as well as determining a number of its cultural characteristics. Some varieties of broom corn are said to be much more susceptible to the disease than others, and it is hoped that through resistant plants the disease may be overcome.

Spraying potatoes for the prevention of blight and rot, W. T. MACOUN (*Canada Expt. Farms Rpts. 1904, pp. 131–134*).—A report is given on comparative tests on different plats of potatoes sprayed with Bordeaux mixture and Bug Death, Bordeaux mixture and Paris green, soda Bordeaux and Paris green, and the insecticides used separately.

Five applications were given the vines, beginning July 2 and continuing at intervals of about 10 days. The potatoes were dug October 6 and the yields, increase in crop, and cost of spraying are shown in tabular form. It appears that the Bordeaux-Bug Death mixture gave the greatest increase, the net increase in value amounting to $21.86 per acre. This was followed by ordinary Bordeaux mixture and Paris green, which gave a net increase of $17.68 per acre The exact cost of application is not given, the expense of applying the fungicides to small plats being relatively much greater than had larger tracts been used.

The cost of applying the Bordeaux-Bug Death mixture was greater than where Bordeaux mixture or Paris green was employed, so that the difference in net gain between the two is less than indicated above. The greater efficiency of the Bordeaux-Bug Death mixture is attributed to its more adhesive power.

Downy mildew, or blight, of potatoes, G. P. CLINTON (*Connecticut State Sta. Rpt 1904, pt. 4, pp. 363–384, pls. 6*).—In 1902 the author began a series of spraying experiments with potatoes to determine the amount of injury due to *Phytophthora infestans*, and, secondly, to determine the most effective and practical method of spraying to prevent it. In this report he presents the results and offers suggestions based upon the experiments thus far carried out.

While the blight fungus is one of the most serious pests of the potato in Connecticut, the author states that frequently injuries caused by other organisms are attributed to it. The results obtained in spraying with Bordeaux mixture vary with different seasons, but depend largely on the thoroughness of the treatments and their application at the proper time. Increased yields due to spraying, varying from almost nothing to over 100 per cent, are noted; to be economically profitable the author says that an average gain of 15 to 20 per cent should be obtained.

Where late potatoes are sprayed for the blight the author advocates 3 to 4 thorough applications of Bordeaux mixture, the first to be made between July 5 and 15 and the last about the end of August or first of September.

"Wet rot" of potatoes, C. T. MUSSON and G. MARKS (*Agr. Gaz. N. S. Wales, 16 (1905), No. 2, pp. 186–193, figs. 4*).—A disease of potatoes, to which the name "wet rot" is given, is described.

In the field the disease rapidly destroys plants here and there in the rows, but seldom are contiguous specimens attacked. The isolated plants exhibit characters which are attributed to attacks of bacteria, and it is believed that the organism is present in the seed tuber and develops with the development of the plant. Investigations have been carried on to determine this fact, and the authors believe it to be thoroughly demonstrated that the disease is transmitted through the seed tubers.

There is no external indication of the presence of the disease in the harvested tubers, but if cut in two characteristic brown spots, running in an irregular line throughout the tuber, are to be found. All such tubers should be rigorously excluded in planting, and if the crop shows signs of disease, all plants attacked should be dug up and destroyed at once.

Downy mildew, or blight, of muskmelons and cucumbers, G. P. CLINTON (*Connecticut State Sta. Rpt. 1904, pt. 4, pp. 329–362, pls. 3*).—A description is given of the downy mildew or blight of muskmelons, in which the early record, distribution, host plants, systematic position of the fungus, its life history, etc., are described. The fungus, which has hitherto been referred to the genera Peronospora and Plasmopara, the author shows is entitled to generic rank, and he proposes for it the name *Peronoplasmopara cubensis*.

A review is given of experiments which have been carried on in different places for the control of this disease. The consensus of opinion seems to favor the spraying of cucumbers with Bordeaux mixture for their protection. From the author's experiments, based on 3 years' investigations with muskmelons, it is concluded that when the downy mildew is very severe spraying the muskmelons is useless, but when seasons are cold and damp and the fungi are not unusually destructive, spraying may show some benefit. During warm dry seasons, such as are necessary for the development of muskmelons in Connecticut, the fungus does not occur abundantly enough to warrant spraying; and everything considered, the spraying of muskmelons is not to be recommended in the State.

A bibliography of nearly 70 publications relating to this fungus and the disease it causes is given.

Notes on Pseudomonas campestris, H. A. HARDING and M. J. PRUCHA (*Abs. in Science, n. ser., 21 (1905), No. 535, pp. 483, 484*).—An account of experiments carried on at the New York State Station with the black rot organism which attacks cabbage, cauliflower, and allied plants.

Previous investigations regarding this parasite have been reported (E. S. R., 16, pp. 170, 480), and in the present paper an account is given of the resistance of the organism to drying. When exposed on sterile cover slips the bacteria did not survive a 10-day drying, but they were found to retain their vitality on cabbage seed for more than a year. Cabbage plants inoculated with pure cultures obtained from seed 13 months after infection showed a blackening of the veinlets in the leaf, and other evidences of disease after an interval of 16 days.

Peach leaf-curl (*Bd. Agr. and Fisheries [London], Leaflet 120, pp. 3, fig. 1*).—A description is given of the peach leaf-curl, caused by *Exoascus deformans*, together with suggestions for its control. It is stated that the remedies recommended in the United States are inadequate in England, repeated experiments having shown that spraying with Bordeaux mixture will not wholly control the disease. In addition to spraying, the removal of the diseased shoots which bear the characteristic tufted leaves is recommended.

Bacterial infection by way of the stomata in black spot of the plum, E. F. SMITH (*Abs. in Science, n. ser., 21 (1905), No. 535, p. 502*).—In continuation of previous investigations (E. S. R., 14, p. 531) the author has studied the bacterial infection of the black spot of the plum.

Numerous infections were obtained through the stomata by spraying dissolved cultures of the *Pseudomonas pruni* over leaves and green fruits. When this was done during damp weather the spots became visible in 7 days. Microscopic investigations showed the characteristic appearance of the disease and the organism was readily recovered by means of agar plates. A neighboring tree inoculated at the same time and in the same way, but with a different organism, never showed any results. No spots were obtained on full-grown plums, although numerous attempts were made under what appeared to be favorable conditions. The disease appears to be one limited strictly to meristomatic tissues.

The cedar and pear rust, P. PASSY (*Rev. Hort. [Paris], 77 (1905), No. 5, pp. 114–118, figs. 8*).—The author describes the relation between the Gymnosporangium occurring on cedars, or species of Juniperus, and the Rœstelia stage occurring on pears, etc.

Diseases of the grape in Ontario in 1904, W. T. MACOUN (*Canada Expt. Farms Rpts. 1904, pp. 123–125*).—The author briefly describes the anthracnose, black rot, brown rot or downy mildew, powdery mildew, ripe rot, and leaf blight of grapes.

A fungicide for use in combating grape gummosis, DE SOKOLNICKI (*Prog. Agr. et Vit. (Ed. l'Est), 26 (1905), No. 12, p. 355*).—A formula is given of a fungicide which is recommended as a wash for grapevines to protect them against gummosis. The fungicide consists of water 100 liters, mercuric nitrate 300 gm., and sulphuric acid sufficient to make the solution clear.

A coffee leaf fungus, H. N. RIDLEY (*Agr. Bul. Straits and Fed. Malay States, 3 (1904), No. 12, pp. 492, 493*).—A disease is described which attacks the leaves and berries of coffee, forming over the leaves a dense white mycelium and causing the unripe berries to become depressed over the surface and more or less blotched with brown.

The author suspects the fungus to be a species of Corticium, but so far has not been able to positively identify it. The disease is most troublesome during wet weather or in thickly shaded portions of the plantation, and it largely disappears with the advent of dry weather. As a precautionary measure it is recommended that where the fungus occurs steps should be taken to secure a better circulation of air and a freedom from too much moisture.

Pecan scab, W. A. ORTON (*Abs. in Science, n. ser., 21 (1905), No. 535, p. 503*).—A description is given of a disease of considerable economic importance caused by attacks of *Fusicladium effusum* on the leaves, twigs, and nuts of cultivated pecans in the Southern States.

The fungus occurs on either side of the leaves and on the petioles, producing dead spots or distortions and defoliation. Sometimes the new growth of the twigs is killed, but the greatest injury is to the nuts. The microscopic and cultural characters of the fungus are described, showing it to be identical with *F. carygenum*. Favorable results from spraying experiments are reported.

Pests of ornamental shrubbery, M. C. COOKE (*Jour. Roy. Hort. Soc.* [*London*], *29 (1904), No. 1–3, pp. 1–25, pls. 3*).—Annotated notes are given on the occurrence of parasitic fungi on a number of ornamental shrubs. The fungi and tneir effect on the hosts are briefly described, and notes given on their distribution, habits, etc.

The bud rot of the cocoanut palm in the West Indies, E. F. SMITH (*Abs. in Science, n. ser., 21 (1905), No. 535, pp. 500–502*).—Attention is called to a serious disease of cocoanut palms, previous notes of which have been given (E. S. R., 14, pp. 671, 882).

The disease is said to have made decided advances since reported in 1901, and in many regions the planters are becoming discouraged, since trees of all ages and on all sorts of soils are being destroyed. In all the cases examined the roots and stem seemed to be sound. The general symptoms of the disease are the yellowing and falling of the outer leaves, the shedding of the nuts, followed in several months by the death of the whole crown.

An examination showed that the disease was located in the crown, where the organism produces an ill-smelling soft rot. The rot is invisible until the outer leaf sheaths are removed, when the entire bud will be found affected. The disease stops very promptly after having destroyed the undeveloped tissues of the bud, and does not seem to be able to attack the harder tissues of the palm stem.

The bacteria are believed to have found entrance through wounds of some kind, and their distribution is undoubtedly favored by flies and other insects. All diseased trees, it is said, should be cut down, and the terminal buds destroyed or treated with some strong fungicide.

Some diseases of loblolly pine timber, H. VON SCHRENK (*Abs. in Science, n. ser., 21 (1905), No. 535, p. 502*).—The author states that the living tree of the loblolly pine is subject to the attacks of several fungi, notably *Trametes pini* and *Polyporus schweinitzii*. After the timber is cut it is said to be very susceptible to fungus attacks, and it is probably the least resistant of all American woods.

A number of fungi are known to grow on the timber, living on the starch or exuding resins, but the most destructive enemy of the loblolly pine is *Lenzites sepiaria*, which causes a brown rot. The various forms of the fruiting body of the fungus are described, and accounts given of experiments to test the susceptibility of timber to this fungus. It was found that proper piling would to a considerable extent protect the timber for some time.

ECONOMIC ZOOLOGY—ENTOMOLOGY.

Ground squirrels and other rodent pests in Nevada, P. FRANDSEN (*Nevada Sta. Bul. 58, pp. 34, pls. 5, figs. 7*).—In Nevada there are 3 species of ground squirrels, *Citellus beecheyi*, *C. oregonus*, and *C. beldingi*. *C. oregonus* is the only one of economic importance. The author discusses in detail the habits and food of ground squirrels. The badger, coyote, hawks, and owls are their chief enemies. Ground squirrels cause great damage by destruction of grain, alfalfa, and garden crops, by eating range grasses, and by interfering with irrigation as a result of their burrowing.

Experiments were made in poisoning ground squirrels with strychnin, corrosive sublimate, red and yellow phosphorus, potassium cyanid, arsenic, etc. Of these strychnin was most satisfactory. It was used on bacon, corn meal, raisins, dutch cheese, wheat, etc. In fumigating carbon bisulphid alone or mixed with gasoline gave excellent results. The use of cultures of disease germ from the Pasteur Institute was without effect. Ground squirrels may also be trapped or destroyed by irrigation and dogs. The author favors poisoning in early spring as the best method of exterminating the pests.

The habits of the pocket gopher are also described. This pest is very injurious to alfalfa and garden crops. They may be drowned out and caught with dogs or poisoned. Good results were had in the use of poisoned baits for destroying jack rabbits and other harmful rodents.

Prairie dogs, J. G. HANEY and O. H. ELLING (*Kansas Sta. Bul. 128, p. 262*).—Prairie dogs were exterminated on 400 badly infested acres for $33.50, or about 8 cts. per acre. At first poison was distributed, after which the inhabited holes were treated with carbon bisulphid and gasoline.

The relation of coyotes to stock raising in the West, D. E. LANTZ (*U. S. Dept. Agr., Farmers' Bul. 226, pp. 24, fig. 1*).—This is essentially a popular edition of Bulletin 20 of the Division of Biological Survey (E. S. R., 16, p. 1055).

The relation of birds to fruit growing in California, F. E. L. BEAL (*U. S. Dept. Agr. Yearbook 1904, pp. 241–254*).—In California birds injure fruit more than in the Eastern States for the reason that wild fruits are comparatively rare in the fruit regions of California and water is scarce. Among the birds which injure fruit in California special mention is made of linnet, Brewer blackbird, black-headed grosbeak, California jay, California Valley quail, Bullock oriole, russet-back thrush, robin, etc. Detailed notes are given on the feeding habits and economic relations of each of these species.

Some benefits the farmer may derive from game protection, T. S. PALMER (*U. S. Dept. Agr. Yearbook 1904, pp. 509–520*).—This subject is discussed with special reference to the following topics: Relation of the farmer to game laws, game protection as a check on hunting, protection of property and useful birds, exclusion of harmful species, and financial and indirect benefits. Practical illustrations are drawn from the working of game laws in various States.

Monthly bulletin of the division of zoology, H. A. SURFACE (*Penn. Dept. Agr., Mo. Bul. Div. Zool., 2 (1905), Nos. 10, pp. 291–320, pls. 2, figs. 7; 11–12, pp. 323–378, fig. 1; 3 (1905), No. 1, pp. 32*).—No. 10 contains brief notes on the feeding habits of birds, the distribution of San José scale in Pennsylvania and methods of combating it, the use of insecticides, the collection of insects, beekeeping, State natural history museum, etc.; No. 11–12 gives general suggestions for spring spraying, together with notes on collecting insects, San José scale, fumigation, "cabbage snake," potato scab, mosquitoes, diseases of bees, cankerworm, etc.; and No. 1, a spray calendar, containing directions for preparing remedies and times of application in the control of insect pests and plant diseases on common cultivated plants. Brief notes are also presented on cankerworm, tent caterpillar, and codling moth.

The annual loss occasioned by destructive insects in the United States, C. L. MARLATT (*U. S. Dept. Agr. Yearbook 1904, pp. 461–474*).—The basis of estimating losses from insects is explained, together with notes on the control of insects. Estimates are made of the insect damage to corn, wheat, hay, cotton, fruits, forests, cattle, stored products, etc. According to these estimates the total loss from insects in the United States is $700,000,000 per year.

Insect pests of house and garden, M. V. SLINGERLAND (*Cornell Reading Course for Farmers' Wives, 2. ser., 1905, No. 10, pp. 185–200h, figs. 11*).—Brief descriptions are presented of clothes moth, carpet beetle, cockroaches, bedbugs, fleas, mosquitoes,

flies, ants, and other insects which are injurious to clothing, furniture, or food, or which annoy man otherwise. Proper remedies are suggested for the control of these pests.

Collecting and preserving insects, F. SHERMAN, Jr. (*N. C. Dept. Agr. Ent. Circ. 15, pp. 14, figs. 9*).—Brief directions are given regarding the necessary apparatus and methods to be adopted in collecting and preserving various kinds of insects.

Entomology in schools, H. S. SAUNDERS (*Canad. Ent., 37 (1905), No. 2, pp. 33, 34, pl. 1*).—A brief account is presented of the classification of the insects with suggestions as to how collections of insects may be made for use in teaching entomology in schools.

The colors of insects, A. U. BATTLEY (*East Kent Sci. and Nat. Hist. Soc. Rpt. and Trans., 2. ser., 4 (1904), pp. 4–6*).—Colors in insects are largely due to the unequal refraction of the light or to actual pigments deposited in definite particles in the integument. The significance of color in insects is briefly discussed.

How do insects pass the winter? J. FLETCHER (*Canad. Ent., 37 (1905), No. 3, pp. 79–84*).—Brief notes were given on the methods of hibernation observed in various species of insects.

Report of the entomologist, J. FLETCHER (*Canada Expt. Farms Rpts. 1904, pp. 210–251, pls. 2*).—During the season under report cereals were attacked by wireworms, cutworms, grasshoppers, Hessian fly, wheat-stem sawfly, grain aphis, and wheat midge.

Wireworms may be partly controlled by 2 plowings in autumn. The Criddle mixture continues to give good results in combating grasshoppers. Locust fungus was effective in a few instances only. There is apparently but one brood of Hessian fly in western Canada. The pea weevil has appeared only in very small numbers for the past 2 years. The cause of its disappearance is not known. It is recommended that all seed peas be treated before sowing and that the crop be harvested as early as possible.

Notes are given on bollworm, *Eriopeltis festucæ*, various cutworms, root maggots on onions, cabbage, and radish, *Nectarophora solanifolii* on potatoes, *Entomoscelis adonidis* on turnips, *Pionea straminalis* on cabbage, San José scale, plum aphis, plum curculio, apple maggot, codling moth, and various pests of forest and shade trees.

J. Fixter reports on the apiary. The best cellar temperature for the winter is 42 to 48° F. Colonies passed the winter well when the tops of the hives were replaced with chaff cushions or propolis quilts. Successful wintering appears to depend on uniformity of temperature and good ventilation. In a comparison of sugar sirup and extracted honey colonies consumed during the winter on an average 62 lbs. 1 oz. of the former and 62 lbs. 8 oz. of the latter. Notes are also given on methods of introducing queens.

Common injurious and beneficial insects of Maryland, T. B. SYMONS (*Maryland Sta. Bul. 101, pp. 125–204, figs. 52*).—The author presents a list of insects contained in the entomological exhibit of the station and used at county fairs and farmers' meetings throughout the State. The insects in the collection are classified in general according as they affect orchards, grains, vegetables, household goods, etc. Beneficial insects are also mentioned and brief directions given for the preparation of insecticides.

Miscellaneous cotton insects in Texas, E. D. SANDERSON (*U. S. Dept. Agr., Farmers' Bul. 223, pp. 24, figs. 29*).—Biological, descriptive, and economic notes are presented on a large number of cotton insects, including cutworms, plant lice, webworms, white-lined sphinx, grasshoppers, May beetles, *Œcodoma fervens, Uranotes melinus*, leaf hoppers, plant bugs, etc. In controlling these cotton pests it is recommended that weeds near cotton fields be destroyed and clean cultivation be adopted.

The cotton bollworm, A. L. QUAINTANCE and C. T. BRUES (*U. S. Dept. Agr., Bur. Ent. Bul. 50, pp. 155, pls. 25, figs. 27*).—This constitutes an elaborate monograph of

the bollworm, including an account of its systematic position, distribution, economic status, appearance in different stages, life history, natural enemies, and methods of control. The literature relating to the pest is reviewed in connection with an extensive bibliography.

The injury of the insect to corn, cotton, and tomatoes is described. The predaceous and parasitic enemies of the pest are discussed, together with a bacterial disease which seems to be contagious but not adapted to practical use in destroying bollworms. The cultural methods of controlling the insect consist in thorough plowing, use of seed of early varieties, use of fertilizers, early planting, thorough cultivation.

Corn may be used as a trap crop. The young larvæ may be killed by application of arsenicals during the last week in July and the first two weeks of August. Dusting seems better than spraying. In dusting, Paris green may be used at the rate of 2 or 3 lbs. per acre for each application. The work should be done at night or when the leaves are moistened with dew. Paris green may be applied in cheap flour or dry slaked lime at intervals of 7 to 10 days as long as the larvæ are found in exposed positions.

The Mexican cotton boll weevil, W. D. HUNTER and W. E. HINDS (*U. S. Dept. Agr., Bur. Ent. Bul. 51, pp. 181, pls. 23, figs. 8*).—This is essentially a revised and enlarged edition of Bulletin 45 of the Bureau previously noted (E. S. R., 16, pp. 73, 74). Part of the information contained in the bulletin is also contained in Farmers' Bulletin 216 (E. S. R., 16, p. 991) and Bureau of Entomology Circular 56 (E. S. R., 16, p. 576).

The present account is a monograph of the boll weevil and contains a discussion of the insect from every standpoint. The investigations of 1904 served to confirm previous studies. The recommendations regarding cultural methods are repeated. A bibliography of the subject is appended to the bulletin.

Present status of the cotton boll weevil in the United States, W. D. HUNTER (*U. S. Dept. Agr. Yearbook 1904, pp. 191–204, pls. 2, fig. 1*).—An account is given of the territory affected by this pest, the amount of damage done, and the investigations of this Department concerning the boll weevil, together with notes on problems still to be solved.

Work of the Bureau of Plant Industry in meeting the ravages of the boll weevil and some diseases of cotton, B. T. GALLOWAY (*U. S. Dept. Agr. Yearbook 1904, pp. 497–508*).—The work of the Bureau in this field is briefly outlined under the heads of plant breeding, tropical cottons, diseases of cotton, diversification farms, cooperative demonstration farms, early maturing varieties of cotton, and farmers' institute work. Considerable improvement in farm economy has been noted as a result of these investigations.

Effect of certain arsenites on potato foliage, W. H. JORDAN, F. C. STEWART, and H. J. EUSTACE (*New York State Sta. Bul. 267, pp. 263–284, pls. 2, fig. 1*).—Paris green and arsenite of lime were tested to determine to what extent they are injurious to potato leaves.

Paris green was applied 4 times either with water, lime water, or Bordeaux mixture. Arsenite of lime was prepared by the Kedzie formula, with lime water and with Bordeaux mixture. In testing Paris green potatoes were sprayed July 7, 22, 29, August 12 and 25. No evidence of injury to the leaves from Paris green was noted, even when used at the rate of 4½ lbs. per acre. Paris green proved to have considerable fungicidal power (one-third as much as Bordeaux mixture) in preventing late blight. The yield in treated rows was much greater than in check rows.

Potatoes were sprayed 4 or 5 times with arsenite of lime. The results obtained indicate that this remedy can not safely be used except with Bordeaux mixture. When applied otherwise, the foliage was badly burned and the yield of potatoes reduced.

Poisoning the potato beetle, F. H. HALL, W. H. JORDAN, ET AL. (*New York State Sta. Bul. 267, popular ed., pp. 11, figs. 2*).—A popular summary of Bulletin 267 of the station noted above.

The bulb mite, R. S. MACDOUGALL (*Jour. Bd. Agr.* [*London*], *11* (*1905*), *No. 12, pp. 748–751, figs. 2*).—*Rhizoglyphus echinopus* feeds on the underground stems and roots of tulips, hyacinths, onions, and on potatoes and other plants. The insect is described in its different stages and notes are given on means of combating it.

In cases of bad infestation it is stated that the best way of controlling the mite is to burn infested bulbs and thoroughly sterilize infested soil. The mite may also be destroyed by spraying bulbs with kerosene, washing them in a solution of sulphid of potassium at the rate of 1 oz. to 3 gal. of water, or fumigating with bisulphid of carbon.

Cabbage root maggot. Poisoned bran for cutworm, W. S. BLAIR (*Canada Expt. Farms Rpts. 1904, pp. 362–364*).—Cabbage was treated for root maggot with hellebore, kerosene emulsion, Paris green, and tar paper disks. Hellebore gave the best results (2 to 4 oz. to the gallon of water).

Paragrotis ochrogaster in gardens was easily controlled by the use of a poisoned bait containing 3 oz. Paris green per 10 lbs. bran.

The imported cabbage worm, F. H. CHITTENDEN (*U. S. Dept. Agr., Bur. Ent. Circ. 60, pp. 8, figs. 6*).—*Pontia rapæ* is described in its various stages and notes are given on its life history. The species was introduced about 50 years ago, and is far more injurious than the native species. It is a serious pest from Canada to the Gulf region.

The imported cabbage butterfly feeds on all crucifers and various ornamental plants such as mignonette, Cleome, etc. Numerous parasites and predaceous insects help to keep the pest in check. The best remedy is spraying with arsenicals. Poisoned bran mash, hot water, kerosene emulsion, pyrethrum, clean cultivation, hellebore, and other remedies have been tried with more or less benefit.

The cabbage hair-worm, F. H. CHITTENDEN (*U. S. Dept. Agr., Bur. Ent. Circ. 62, pp. 6, fig. 1*).—*Mermis albicans*, a species of hair-worm, was found in heads of cabbage in certain Southern States in 1903. Exaggerated stories were circulated regarding its poisonous properties. These were shown to be without foundation. Repeated experiments showed that the worm is not poisonous. It lives as a parasite in the body of grasshoppers, codling moth, and other insects. The life history of the worm is discussed, and miscellaneous information presented concerning it.

The biology and systematic position of Otiorhynchus turca, A. A. SSILANTJEW (*Zool. Jahrb., Abt. System. Geogr. u. Biol. Thiere, 21* (*1905*), *No. 4, pp. 491–502, figs. 8*).—This pest of the grape vine has been known since 1843. The insect is carefully described with particular reference to anatomical details and to its life history. The hibernating beetles attack the buds and young leaves in early spring. The eggs are laid about the middle of June. The author reports that all the beetles which he collected from June to September were females and he was unable to explain this fact.

Insect injuries to forest products, A. D. HOPKINS (*U. S. Dept. Agr. Yearbook 1904, pp. 381–398, figs. 14*).—An account is presented of the injuries caused by ambrosia beetles, round-headed borers, flat-headed borers, timber worms, powder post borers, white ants, carpenter bees, etc. The conditions which are favorable to insect injury of this sort are also outlined.

The nut weevils, F. H. CHITTENDEN (*U. S. Dept. Agr. Yearbook 1904, pp. 299–310, pls. 3, figs. 10*).—A detailed discussion is presented on *Balaninus proboscideus, B. rectus, B. caryæ*, and *B. obtusus*. The first two species affect chestnuts, the third pecans, and the last hazelnuts. Successful remedies against chestnut weevils are bisulphid of carbon, scalding and drying, dry heat or cold storage. Hogs may be allowed in pecan orchards to destroy infested nuts.

Black check in western hemlock, H. E. BURKE (*U. S. Dept. Agr., Bur. Ent. Circ. 61, pp. 10, figs. 5*).—Black check is a defect of western hemlock due to the attack of a bark beetle (*Hylesinus* n. sp.), in the burrows of which a bark maggot (*Cheilosia alaskensis*) penetrates and increases the injury. On low land a large percentage of the wood is thus rendered worthless for finishing, staves, or woodenware. *C. hoodianus* causes a similar injury to *Abies grandis*. In order to avoid getting lumber with this defect, it is suggested that trees be selected from altitudes of 1,800 ft. or more.

The felted beech coccus, R. NEWSTEAD (*Jour. Bd. Agr.* [*London*], *11* (*1905*), *No. 12, pp. 755–760, figs. 7*).—*Cryptococcus fagi* confines its attacks to the beech and is considered one of the most destructive pests which attacks this tree. It occurs generally in England and in some parts of Scotland. The insect is described and notes are given on its life history. It may usually be controlled by spraying with kerosene emulsion with or without the addition of sulphur and turpentine or by treatment with caustic-alkali wash.

The chief injurious scale insects of Connecticut, W. E. BRITTON (*Connecticut State Sta. Bul. 151, pp. 16, figs. 17*).—The more important scale insects of Connecticut are described and arranged in a convenient manner for identification. In this manner the author discusses 29 species including elm scale, cottony maple scale, tulip scale, oleander scale, San José scale, oyster-shell scale, etc.

Spraying for scale insects, H. J. QUAYLE (*California Sta. Bul. 166, pp. 24, figs. 2*).—Spraying experiments were conducted against the brown apricot scale and San José scale.

Lime-sulphur-salt wash was tested in various formulas. Lime, sulphur, and salt were used at the rate of 40, 20, and 15 lbs., respectively, for each 60 to 120 gals. of water. All dilutions up to 90 gals. of water were effective. In another set of tests the amount of lime for each 60 gals. of water varied from 20 to 50 lbs. All combinations were effective, but a slight excess of lime seemed to be beneficial. In other experiments the amount of sulphur ranged from 5 to 40 lbs. Solutions containing small amounts of sulphur were less efficient. The author is not prepared to recommend the disuse of salt. Copper sulphate used to replace salt removed the moss from trees but otherwise had no advantage.

In general the lime-sulphur-salt wash proved effective against San José scale, but not against the brown apricot scale. It should be used chiefly on dormant trees. Preparation of the wash without boiling does not reduce the cost. Resin wash was satisfactory for brown apricot scale but not for San José scale. It should be applied in January and February. Patent compounds have no advantages over standard remedies. The standard 3 per cent distillate insecticide was not very effective against the brown apricot scale.

Insects injurious to roses, P. LESNE (*Rev. Hort.* [*Paris*], *77* (*1905*), *No. 7, pp. 167–170, pl. 1*).—Descriptive, economic, and biological notes are given on a number of rose pests, including gypsy moth, brown-tailed moth, rose scale, *Cladius pectinicornis*, etc.

Insecticides and fungicides, R. HARCOURT (*Ann. Rpt. Ontario Agr. Col. and Expt. Farm, 30* (*1904*), *pp. 63, 64*).—Brief notes are given on the preparation of lime-sulphur washes and an analysis of fungeroid is reported.

Bees, S. A. BEDFORD (*Canada Expt. Farms Rpts. 1904, pp. 394, 395*).—Brief notes on apiculture in Manitoba.

FOODS—HUMAN NUTRITION.

Wheat and flour, R. HARCOURT (*Ann. Rpt. Ontario Agr. Col. and Expt. Farm, 30* (*1904*), *pp. 54–60*).—Milling tests were made with ten samples of different grades of wheat grown near Winnipeg, as well as studies of the moisture and proteids and

acidity of the flours, and baking tests made immediately after grinding and after storing the flour for ten weeks. Data regarding tests of the baking quality and grade of some of the samples which were sent to the Columbus Laboratories of Chicago for examination are also reported.

In the author's opinion it is evident that there is not much difference in the real value of the different grades of wheat tested. No regular variation was noted in the quantity of total proteids and gluten or in the quality of the gluten of the highest and lowest grades. All the samples gave fairly satisfactory bread as judged by quality and yield. In the majority of cases the yield of bread was practically the same. As regards the amount of bread obtained from new and stored flour, the agreement was fairly close except with two samples. The flours were all straight grade and the gluten content and consequently the loaf volume was small.

"It must be remembered that . . . [the results were] obtained from a very few samples of wheat. The nature of the soil, the number of crops grown in it since 'breaking,' the weather at the time of ripening, etc., all have an influence on the quality of the wheat. Therefore, these results, while accurate for the samples submitted, should not be given too much importance until they are confirmed by further work."

Three varieties of wheats received from the Northwest Territory government were also examined. They were found to contain "a fairly high percentage of proteids, fully as high as the samples of the various grades previously mentioned. They also contain as much alcohol soluble proteids, or gliadin, as the wheats referred to, and, so far as can be judged from these results, ought to be equal to them for flour purposes."

In a study of the quality of flour from wheats grown in Manitoba in the Northwest Territories in 1904, it was found that the gliadin content was uniformly low.

"The effect of low gliadin content would be that the gluten would be weak, the acids developed during fermentation would more quickly dissolve or 'rot' the tenacious part of the gluten and allow the gases to escape. As a result the bread would be heavy. Just what causes this low gliadin content in the wheat is not known. It apparently is not caused by the soil, for these variations in strength come from year to year in wheat grown on the same soils. It is more likely due to weather conditions at the time the nitrogenous substances are being transferred from stem to seed, or during the ripening process."

In connection with the studies of flour, determinations have been made of the acidity of a large number of samples, with a view to learning the limits of acidity and devising a method for judging of the soundness of flour by the amount of acid present. Definite conclusions were not drawn. According to the author, "The better grades of flour show a very small acid content, but the amount increases with the lower grades. Flours which have taken up an undue amount of moisture, or which have been made from damp wheat, also show high acid content."

Inspection of foreign food products, H. W. WILEY (*U. S. Dept. Agr. Yearbook, 1904, pp. 151-160*).—The scope of the law regarding the inspection of imported food products, the extent of the work, and some of the results obtained and related topics are spoken of. It is pointed out that under the law the inspection work includes foods, drugs, beverages, condiments, and the ingredients of such articles.

An idea of the extent of the work and the character of the goods imported may be gathered from the fact that of 1,880 samples of wine, meat, olive oil, and miscellaneous products, 223 were found to be contrary to the law, while the remaining 1,657 were found to comply with the law. In the author's opinion the inspection of imported food products, although it has been in force less than two years, has already given beneficial results.

"It is gratifying also to know that the exporters in foreign countries, as a rule, have been eager to learn of the exact character of the requirements of the law, and in many

cases have made an earnest effort to comply with them. Nevertheless, as in all cases, there are some instances where it is evident that compliance with the law will only be secured by its rigid execution, and not by voluntary action."

Food consumption in Southern Italy, H. LICHTENFELT (*Arch. Physiol. [Pflüger], 107 (1905), No. 1-2, pp. 57-80*).—The author has summarized a large amount of data regarding the food consumption in different regions of Southern Italy, which is discussed with reference to the productive power of the people.

In his opinion the inhabitants of Southern Italy are smaller in size and do not work as effectively as inhabitants of other parts of Italy. This is attributed to the low energy value of the diet, the excess of carbohydrates, and the insufficiency of animal food. The author believes that, in general, growth is hindered and physical condition lowered if the supply of animal food is insufficient.

Analyses of fresh chestnuts, B. TOMEI (*Staz. Sper. Agr. Ital., 37 (1904), No. 2-3, pp. 185-199*).—The proximate and ash analyses reported are discussed with reference to the food value of chestnuts and the fertilizers which the tree requires.

Prussic acid in cassava roots (*Bot. Dept. [Trinidad], Bul. Misc. Inform., 1904, No. 41, pp. 26, 27*).—Attention is called to the fact that sliced or grated cassava when allowed to stand sometimes becomes poisonous. The whole question of cassava poison is briefly discussed from the standpoint of the possibility of the formation of hydrocyanic acid from a glucoside by the aid of a ferment. The need of investigating this question is spoken of.

The preservation of fruits and vegetables, V. VALVASSORI (*Bul. Off. Gouvt. Gén. Algérie, 1904; abs. in Rev. Soc. Sci. Hyg. Aliment., 1 (1904), No. 5, p. 592*).—A summary of data regarding the length of time fruit and vegetables may be kept in cold storage.

The use of food preservatives, V. C. VAUGHAN (*Jour. Amer. Med. Assoc., 44 (1905), No. 10, pp. 753-756*).—A summary of data on legal enactments, the effects of preservatives on digestion, and related questions.

The importance of studying food in connection with nutrition as a part of a course in domestic economy, C. NOURRY (*Rev. Soc. Sci. Hyg. Aliment., 1 (1904), No. 3, pp. 216-218*).—A number of suggestions regarding the teaching of nutrition are made.

Handbook of sanitation, G. M. PRICE (*New York: John Wiley & Sons; London: Chapman & Hall, Ltd., 1905, pp. XV+301, figs. 29*).—In this, the second edition, the author states that many changes have been made and that the subject matter of the section dealing with foods and some other sections have been very largely rewritten. The volume is designed as a manual of theoretical and practical sanitation for students, physicians, building inspectors, and others interested in sanitary problems.

The respiration calorimeter, W. O. ATWATER and F. G. BENEDICT (*U. S. Dept. Agr. Yearbook, 1904, pp. 205-220, pl. 1, figs. 2*).—The respiration calorimeter used in the Department nutrition investigations for studying the total income and outgo of matter and energy is described, and some of the more important results of experiments are summarized.

It was found that the output of carbon dioxid and heat is very nearly proportional to the amount of muscular work performed, the figures given ranging from 25 gm. of carbon dioxid and 65 calories of heat per hour with a man at rest and sleeping, to 210 gm. and 600 calories with a man at very severe muscular work. Other topics discussed have to do with problems of ventilation, the normal variations in body temperature, etc.

Approximately complete analyses of thirty normal urines, O. FOLIN (*Amer. Jour. Physiol., 13 (1905), No. 1, pp. 45-65*).—Detailed analyses of the urine samples were made, the methods followed being described. The subjects were healthy men. The diet which the urines represent was made up of whole milk, cream, eggs, malted milk, sugar, and salt, mixed with water and taken in liquid form.

Water was also used as a beverage. The chlorin, sulphur, phosphoric acid, and nitrogen in the diet was determined, the amount of nitrogen furnished per day ranging from 18.80 to 19.05 gm.

Laws governing the chemical composition of urine, O. FOLIN (*Amer. Jour. Physiol., 13 (1905), No. 1, pp. 66–115*).—A study of the urine of a subject who was accustomed to live on a diet containing small amounts of protein showed that the constituents were not present in the same proportions as in so-called normal urine, the urea nitrogen constituting a much smaller percentage of the total than is generally the case. Differences in the proportions of other constituents were also found.

A number of studies were, therefore, undertaken with healthy subjects in which a period of 3 or 4 days on a diet furnishing about 19 gm. of nitrogen was followed by a period of 7 or 10 days' duration with a diet made up of 300 cc. of cream and 400 gm. of pure arrowroot starch, the total nitrogen supplied being only about 1 gm. per day. The experiments closed with a period of 1 or 2 days' duration on a diet like that in the first period.

The results obtained with the different subjects were uniform, quantitative changes in the daily proteid metabolism on the different diets being accompanied, according to the author, by pronounced changes in the distribution of the urinary nitrogen and sulphur, and the author believes that "the distribution of the nitrogen in urine among urea and the other nitrogenous constituents depends on the absolute amount of total nitrogen present. . . . The distribution of the sulphur in urine among the 3 chief normal representatives—inorganic sulphates, ethereal sulphates, and 'neutral sulphur'—depends on the absolute amount of total sulphur present."

As regards the different urine constituents "the absolute quantity of creatinin eliminated in the urine on a meat-free diet is a constant quantity, different for different individuals, but wholly independent of quantitative changes in the total amount of nitrogen eliminated. . . . When the total amount of protein-metabolism is greatly reduced, the absolute quantity of uric acid is diminished, but not nearly in proportion to the diminution in the total nitrogen, and the per cent of the uric acid nitrogen in terms of the total nitrogen is therefore much increased. . . . With pronounced diminution in the protein metabolism (as shown by the total nitrogen in the urine), there is usually, but not always, and therefore not necessarily, a decrease in the absolute quantity of ammonia eliminated. A pronounced reduction of the total nitrogen is, however, always accompanied by a relative increase in the ammonia nitrogen, provided that the food is not such as to yield an alkaline ash."

As regards the urea, this suffers a relative as well as an absolute diminution with a diminution in the total proteid metabolism, 60 per cent being recovered in the urine, when the total nitrogen elimination is reduced to 3 or 4 gm. as compared with about 90 per cent of the total nitrogen in normal urine.

Decided diminutions in the daily elimination of total sulphur were accompanied by reductions in the percentage of sulphur present as inorganic sulphates, the reduction being as great as in the case of urea. The neutral sulphur elimination was analogous to that of creatinin and, according to the author, it represents products which in the main are independent of the total amount of sulphur eliminated by protein catabolism. The percentage of total sulphur excreted as ethereal sulphates increased and, according to the author, these ethereal sulphates represent a form of sulphur metabolism which becomes more prominent when the food contains little or no protein.

The volume of urine it was found depended entirely upon the amount of water consumed. The chlorin elimination, as is generally conceded, was found to vary chiefly with the volume of urine provided the amount consumed was constant.

Studies of the acidity of urine and methods of estimating acid led to the conclusion that "the phosphates in clear acid urine are all of the monobasic kind, and the acidity of such urines is ordinarily greater than the acidity of all the phosphates,

the excess being due to free organic acids." The excess of inorganic acids observed in urine diminished under the influence of the starch and cream diet until it frequently became a minus quantity.

When potatoes replaced pure starch in the diet, "the total acidity of the urine is but slightly reduced, and the total amount of organic acids eliminated is greatly increased, yet the ammonia is still considerable. This would seem to indicate that a part of the acid and ammonia formation within the organism is not affected by the alkalies of the food."

A theory of protein metabolism, O. Folin (*Amer. Jour. Physiol., 13 (1905), No. 2, pp. 117–138*).—On the basis of investigations noted above, various questions connected with the metabolism of protein in the animal body are discussed.

The fact that, generally speaking, the proportion of urea to total nitrogen in the urine diminished with a decrease in the amount of nitrogen consumed, while the other nitrogenous constituents in the urine remained practically constant, led the author to conclude that there are 2 distinct processes of proteid metabolism in the body. In his opinion the metabolic processes resulting in the end products which tend to remain constant (creatinin, neutral sulphur, and to a less extent uric acid and ethereal sulphates) are needed for the continuation of life; or, in other words, the metabolic processes which they represent constitute an essential part of the activity which distinguishes living from dead cells.

He, therefore, proposes the term "tissue" metabolism or "endogenous" metabolism for this form of proteid cleavage, and "exogenous" or intermediate metabolism for the proteid cleavage which is variable and yields chiefly urea and inorganic sulphates, this form of metabolism being looked upon as an attempt on the part of the body to remove rapidly the surplus nitrogen supplied which is not required for vital processes.

Attention is called to the fact that the nitrogen of protein is linked to carbon on the one hand and to hydrogen on the other—i. e., exists as amido or imido groups—and that from a chemical standpoint the cleavage of such groups is more readily accomplished by hydrolysis than by oxidation.

In the author's opinion exogenous proteid catabolism consists of a series of hydrolytic cleavage processes resulting in a rapid elimination of proteid nitrogen as urea. "According to the views here presented . . . only a small amount of protein, namely, that necessary for the endogenous metabolism, is needed. The greater part of the protein furnished with standard diets like Voit's—i. e., that part representing the exogenous metabolism—is not needed, or, to be more specific, its nitrogen is not needed.

"The organism has developed special facilities for getting rid of such excess of nitrogen so as to get the use of the carbonaceous part of the protein containing it. The first step in this process is the decomposition of protein in the digestive tract into proteoses, amido acids, ammonia, and possibly urea. The hydrolytic decompositions are carried further in the mucous membrane of the intestines, and are completed in the liver, each splitting being such as to further the formation of urea.

"In these special hydrolytic decompositions, the result of which is to remove the unnecessary nitrogen, we have an explanation of why and how the animal organism tends to maintain nitrogen equilibrium, even when excessive amounts of protein are furnished with the food. This excess of protein is not stored up in the organism, as such, because the actual need of nitrogen is so small that an excess is always furnished with the food, except, of course, in carefully planned experiments. The ordinary food of the average man contains more nitrogen than the organism can use, and increasing the nitrogen still further will therefore necessarily only lead to an immediate increase in the elimination of urea, and does not increase the protein catabolism involved in the creatinin formation any more than does an increased supply of fats and carbohydrates.

"All the living protoplasm in the animal organism is suspended in a fluid very rich in protein [which is the protein reserve material of the body], and on account of the habitual use of more nitrogenous food than the tissues can use as protein the organism is ordinarily in possession of approximately the maximum amount of reserved protein in solution that it can advantageously retain."

The view that exogenous metabolism is in the main dependent upon hydrolytic cleavage does not preclude the possibility that a certain amount of oxidation is associated with this form of catabolism and, indeed, the author considers that some oxidation is necessary and discusses its character.

The endogenous proteid metabolism, in the author's opinion, has to do with those forms of proteid cleavage which are actually concerned with the vital processes. The theories advanced by the author are discussed in relation to nitrogen equilibrium, standard diets, diets and diseases, and the effect of work on protein metabolism.

The course of the renal excretion of nitrogen when different sorts of food are taken, N. W. SCHEPSKY (*Inaug. Diss., St. Petersburg, 1900, pp. 38; abs. in Physiol. Russe, 3 (1904), Nos. 48-60, p. 177*).—The conclusion was reached that the increased excretion of nitrogen after food is taken varies with different foods and is parallel to the curve showing the power of each food to induce secretion of digestive juices. In other words, the increased nitrogen excretion shortly after taking food is an expression of the activity of the digestive glands.

The work of the digestive glands when different sorts of food containing fat are eaten, A. M. WIRSCHUBSKIJ (*Inaug. Diss., St. Petersburg, 1900, pp. 55; abs. in Physiol Russe, 3 (1904), Nos. 48-60, p. 177*).—Experiments with dogs with fistulæ showed that fat added to any sort of food had a retarding influence on stomach digestion. The quantity of gastric juice secreted depended upon the character of the food with which the fat was mixed.

The production of fat from proteid by the Bacillus pyocyaneus, S. P. BEEBE and B. H. BUXTON (*Amer. Jour. Physiol., 12 (1905), No. 5, pp. 466-470, fig. 1*).—The authors found that when *Bacillus pyocyaneus* grew in fat-free meat extract broth, a thick pellicle was produced on the surface, which yielded fat on extraction with chloroform, the amount obtained being about 0.3 to 0.4 gm. per liter. Some 10 gm. of the fatty material was collected and its characteristics studied.

Control tests showed that the fat was also formed from sugar-free meat broth and sugar-free meat extract broth containing Witte peptone; therefore, it could not have been formed from sugar. During the growth of the bacillus the medium becomes very alkaline owing to the presence of free ammonia, which is obviously split off from the proteids. It seems probable, according to the authors, that the fat is formed at any rate in part by the oxidation of the fragments of the albumoses and peptones apart from any carbohydrate nucleus which they may contain.

"That it is an oxidation process appears more than likely from the fact that the crystals are formed solely in the surface pellicle. Again under anaerobic conditions the bacilli grow sparingly, and no trace of pellicle or fat crystals is formed."

In addition to the fats a considerable amount of mucin-like substance was formed during the bacterial growth. This gave some of the mucin reactions, yet only traces of a reducing substance could be detected. "Since the mucinous substance, therefore, does not appear to call for any carbohydrate, we may relegate all of the carbohydrate nuclei of the albumoses to the formation of the fat; but even so . . . there could not be sufficient to account for all of it."

The calcium content of different animal organs, M. TOYONAGA (*Bul. Col. Agr., Tokyo Imp. Univ., 6 (1904), No. 2, pp. 89-96*).—The author reports results of analyses, and summarizes the results of other investigators. The occurrence of calcium in different animal tissues and its relation to magnesium is discussed.

ANIMAL PRODUCTION.

Animal breeding and feeding investigations by the Bureau of Animal Industry, D. E. Salmon (*U. S. Dept. Agr. Yearbook, 1904, pp. 527–538, pl. 1*).—The investigations undertaken under the auspices of the Bureau of Animal Industry in breeding sheep, poultry, and horses, the studies of animal nutrition, and of beef and pork production under southern conditions are described, and plans for future work outlined. A considerable proportion of the work referred to has been undertaken in cooperation with agricultural experiment stations.

Fodders and feeding stuffs, F. T. Shutt (*Canada Expt. Farms Rpts. 1904, pp. 166–182*).—Analyses are reported of fodder corn grown in hills and drills, including dent and flint varieties, rape, rape silage, rape and corn silage, mangels, carrots, turnips, and sugar beets, linseed cake, gluten feed, cotton-seed meal, "Uveco" and "Flakerine" (both made apparently by flaking steamed or partially cooked Indian corn), meat meals for poultry, pea meal, pea dust, ground pea bran, barley feed, meal seeds, oat dust, spoiled raisins (with a view to learning their value as poultry feed), ground seeds (largely weed seeds, screenings, etc.), and a commercial mixed feed.

The percentage composition of the rape silage was: Water 78.19, protein 2.67, fat 0.84, nitrogen free extract 12.93, crude fiber 2.00, and ash 3.37; and of rape and corn silage 1 : 1, water 79.66, protein 2.18, fat 0.37, nitrogen-free extract 10.40, crude fiber 5.29, and ash 2.10.

The rape silage contained 1.36 per cent albuminoid and 1.31 per cent non-albuminoid nitrogen; the rape and corn silage 1.04 and 1.14 per cent, and the rape 1.30 and 0.61 per cent, respectively.

"The observed increase in the non-albuminoids and the concomitant decrease in the albuminoids that has followed upon ensiling the rape marks the most important change in the composition of the dry matter of the rape. This in conjunction with the destruction of a part of the carbohydrates necessarily increases the percentages of the fiber and ash. The changes are such as might have been expected and indicate a certain deterioration in the silo of the dry matter of the rape."

Commercial feeding stuffs (*Connecticut State Sta. Rpt. 1904, pt. 5, pp. 385–437*).—This is a reprint of Bulletin 147 of the station (E. S. R., 16, p. 903).

Commercial feeding stuffs, J. L. Hills, C. H. Jones, and F. M. Hollister (*Vermont Sta. Bul. 109, pp. 8*).—Under the provisions of the State feeding stuff law, a number of samples were examined, including cotton-seed meal, linseed meal, gluten meals and feeds, dried distillers' grains, oat feeds, hominy chop and similar goods, provenders (corn and oat products), and wheat offals.

In discussing the feeding stuffs sold in the State, the results of five years' work are taken into account. "No material change in the average grade of the richer concentrates [now sold] appears, save in the gluten meals. This improvement, however, is due to an alteration in a manufacturer's process rather than to any direct effect of inspection. The by-products of the oatmeal mills have been quite decidedly upgraded, and farmers are less inclined than formerly to regard a liberal showing of oat hulls in a provender as a guaranty of excellence." As in past years, some of the corn and oat provenders contained too large a percentage of oat hulls.

Regarding the success which has followed the passing of a feeding stuff law, the authors state that "five years ago guaranties were few and far between. To-day they are in general use, and, while too often disregarded, or, indeed, misinterpreted, they are at once protective and educative."

The data presented in a comparison of the amount of protein furnished by different classes of concentrated feeds, as compared with their cost, shows that cotton-seed, linseed, and gluten meals, and dried distillers' grains rank highest and low-grade oat feeds lowest of the materials considered.

Commercial feeding stuffs, J. L. HILLS, C. H. JONES, and F. M. HOLLISTER (*Vermont Sta. Bul. 110, pp. 11-20*).—In addition to the analysis of 250 samples of commercial feeding stuffs in connection with the inspection, some microscopical examinations were also made.

The feeding stuffs included cotton-seed meal, linseed meal, gluten meals and feeds, dried distillers' grains, oat feed, hominy chop and similar products, provenders, wheat offals, mixed feeds, malt sprouts, ground malt, hay feed, proprietary feeds, meat meal, and calf meal.

During the year attention was directed especially to the collection of samples of wheat offals, more particularly the so-called mixed feeds, as well as unlabeled and unidentified brans and middlings. The grade of such feeds "appears to be worse this fall than at any time since the law went into effect. It behooves buyers more than ever before to be judicious in their purchases, particularly of wheat offals, lest they buy goods laden with ground corn cobs or other offal, oat hulls, clippings, or the like."

Sugar in the feeding of animals, E. CUROT (*Le sucre dans l'alimentation des animaux. Paris: L. Lavaur, 1905, pp. 380; rev. in Rev. Sci.* [*Paris*], *5. ser., 3* (*1905*), *No. 14, pp. 429-431*).—A summary and discussion of data on the importance of sugar as a feeding stuff.

The cattle industry in Germany and elsewhere, J. HANSEN and A. HERMES (*Die Rindviehzucht im In- und Auslande. Leipsic: R. C. Schmidt & Co., 1905, vols. 1 and 2; abs. in Vrtljschr. Bayer. Landw. Rat., 10* (*1905*), *No. 2, pp. 242, 243*).—The condition of the cattle industry in different countries, methods followed to build up the industry, and related questions are taken up in these volumes.

Feeding trials, J. G. HANEY and O. H. ELLING (*Kansas Sta. Bul. 128, pp. 304-307*).—Two feeding trials were made at the Fort Hays Branch Station.

In the first trial the comparative value of corn, barley, and wheat with alfalfa hay, corn with sorghum hay, prairie hay and oat straw, and mixed grains and mixed hays for the production of baby beef, was tested with 7 lots of 8 calves 8 to 10 months old, the feeding period covering 182 days. All the calves were fed at first a ration of a pound of grain and ten pounds of coarse fodder, the grain being increased and the coarse fodder correspondingly decreased until they were given all they would eat up clean.

The average daily gains ranged from 1.23 lbs. per head on corn and sorghum hay to 1.85 lbs. on corn and alfalfa hay, the grain required per lb. of gain ranging from 4.04 lbs. on a wheat and alfalfa hay ration to 7.17 lbs. on corn and oat straw. The smallest amount of coarse fodder per lb. of gain, 3.54 lbs., was also noted with the last ration, and the largest gain, 5.92 lbs., with the corn and sorghum hay ration. The estimated profit per lot ranged from $27.09 with the lot fed corn and sorghum hay, to $109.74 with the lot fed corn and alfalfa hay.

"There was a more marked difference in the appearance of the lots than the results show, though the rank would be in the same order as the daily gains. The alfalfa lots fed much more evenly than the sorghum, straw, or prairie-hay fed lots." An account was kept of the cost of labor involved in caring for the cattle and grinding their feed. On an average it amounted to 2 cents per head per day.

In the second test pencillaria stover and Kafir-corn stover were compared with two lots of 8 cows each. The pencillaria was somewhat overripe when cut, and part of the crop had been irrigated. The Kafir-corn stover was of fair quality. In the 22 days of the test there was an average gain of 6.9 lbs. per head on the Kafir-corn stover, and an average loss of 30 lbs. on the pencillaria stover, the total amounts eaten in the two cases being 4,990 and 2,520 lbs., respectively.

"During the experiment it was easily observed that the cows getting pencillaria were not doing so well, were getting thinner and in poorer condition, but their appetite seemed to be good. However, it is believed that had the experiment been carried longer . . . they would have shown a lack of appetite for the feed, both Kafir corn and pencillaria."

The irrigated pencillaria had large stems and consequently more of it was wasted than was the case with that which was not irrigated.

Beef production, J. H. Grisdale (*Canada Expt. Farms Rpts. 1904, pp. 61–70*).—In studying the relative merits of different methods of handling steers, it was found that a lot of eight three-year-olds loose in their stalls made an average daily gain of 2.28 lbs. at a cost of 5.22 cts. per pound in a test covering 129 days. With a similar lot of two-year-olds the average values were 2.53 lbs. and 4.3 cts. Three-year-olds and two-year-olds tied (9 in a lot) made an average daily gain of 2.12 and 2.15 lbs. respectively, the cost of a pound of gain being 5.59 cts. and 5.16 cts. The results "are decidedly in favor of loose box feeding."

When the cost of producing beef from 3-year-olds, 2-year-olds, yearlings, 6-months calves, and new-born calves was studied, it was found that the average daily gain in the 129 days of the test ranged from 1.68 lbs. with the new-born calves to 2.53 lbs. with the two-year-old steers, and the cost of a pound of gain from 2.77 cts. with the new-born calves to 5.62 cts. with yearling steers. All the lots were fed roots, silage, and hay. In addition the calves were given a mixed grain ration and the other lots gluten meal.

Data are also briefly reported regarding the feeding of 2 lots of 5 yearlings and two lots of 6 steer calves each for the production of baby beef on fattening and on limited rations, the feeding period with the first mentioned lots covering a year and with the others 214 days. On a fattening ration, the yearlings made an average daily gain of 1.65 lbs. per head at a cost of 3.59 cts. per lb. and the calves of 1.68 lbs. at a cost of 2.77 cts. per lb. Similar values for the yearlings on a limited ration were 1.06 lbs. and 3.3 cts. and for the steers 1.58 lbs. and 2.83 cts.

As regards the feeding value of a commercial sugar beet pulp containing molasses, the author states that it has been found particularly valuable for feeding young stock and beef animals on account of its palatability and the fact that it stimulates appetite. When fed to dairy cows in excess of the normal meal ration or as replacing a part of it, the feeding value was low, being equal to about half that of a like quantity of bran. Fed in the same way to two and three year old steers it had about the same comparative value, but improved the appearance of the cattle, "giving them a sleek look scarcely attainable otherwise."

A test is reported in which the value of this molasses beet-pulp feed was tested as a substitute for coarse fodder (roots and silage).

When a lot of three steers was fed a ration of 8 pounds of molasses feed and an equal quantity of silage roots and straw, the average daily gain was 2.47 lbs. per head and the cost of a pound of gain 3.38 cts. When 12 lbs. of the molasses feed was fed with 4 lbs. of straw to a similar lot, the average daily gain per head was 1.87 lbs. and the cost of a pound of gain 5.15 cts. On a ration of silage, roots, and straw only, similar values for a like lot were 2 lbs. and 2.35 cts.

Brief statements are made regarding the value of "Uveco," a commercial feed apparently consisting of steamed corn, flaked and dried. It was found that 2 steers receiving this feed exclusively as a grain ration gained 1.4 lbs. per head per day for a period covering 45 days.

"The meat from these steers was of very excellent quality, due in some measure no doubt to the good quality of the food fed. So far as gains are concerned, it will of course be noted that much larger daily gains were quite possible."

Experiments with steers, R. Robertson, S. A. Bedford, and A. Mackay (*Canada Expt. Farms Rpts. 1904, pp. 341–348, 390–392, 446–449*).—At the Maritime Provinces Farm, the relative merits of feeding steers loose and tied in stalls was tested in continuation of earlier work (E. S. R., 16, p. 292), with two lots of 8 dehorned steers fed like rations. The loose steers made a total gain of 2,325 lbs. and those which were tied of 2,125 lbs. in 165 days. With all the steers, the average profit was calculated to be $2.97 per head.

In a comparison of the relative value of full fattening rations and limited growing rations, it was found that five calves fed a limited growing ration for 180 days made an average daily gain of 1.52 lbs. at a cost of 6.15 cts. per lb.

In a second test, five calves continued on a full fattening ration until finished for market (120 days) made an average daily gain of 1.68 lbs. per head at a cost of 8.16 cts. per lb. Five similar animals fed a limited growing ration, in a year made an average daily gain of 0.97 lb. per head, the cost of a pound of gain being 6.48 cts. With five other steer calves, the average daily gain was 1.05 lbs. per head and the cost of a pound of gain 6.35 cts. for a like period.

In a fourth test, which was begun with 5 calves on a full fattening ration, the average daily gain in 180 days was 1.9 lbs. at a cost of 6.49 cts. per pound as compared with 1.51 lbs. and 5.27 cts. in the case of a like number fed a limited growing ration for 183 days.

At the Manitoba Experimental Farm the relative gains made by 6 yearlings and 6 two-year-old steers fed similar rations were tested. In the 16 weeks of the test the yearling steers made a total gain of 1,152 lbs. and the 2-year-olds of 1,170 lbs., the profit per steer in the two lots being $1.85 and $2.23, respectively.

At the Indian Head Farm the gains made by young and old steers was also studied. Eight animals a year and a half old at the beginning made a total gain of 1,220 lbs. in the 16 weeks of the test proper as compared with 2,040 lbs. in case of an equal number of steers two and a half years old. The calculated profits per head in the two lots were $6.15 and $5.00, respectively.

In connection with the tests brief notes are given regarding the cattle kept at the several experimental farms.

Sheep breeding experiments (*Field Expts. Staffordshire and Shropshire and Harper-Adams Agr. Col., Joint Rpt. 1904, pp. 11, 12*).—Continuing the college sheep-breeding experiments, 3 lots of 25 Welsh ewes each were crossed with Welsh, Southdown, and Shropshire rams.

The lambs dropped ranged from 25 with the Shropshire to 29 with the pure-bred Welsh. In the test as a whole the best results, the author states, were obtained with the Welsh lambs. "This is principally due to the larger proportion of lambs reared and sold." At birth the Welsh lambs were hardier and withstood adverse weather conditions better than the others and were ready for slaughtering nearly 3 weeks earlier.

Sheep and swine, W. Dinsmore (*Iowa Agr., 5 (1905), No. 9, pp. 292–298, figs. 7*).—Different methods of cutting pigs are described and data given regarding slaughter tests made in connection with class-room work. The author points out that lambs of moderate weight produce carcasses with a higher percentage of lean meat than older wethers and that such carcasses are more choice, if the lambs have been properly finished.

"In beef, pork, and mutton the percentage of flesh element is the determining factor in deciding the value. We must produce this flesh element by selecting sire and dams that possess it; and must avoid fattening mature animals for too long a period, as this results in waste."

Pork production, J. H. Grisdale (*Canada Expt. Farms Rpts. 1904, pp. 70–74*).—It was found to cost about 25 per cent more to maintain brood sows in good condition in small board cabins than in a regular run or house. Young pigs wintered indoors made slightly larger and considerably cheaper gains than pigs wintered outdoors.

Several mixed rations were tested with pigs fed inside and outside, without an abundance of skim milk or whey. With pigs fed outside without skim milk, equal parts of shorts and gluten meal, and shorts and linseed meal, 4:1, both gave satisfactory results; but the addition of some skim milk cheapened the rations considerably. Similar lots fed indoors gave much better results, the rate of gain being

slightly increased and the cost of production lowered. The most satisfactory grain mixture was shorts and linseed meal, 4:1.

The value of a number of stock foods for pork production was tested, using 8 lots of 4 pigs each, the test covering 90 days. The list included International Stock Food, Anglo-Saxon Stock Food, Herbageum, and sugar and flax. A grain mixture composed of half shorts and half oats, peas, and barley, fed in connection with skim milk or pasturage, was the cheapest. All the stock feeds had the effect of raising the cost of production.

With Uveco, which is apparently made by passing cooked or steamed Indian corn between rollers, the gain was somewhat larger than on shorts and oats, and the cost cheaper. "The food was evidently very palatable, as the pigs ate it with avidity."

Large Blacks have been tested as to their value for pork production for several years, with the following results: "As prolific and healthy breeding stock they can not be surpassed by any of the breeds now commonly bred in Canada. As pigs for crossing they are exceedingly impressive, whether male or female, and leave their mark stamped very distinctly, no matter what the other cross may be. The cross-breds have also been uniformly healthy and quick feeders, the cross with the Tamworth being particularly remarkable in this respect. As pure-bred pigs they have been found to be rapid and easy fatteners, exceedingly good grass or pasture pigs, and have stood all kinds of weather without any apparent evil effects. As pigs for bacon production, however, they have proven to be a complete failure."

Experiments with swine, R. Robertson, S. A. Bedford, and A. Mackay (*Canada Expt. Farms Rpts. 1904, pp. 348, 349, 392, 393, 449, 450*).—The relative merits of feeding in pasture and in pens were studied with 2 lots of 10 pigs each, the rations being essentially the same for both lots. In the 153 days of the test, the total gain made by the pigs fed most of the time in pasture was 1,439 lbs. and by those fed in pens 1,287 lbs., the cost of a pound of gain in the two cases being 3.55 cts. and 3.94 cts.

At the Manitoba Experimental Farm ground barley was compared with ground mixed grain (wheat, oats, and barley 1:1:1). In the 70 days of the test, four pigs fed barley made a total gain of 254 lbs. A similar lot fed the mixed grain gained 205 lbs., the profit in the two cases being $7.85 and $5.52, respectively. "The pen fed on barley consumed 40 lbs. more grain during the fattening period than those fed on mixed grain."

Ten pigs pastured on an acre of nearly ripe peas gained 277 lbs. in 47 days.

At the Indian Head Experimental Farm a test was made of rape pasturage supplemented by a small amount of meal. In three months seventeen pigs made an average gain of 26.5 lbs. per head. Only about two-thirds of the rape on the half acre on which they were pastured was eaten. As shown by a comparative test, the yield of rape was 32 tons to the acre. The growth was quite rank and the pigs did not eat large amounts at first, and they seemed always hungry until their meal ration was increased.

Some data are also given regarding the pigs kept at the several experimental farms.

Experiments with swine, M. Cumming (*Ann. Rpt Ontario Agr. Col. and Expt. Farm, 30 (1904), pp. 97-101*).—In a comparison of large and small amounts of blood meal and tankage with skim milk as part of a ration, and with meal alone, made with 8 lots of 4 pigs each, it was found that the greatest gain, 597 lbs., was made by a lot fed tankage, meal, and skim milk, 1:15:13, and the smallest gain, 461 lbs., by a lot fed blood meal and meal, 1:14.

The cost of a pound of gain ranged from 3.48 cts. on a ration of tankage and meal 1:15 to 4.23 cts on blood meal and meal 1:9. The test began June 27 and closed Nov. 23. All the lots received uniform treatment and were given some green feed and roots in addition to the other feeds mentioned. According to the author, the pigs fed on meal alone made very satisfactory gains but not as large as those made

by the other groups. Considering both the rate and cost of gain the skim milk and meal ration was rated highest, and the ration containing a large amount of blood meal with meal lowest.

"Blood meal, mainly on account of its extra cost, proved the least satisfactory of these supplemental foods. Tankage proved much more satisfactory and, while not quite equal to skim milk, yet, when fed in small quantities along with a small quantity of skim milk, gave about the best results."

"Judging from this, we would say that tankage would prove itself an excellent food to add to a ration for pigs when only a limited amount of skim milk was available, which is often the case on the average farm. In both cases where tankage and blood meal were fed in different proportions, the smaller proportion proved more satisfactory. This is about what we would expect in considering the nature of the main meal ration, viz, middlings, barley, and oats. Had the ration consisted of a large amount of corn, it is very likely that the larger amount of these by-products would have proved more satisfactory."

In a test of the value of pasturage, two lots of 1[illegible]gs were pastured for five weeks on clover and then for ten weeks on rape—one lot being fed all the grain they would eat up clean and the other about two-thirds as much. After the period on pasture, both lots were fed in pens for seven weeks on roots and a full meal ration. The total gains made during the test as a whole by the lot on a heavy ration was 1,334 lbs., and and by those fed a light ration, 1,339 lbs. While on pasturage, the two lots required respectively 4.21 and 3.53 lbs. of meal per pound of gain. Considering the test as a whole, the amounts required were 5.17 and 4.45 lbs. and the cost of meal per pound of gain 4.65 cts. and 4 cts.

"The importance of carefully husbanding the grain fed to pigs on pasture is strongly emphasized in this experiment. At the time the pigs went inside, the light feed ones were considerably thinner than the heavy ones, but they had developed just as big frames and went ahead more rapidly during the last stages of feeding, at which time they, too, were fed a full ration."

Soy beans and rape were compared with two lots of 6 pigs each, fed like rations of meal and skim milk in addition to the green feed. About 5 lbs. of soy beans and about 5.5 lbs. of rape was eaten per head per day. In the five weeks of the test, the total gain on rape was 145 lbs. and on soy beans 159 lbs.

"It is evident that the soy beans are a richer food than rape, a lesser quantity producing a greater gain. On the other hand, rape is a heavier yielder per acre than soy beans. From this it is evident that, for purposes of feeding green forage to pigs in pens, a given amount of land might be equally profitably sown with either soy beans or rape. When, however, it is desired to pasture pigs on one or the other crop, rape will stand the tramping, etc., much better, and is the more profitable crop."

Canadian and Danish bacon, G. E. DAY (*Ann. Rpt. Ontario Agr. Col. and Expt. Farm, 30 (1904), pp. 89-96*).—On the basis of personal observations, the author discussed the market qualities of Danish and Canadian bacon with a view to suggesting methods of improving the Canadian product. The Danish bacon is of superior quality and the bulk of it comes from crossbred pigs fed largely on barley though other grains including corn are sometimes used. The pigs are not given any considerable amount of exercise.

Some notes are given regarding the crops raised at the Ontario Experimental Farm and also regarding the feeding of cattle and pigs and experiments with live stock. The work with pigs has been summarized in another publication (E. S. R., 15, p. 69).

Horses, J. H. GRISDALE (*Canada Expt. Farms Rpts. 1904, pp. 44-47*).—Some data are given regarding the cost of the feeding and care of the station farm horses and the work required of them, and feeding tests are reported. Using 6 lots of

2 horses each, different mixtures of bran, oats, and oil meal were compared with oats to determine whether a mixed grain ration could replace oats to any considerable degree with advantage.

An average of about 20 pounds of grain was fed per head per day, with about 17 pounds of oat hay. In the 40 days of the test, losses in weight were noted on all the rations except bran and oats, 1:1, apparently owing to the fact that the oat hay was not well liked.

As regards the relative economy of the rations, the author calculated that, except in the case of the ration of oil meal and oats 1:10 which cost $1.25 per year more than oats alone, substituting a mixed ration for oats would effect an annual saving ranging from $2.92 with bran, oil meal, and oats 2:1:10 to $19.53 on bran and oats 2:1.

The ration of bran and oats 2:1 "may be recommended as a good meal ration for working horses and is certainly very economical in comparison with pure oats." The ration of bran, oil meal, and oats 2:1:10 "would be considered by most horsemen as an ideal ration." At the close of the period, timothy hay was substituted for oat hay and in every case the horses gained in weight.

In a comparison of roots and silage, horses fed turnips in addition to oats, bran, and hay maintained their weight while the lots fed carrots, mangels, and silage, respectively, lost somewhat in the 14 days covered by the test. A check lot fed oats, hay, and bran only gained somewhat in weight.

The average amount of silage fed was 10 pounds and of roots 6 to 10 pounds per head per day. The average amounts of meal and hay were 18 and 15 pounds, respectively. According to the author, when such amounts of roots and silage are fed to work horses, the results are not very favorable as the succulent feeds are laxative in character.

As regards palatability the turnips and carrots were most relished, with silage almost as welcome, and mangels not at all in favor.

"It was observed that fed in smaller amounts per day or fed to idle horses no evil effects were noticeable. The roots or silage did not seem to replace any of the regular ration of meal and hay, and the feeding of these feeds was an added expense rather than an economy.

"Where fed to idle horses, however, or where fed to horses it was desired to put in better condition, a small amount of roots—5 to 8 pounds per day—has been found beneficial, as serving to prevent digestion troubles."

Report of the poultry manager, A. G. GILBERT (*Canada Expt. Farms Rpts. 1904, pp. 283–311, pl. 1*).—Factors of especial interest with respect to poultry production are discussed and data given regarding the effects of introducing superior breeding stock into the Station flock, the stock on hand, the poultry exhibit at the Central Canada Fair, the time of laying of pullets and old hens, the management of the Station poultry, poultry diseases and similar topics, together with some details of experimental work.

As regards the effect of variety "experience has shown that where there is variety in rations and care in feeding them, with requisite allowance for floor space, there is little likelihood of egg eating or feather picking."

Steamed lawn clippings were fed to the Station poultry stock three or four times a week and eaten with evident relish. "It is a very beneficial way of utilizing a form of waste. Clover leaves treated in the same way are equally effective."

The eggs laid by different breeds ranged in weight from 4.5 lbs. per dozen with ordinary brown Leghorns to 13.75 lbs with selected Buff Orpingtons.

In the 5 or 6 months of a test of different cheap grain mixtures the largest number of eggs was obtained with nine pullets fed twice a day a ration of 0.75 lb. of oats and wheat 2:1 with roots. The smallest number of eggs was obtained with a similar lot fed mangels with a like amount of the same grain mixture and a lot fed beets with a ration of 0.75 lb. of wheat and oats 2.1.

Continuing the studies of the cause of weak germs in early spring eggs (E. S. R., 16, p. 296), it was found that hens kept in cold quarters and fed heavily produced eggs with strong germs which hatched well. On the other hand, poultry kept in artificially warmed houses laid eggs with weak germs which hatched weak chicks. The "results were considered in favor of fresh air and plenty of it even if it was cold."

Data are recorded regarding hatching tests, to compare different sorts of incubators with hens, but definite deductions are not drawn.

In a study of the duration of fertilization after the removal of the male bird, records were kept of the number of eggs laid and the eggs which hatched or which were shown to be fertile. The last trace of fertility was noticed eleven days after separation. In accord with earlier observations, the unfertilized eggs had superior keeping qualities, so the author recommends that as a rule male birds should not be kept with hens depended upon for market eggs.

A test was also reported made by F. T. Shutt, in which chickens and old hens were compared, some of the chickens being fed in pens with limited runs and others in crates. The hens were fed in pens. The average gain per head per week in the month covered by the trial ranged from 4.4 lbs. with old hens to 7.1 lbs with chickens fed in pens. In general the chickens fed in pens made greater gains than those fed in crates. It was also true that the chickens fed a mixture containing meat meal made greater gains than similar lots fed a ration without this form of animal feed.

Considering the test as a whole, the cost of a pound of gain ranged from 4.3 cts. with one of the lots of old hens to 6.1 cts. with one of the lots of chickens fed in crates. The deductions which were drawn from the test follow:

"The pullets, with one exception, did not make as great gains as cockerels of the same age. Old hens which are well fed require no further treatment to make them fit for killing. The older the hen the more readily does she take on fat rather than flesh. The crossbred chicken, although fed on a more nutritive ration, did not make as much weight as pure-bred ones. The chickens which were loose in their pens with limited runs made slightly greater weight development, at cheaper cost, than those in crates."

Poultry, R. Robertson, S. A. Bedford, and A. Mackay (*Canada Expt. Farms Rpts. 1904, pp. 350, 393, 394, 450*).—Data are given regarding the poultry kept at the Maritime Provinces, Manitoba and Indian Head Experimental Farms, and tests carried on at the Manitoba Farm are also briefly reported.

Four pure-bred Plymouth Rock cockerels fed all they would eat of a mixture of equal parts of ground wheat, oats, and barley mixed to a thin porridge with skim milk gained 6 lbs. in 21 days at a cost of 3.25 cts. per lb., as compared with 5 lbs. 2 oz. at a cost of 3.5 cts. per lb. in the case of four white Wyandottes fed the same ration. (For earlier work see E. S. R., 16, p. 296.)

An incubator test led to the following conclusions: "The percentage of chickens from fertile eggs was the same, whether setting hens or incubator were used. It is possible to secure earlier chickens by using an incubator. A large proportion of the eggs laid in early spring before the fowls have an opportunity to take exercise are not fertile."

Poultry, W. R. Graham (*Ann. Rpt. Ontario Agr. Col. and Expt. Farm, 30 (1904), pp. 135–141, fig. 1*).—Statements are made regarding early and late hatching, the Station poultry houses, the treatment of breeding stock, varieties of geese kept, etc. In a test, which began in July, of the possibilities of inducing early moulting, it was found that in general old hens confined and fed a low ration for two weeks and then an abundant ration began to moult during the third week of the test, while those fed the same way but allowed to range did not. This would indicate, according to the author, that it is possible to control the moulting season more or less.

In a test of the value of skim milk, animal meal, beef scrap, and blood meal as part of a ration, made with 7 lots of 12 chickens each, the greatest gain, 16.5 lbs., was made in 2 weeks with a lot fed grain and skim milk and the smallest gain, 9 lbs., by a lot fed grain and animal meal. The cost of a pound of gain ranged from 3.9 cts. with a lot fed grain and skim milk to 7.3 cts. with a lot fed grain and beef scrap. According to the author, the skim milk substitutes tend to produce yellowish flesh, while skim milk is one of the best feeds for producing white flesh.

To test individuality data were recorded regarding the gains made in three weeks by 12 chickens, and were found to vary in amount from 1 lb. 1 oz. to 2 lbs. 1 oz. All the chickens were selected from a flock which would be considered of fair average quality.

Distribution and magnitude of the poultry and egg industry, G. F. THOMPSON (*U. S. Dept. Agr., Bur. Anim. Indus. Circ. 73, pp. 22, fig. 1*).—An abridgment of a previous publication (E. S. R., 15, p. 502).

The early development of guinea eggs, I. TUR (*Abs. in Physiol. Russe, 3 (1904), Nos. 48–60, pp. 208, 209*).—The fact that guinea eggs require 4 weeks for incubation, as compared with 3 weeks in the case of hens' eggs, led the author to undertake the studies reported of the changes which take place in the early part of the incubation period.

Judging of the animal body by photogrammetric methods, E. LIEBENAU (*Mitt. Landw. Inst. Leipzig, 1905, No. 6, pp. 1–60, pls. 21*).—The use of photographic methods in judging of the animal body are spoken of, the different methods employed, accuracy, and related questions being considered.

DAIRY FARMING—DAIRYING—AGROTECHNY.

Report of the professor of dairy husbandry, H. H. DEAN (*Ann. Rpt. Ontario Agr. Col. and Expt. Farm, 30 (1904), pp. 73–88*).—Brief notes are given on the work of the dairy department during the year, and experiments in cheese making, butter making, and feeding cows, many of which are in continuation of previous work (E. S. R., 15, p. 1110), are reported.

Experiments in cheese making (pp. 74–81).—A comparison was made of pepsin and rennet for coagulating milk in cheese making. One ounce of pepsin was dissolved in 20 oz. of water and 6¾ oz. of this solution was used per 1,000 lbs. of milk. Rennet extract was used at the rate of 3½ oz. per 1,000 lbs. of milk. Eight comparative tests were made during the month of August. When rennet was used the average yield of marketable cheese per 1,000 lbs. of milk was 91.6 lbs. and when pepsin was used 91.1 lbs. The average of all scorings for flavor was 35.5 out of 40 for the rennet cheese and 35.8 for the pepsin cheese. The average total scores were, respectively, 90.7 and 91.1. Mention is made of the greater difficulty in preparing the pepsin solution for use.

Comparisons were made of cheese containing normal and excessive amounts of moisture. In one series the percentage of moisture was 57.377 at the time of dipping, 42.438 at the time of milling, and 35.979 in the green cheese, while in the normal series the percentages were, respectively, 54.431, 40.965, and 34.571. The acidity was also higher at the time of milling and salting in the cheese containing excessive moisture.

The increased yield of marketable cheese in the first series amounted to about ½ lb. per 1,000 lbs. of milk. "There was little difference in the quality of the cheese. From 2 years' experiments we may conclude that an excess of 1 to 2 per cent moisture may be left in cheese ripened in cold storage without much danger of the quality deteriorating, although the normal cheese scored slightly better."

In 7 experiments comparisons were made of 3½ and 6¾ oz. of rennet per 1,000 lbs. of milk, the cheese being ripened in one series in mechanical cold storage at about

40° F. and in another in ice cold storage at the same temperature. There was little or no difference in the yield and quality of the cheese whether a normal or a larger amount of rennet was used. Cheese ripened in mechanical cold storage lost more in weight than cheese ripened in ice cold storage, but averaged slightly better in quality. It is believed that an excessive amount of rennet may be used with safety where cheese makers desire the cheese to ripen more rapidly after placing in cold storage.

Placing cheese on shelves and boxing directly from the press were again compared in a number of experiments. The cheese in boxes lost less in weight than cheese placed on shelves. There was practically no difference in the quality of the cheese treated by the 2 methods. The cheese in boxes, however, showed a greater tendency to mold. Boxing cheese directly from the press is believed to be quite practicable.

Comparative tests were made of ripening cheese in mechanical cold storage at average temperatures of 31.7, 39.3, and 42°; ice cold storage at 41.2°, and in a cellar at 51.4°. There was not much difference in the quality of the different lots of cheese. The higher the temperature the greater was the loss in shrinkage.

Ice cold storage and mechanical cold storage were compared in experiments in which the cheese was moved from the ordinary ripening room to cold storage at the end of 1 week. There was practically no difference in the quality of the cheese whether placed directly in cold storage or at the end of 1 week. The shrinkage was greater in the latter case and also greater in mechanical cold storage than in ice cold storage.

Experiments in butter making (pp. 81-85).—In 4 experiments in butter making pasteurizing milk was compared with pasteurizing cream. While the experiments are not considered sufficient in number to warrant positive conclusions, the results are considered as indicating that when first made there is little or no difference in the quality of butter in summer whether the whole milk or cream is pasteurized, but that the butter holds its flavor slightly better when made from pasteurized milk as compared with pasteurized cream. It is thought probable that the extra labor involved in cleaning the separator bowl when separating pasteurized milk counterbalances any difference in quality.

Churning sweet cream to which 27½ per cent of butter culture had been added was compared with churning ripened cream. The yield of sweet cream butter was slightly less, though the quality was superior not only when first made but at later periods. A comparison was also made of churning sweet cream without the addition of culture and similar cream to which from 20 to 30 per cent of culture had been added. There was less loss of fat in the buttermilk when the culture was used and the flavor of the butter was also better.

The results of several tests failed to show any advantage in using dry parchment paper as compared with moist paper for wrapping pound prints of butter. The value of formalin as a preventive of mold on butter is considered doubtful.

Several experiments were made in the cold storage of butter. Mechanical cold storage at about 40° F gave slightly better results than ice cold storage at the same temperature. A temperature of 28° gave better results than a temperature of 40°. None of the July butter was suitable for table use when examined at the end of November. It is therefore not believed to be possible to hold butter in cold storage for 3 or 4 months and have it retain its fine flavor.

Feeding experiments (pp. 85, 86).—Tests were made of 2 proprietary stock foods. Blatchford's Sugar and Flaxseed Meal increased slightly the yield of milk, but not sufficient, in the opinion of the author, to warrant the additional expense. The results of a calf feeding experiment were considered favorable to the use of this material as a food for calves.

The Improved Molasses Cattle Food, a by-product from the beet-sugar factory, was tested with 21 cows with results indicating, in the opinion of the author, that this

material will prove a valuable addition to the foods available for the production of milk.

Dairy herd record (pp. 86–88).—Records are given of the dairy herd of 24 cows for 1 year. The yield of the individual cows ranged from 9,161 lbs. of milk to 2,515 lbs., and the profit on milk from $117.77 to $22.41.

Dairy school bulletin (*Ontario Agr. Col. and Expt. Farm Bul. 143, pp. 56, figs. 5*).—This bulletin has been prepared by the staff of the dairy school of the Ontario Agricultural College, and contains introductory notes by H. H. Dean on dairy stables, feeding cows, digestible nutrients in feeding stuffs, paying patrons, and other topics, and the following articles: The Alkaline Solution—Its Preparation and Use, by R. Harcourt; Milk and Cream Testing, by J. A. McFeeters; Hints on the Care of Milk for Creameries and Cheese Factories, and Canadian Cheddar Cheese Making, by W. Waddell and A. McKay; Separators and the Separation of Milk, by R. W. Stratton; Creamery Butter Making, by C. W. McDougall; Hand Separators, by G. R. Taylor, and Farm Butter Making, by Laura Rose.

The dairy produce act of Queensland, 1904.—Instruction to dairymen, G. S. Thomson (*Queensland Agr. Jour., 15 (1905), Nos. 7, pp. 826–832; 8, pp. 879–887, pls. 15, fig. 1*).—The chief provisions of this law are noted and instructions are given on milking and on the handling of milk and cream with a view of enabling dairymen to comply with the requirements of the act. Some experiments on aeration and cooling are briefly reported. Numerous illustrations are given of plate cultures inoculated in various ways.

Cleanliness in dairy management, J. F. Blackshaw (*Jour. Bd. Agr. [London], 12 (1905), No. 3, pp. 136–144, figs. 6*).—The importance of cleanliness in dairying is emphasized in this discussion and illustrations from photographs are given showing the appearance of plates exposed in badly ventilated and well ventilated stables, exposed under dirty and clean cows, and inoculated with milk drawn into dirty and clean pails.

Experiments with dairy cows, J. H. Grisdale (*Canada Expt. Farms Rpts. 1904, pp. 54–61*).—Tabulated data are given for several feeding experiments.

A ration containing mangels was practically no better for milk production than one containing about the same quantity of silage but was more expensive. The results of a comparison of dry and succulent forage showed the greater value of the latter in maintaining the yield of milk. Comparative tests were also made of silage, sugar beets, sugar mangels, and turnips. The turnips were more expensive than the other feeding stuffs and not so effective. They also imparted a bad flavor to the butter, rendering it quite unsalable. The best results so far as the yield of milk was concerned were obtained by the sugar beets.

Feeding cows twice a day was found as effective as feeding three times a day. A test was made of the feeding value of refuse apples for cows. From the data obtained it is estimated that the apples were worth $2.40 per ton or about 7 cts. per bushel as compared with roots and silage at $2 per ton. The cows seemed to relish the apples and made considerable gains in live weight.

Dairy herd records, J. H. Grisdale, R. Robertson, and S. A. Bedford (*Canada Expt. Farms Rpts. 1904, pp. 47–54, 339, 340, 390*).—Records are given of 28 cows of different breeds at the Central Experimental Farm, 21 cows at the Experimental Farm for the Maritime Provinces, and of 7 cows at the Experimental Farm for Manitoba. Notes are also given on the feeding of the cows at the 2 farms first mentioned.

Tests of Guernsey cows for advanced registry (*Connecticut State Sta. Rpt. 1904, pt. 5, p. 460*).—Yearly tests of 15 cows admitted to advanced registry are reported. Tests of 2 other cows are also noted.

Experiments in aseptic milking, V. Willem and A. Miele (*Rev. Gén. Lait, 4 (1905), No. 18, pp. 409–419*).—In the series of 35 experiments here reported, great precautions were taken to prevent the contamination of milk during milking. The

milk was bottled, cooled, and shipped by railroad to the laboratory where bacteriological examinations were made after intervals averaging 39 hours. The number of bacteria found in the different samples ranged from 8 to 356 and averaged 102.

The results were essentially the same whether the milk was from 1 cow or was the mixed milk of several cows. The samples remained sweet at least 10 days, more often 17 to 20 days, and occasionally 2 to 3 months at a temperature of 13 to 15° C. Lactic-acid bacteria developed over the peptonizing forms and finally produced coagulation of the milk. It is believed that as good results may be obtained in the future in ordinary practice.

The milking machine, P. H. SUTER (*Jour. Dept. Agr. So. Aust., 8 (1905), No. 11, pp. 658–661, figs. 3*).—A favorable report is made upon the Lawrence-Kennedy milking machine, which it is stated is becoming quite extensively used in Australia. The advantages and disadvantages of the machine are briefly discussed. Its use is not considered profitable with herds of less than 30 cows.

Effect of the heat of cows on the composition of milk, G. FASCETTI (*Rev. Gén. Lait, 4 (1905), No. 17, pp. 385–388*).—On the basis of observations made with 2 cows the author concludes that during estrum the yield of milk is slightly decreased while the percentages of fat, total solids, and proteids show a tendency to increase. The variations from the normal were not very marked.

Influence of food on the quality of milk, C. QUILLARD (*Rev. Soc. Sci. Hyg. Aliment., 2 (1905), No. 1, pp. 112, 113*).—The author discusses briefly the unsuitability of certain feeding stuffs for cows which are used in the production of milk for infants, and concludes from the results of his studies that sugar-beet pulp except when dried has injurious effects.

Observations on the milk of cows in Jamaica, H. H. COUSINS (*Bul. Dept. Agr. [Jamaica], 3 (1905), No. 6, pp. 118–122*).—The average composition of the milk of 92 Jamaica cows was as follows: Specific gravity 1.028, total solids 13.83 per cent, fat 5.1, solids-not-fat 8.69, and ash 0.70. The highest percentage of fat was 8.7 and the lowest 2.9. The Holstein breed is believed to be unsuited to Jamaica conditions. Of 14 samples of market milk collected in Kingston 6 were certified as adulterated with water.

Report on the milk of Jamaica cows, H. S. HAMMOND (*Bul. Dept. Agr. [Jamaica], 3 (1905), No. 6, pp. 122–127*).—This gives the detailed analytical data upon which the above discussion is based.

Average composition of the milk of sheep in Southern Sardinia, A. SANNA (*Staz. Sper. Agr. Ital., 38 (1905), No. 4, pp. 289–306*).—The average composition of 55 samples from one locality was as follows: Specific gravity 1.0385, total solids 18.13 per cent, fat 7.53, casein 4.65, albumin 1.01, sugar 4.05, and ash 0.89.

The average composition of 15 samples from different localities analyzed in 1900 was as follows: Specific gravity 1.0376, total solids 18.34 per cent, fat 7.29, casein 4.60, albumin 1, sugar 4.23, and ash 0.96. The average composition of 62 samples from different localities examined in 1901 was as follows: Specific gravity 1.0381, total solids 17.79 per cent, fat 6.64, casein 4, albumin 1.03, sugar 4.85, and ash 0.91.

On the nature of the cellular elements in human colostrum and milk, V. WALLICH and C. LEVADITI (*Ann. Inst. Pasteur, 19 (1905), No. 5, pp. 321–334, pl. 1*).—The results of morphological studies and inoculation experiments with guinea pigs are reported.

The cellular elements in human milk were found to vary under different conditions. When lactation was suddenly terminated mononuclear but more especially polynuclear leucocytes appeared in large numbers. The colostrum corpuscles were believed to have two sources, one epithelial or glandular and one mesodermic. When milk was injected into the peritoneal cavity of a guinea pig cellular elements were later observed which had the appearance of colostrum bodies and which were believed to have arisen from the phagocytes.

Leucocytes in milk and their significance, C. F. DOANE (*Maryland Sta. Bul. 102, pp. 205–223*).—The author calls attention to the absence of definite knowledge concerning the milk of diseased cows, describes a method devised at the station for determining the number of leucocytes in milk, gives the results of numerous leucocyte counts, reports studies of the occurrence of fibrin in normal and diseased milk, and concludes that the presence of clumps of fibrin and leucocytes in milk is a proof that such milk came from a diseased udder.

The Doane-Buckley method of determining the number of leucocytes in milk as well as some comparisons of this method with the older one of W. R. Stokes have already been noted (E. S. R., 16, p. 617). The author counted the leucocytes in the milk of the station herd and found that in a large number of samples the numbers ranged from 3,000 to 1,600,000 per cubic centimeter. Even greater variations were observed in the milk of individual cows of a large and well kept private herd. In no instance in either herd was the milk free from leucocytes.

Several tests were also made of the milk from the different quarters of the udder, the lowest number of leucocytes recorded being 1,000 per cubic centimeter. These observations are believed to show quite conclusively that leucocytes are never absent from milk, and that with most cows their numbers run into the thousands per cubic centimeter. No significance is attached to even considerable variations.

It is not believed that the mere presence of leucocytes in the milk necessarily means an inflamed area in the udder, but that the leucocytes may escape normally from the blood into the milk. However, when inflammation was evidently present the number of leucocytes was large. The adoption of some definite number of leucocytes as a standard for indicating the presence of pus in milk is therefore believed to be by itself arbitrary and unreliable.

While studying the characteristics of pus the author observed threads identified as fibrin. These were found to be most satisfactorily stained by using Delafield's hematoxylin, to which 15 per cent of carbolic acid had been added, and counter staining with eosin. Such threads were also found in milk and when present in any quantity large numbers of leucocytes were found collected in masses. "There can be little doubt that these leucocyte masses or clumps furnish the most practical and the easiest means of determining the presence of pus and the healthfulness of the milk."

When the number of leucocytes is low the presence of clumps need not be expected, but when the number is high search should be made for them. "The presence of fibrin, as shown by clumps of leucocytes in the blood counter, or as demonstrated by stained threads, combined with an abnormal number of leucocytes, is the only satisfactory proof that inflammation exists in the udder. Without the fibrin any serious inflammation is to be doubted."

Contrary to statements that the milk of cows once affected with garget is never again fit for use, tests by the author's method failed to show that milk after such attacks is always unwholesome.

Reference is made to the work of Babcock on the occurrence of fibrin as a natural constituent of milk (E. S. R., 1, p. 162), which the author believes has not heretofore been established, but which can be demonstrated microscopically in suitable preparations.

Experiments with Fliegel's apparatus for determining dirt in milk, J. KLEIN (*Milchw. Zentbl., 1 (1905), No. 7, pp. 305–307*).—The milk is filtered through a layer of cotton previously dried at 100°. The cotton filter is then washed successively with water, alcohol, and ether, and again dried to a constant weight, the difference in the 2 weighings representing the amount of insoluble impurities in the milk. Several determinations are reported. The method is considered more satisfactory than the others which have been devised for this purpose.

Examination of Babcock test apparatus (*Connecticut State Sta. Rpt. 1904, pt. 5, p. 448*).—Of 151 pieces of glass apparatus tested in 1904 only 1 was found inaccurate.

Milk consumption in Lille, A. BONN (*Rev. Soc. Sci. Hyg. Aliment., 2 (1905), No. 1, p. 114*).—The total daily consumption of milk in the city of Lille is estimated at 32,590 liters, of which skim milk constitutes 20,440 liters. The average fat content of the whole milk was 3.08 per cent and of the skim milk 1.61 per cent. The large infant mortality in Lille is attributed in part to this unusually large consumption of skim milk.

Cooperative dairying in England, H. C. FAIRFAX-CHOLMELEY (*Jour. Bd. Agr. [London], 12 (1905), No. 4, pp. 193-201*).—A brief account is given of the actual working of one of the dairies. There are in all 14 cooperative societies.

Milk depots in Germany, VON OHLEN (*Pub. Health [London], 17 (1905), No. 10, pp. 655-663*).—This is an account of the milk depots in Germany with special reference to the conditions in Hamburg.

The addition of formalin to milk, H. DE ROTHSCHILD (*Rev. Soc. Sci. Hyg. Aliment., 2 (1905), No. 1, pp. 110-112*).—This is a brief preliminary note on experiments conducted to determine the physiological effects of formalin. Milk preserved with formalin in the proportion of 1 to 10,000 produced bad effects when fed to infants affected with gastro-enteritis. Experiments are also being conducted with dogs in which, by means of a gastric fistula, the effect of formalin upon digestion is being studied.

Investigations on the presence of tubercle bacilli in milk, butter, and margarin in Christiania, H. THUE (*Tidskr. Norske Laegefor., 1904, No. 8, p. 306; abs. in Centbl. Bakt. [etc.], 1. Abt. Ref., 36 (1905), No. 18-20, p. 597*).—In no instance in the 44 samples of market milk, 16 of butter, and 15 of margarin examined were virulent tubercle bacilli found.

On the pasteurization of milk in the feeding of infants, E. VON FREUDENREICH (*Rev. Gén. Lait, 4 (1905), No. 19, pp. 433-437*).—This is a description of a pasteurizing apparatus devised by the author and O. Jensen.

Pasteurization of milk for infants, ZELEŃSKI (*Abs. in Deut. Med. Wchnschr., 31 (1905), No. 29, p. 1167*).—On the basis of extended investigations the author concludes that the present methods of pasteurization are not free from objections.

Influence of heat on milk, E. KAYSER (*Rev. Soc. Sci. Hyg. Aliment., 2 (1905), No. 2, pp. 147-153*).—This is a discussion of the changes brought about in milk by the influence of different degrees of heat.

On the value of a good separator, with brief descriptions of different systems, E. FREUND (*Maschinen Ztg., 3 (1905), Nos. 10, pp. 109-117, figs. 37; 11, pp. 127-132*).—This is an illustrated description of the different types of centrifugal separators.

Butter preservatives, H. H. DEAN and R. HARCOURT (*Ontario Agr. Col. and Expt. Farm Bul. 145, pp. 18*).—The use of preservatives in food is briefly discussed, references being made particularly to Bulletin 84 of the Bureau of Chemistry of this Department (E. S. R., 16, p. 684), and to the report of the British committee (E. S. R., 13, p. 1070).

In a test at the college 12 men consumed daily a total quantity of about 3 lbs. of butter preserved with ½ per cent of borax. No injurious effects were observed by the men during a first period of 26 days or a second period of 50 days. This experiment is therefore considered as tending to prove the conclusion arrived at by the British committee. It is nevertheless considered unwise to recommend the use of preservatives except in cases where the necessity is clearly manifest and where other methods of preservation can be demonstrated as inapplicable.

Numerous comparative tests were made of salt, borax, boric acid, sodium chlorid, and commercial preparations as regards their efficiency in preserving the flavor of butter.

Borax gave practically as good results as the commercial preservatives. Under ordinary conditions ½ per cent is considered sufficient, but when the butter is likely

to be held for over 3 months or subjected to high temperatures ½ per cent may be added. Butter made from sweet cream was preserved better than that made from ripened cream. Salt was more effective in preventing mold than the other preservatives.

"At the present time we are not prepared to recommend the use of milk or cream preservatives.

"For the home trade, with proper means for pasteurizing the cream and suitable cold-storage facilities, we do not consider that preservatives, other than salt, are needed to keep butter for a reasonable length of time.

"For the export trade which allows one-half of one per cent boracic acid in butter it would seem as if this amount might be used to advantage in some cases, but with suitable cold storage and especially where pasteurization is followed, less than this amount would preserve the butter and be less liable to injure the consumer.

"Salicylic acid, sodium fluorid, and formalin may not be recommended as butter preservatives. The first one is more or less harmful, and gives an objectionable flavor to butter, while the latter two are considered quite harmful to the human system."

Notes on abnormal butters, L. HOTON (*Abs. in Rev. Gén. Lait, 4 (1905), No. 17, pp. 398–404*).—Variations in the composition of butter are discussed, and studies on the solubility of glycerids in acetic acid with experiments on the critical temperature of butter fat in the same acid are reported.

The value of the different determinations (Reichert-Meissl number, soluble acids, volatile insoluble acids, critical temperature in alcohol or Crismer index, critical temperature in acetic acid or Valenti index, Hubl number, Hehner number, and the index of refraction) in detecting adulteration is discussed. It is stated that some Holland butters, pure but abnormal in composition, can not always be distinguished from adulterated samples.

Experiments on the manufacture of Parmesan cheese with pure cultures of bacteria, F. SAMARANI (*Milchw. Zentbl., 1 (1905), No. 6, pp. 251, 252*).—The results of experiments conducted in 1903 and 1904 were considered very favorable to the use of Gorini's pure cultures in the manufacture of Parmesan cheese.

Micro-organisms in the cheese industry, P. MAZE (*Ann. Inst. Pasteur, 19 (1905), No. 6, pp. 378–403*).—Part 1 of this quite full discussion of the subject deals with molds and part 2 with lactic-acid bacteria.

Twenty-eighth annual meeting of the Iowa State Dairy Association (*Iowa Yearbook Agr. 1904, pt. 4, pp. 199–323*).—This report of the proceedings contains the score in detail of the butter exhibit at the Iowa State Dairy Convention held in February, 1905, and articles on the care of milk on the farm, value of silos, value of corn for milk production, qualifications of a good butter maker, pasteurization of hand-separator cream, breeding up the dairy herd, and other subjects.

Missouri State Dairy Association (*Ann. Rpt. Mo. Bd. Agr., 37 (1904), pp. 267–337, pl. 1, fig. 1*).—This is a summarized account of the proceedings of the fifteenth annual meeting of the association, held in February, 1905. Among the several articles in this report is one entitled The Farmer's Dairy Cow, by A. J. Glover, which contains the results of farm tests of 10 dairy herds in Illinois. The average yield of milk for all the herds was 4,944 lbs. the first year tested and 5,611 lbs the second year. The average fat content for the 2 years was, respectively, 4.06 and 4.07 per cent.

United States and State standards for dairy products, 1905 (*U. S. Dept. Agr., Bur. Anim. Indus. Circ. 74, pp. 2*).—This gives in tabular form the standards for dairy products as proclaimed by the Secretary of Agriculture and as established by law in the several States, and is a revision of Circular 49 of the Bureau (E. S. R., 16, p. 601).

Manufacture of dry wines in hot countries, F. T. BIOLETTI (*California Sta. Bul. 167, pp. 67, figs. 17*).—Methods for improving the manufacture of dry wines in

hot climates are discussed under the headings of (1) amelioration of the character of the raw material and (2) the control of fermentation.

Under the first heading are considered the suitability of varieties of grapes, methods of culture, time of gathering grapes, the more complete utilization of the substances in grapes, and the addition of substances deficient in grapes or not normally present, and under the second heading modifying the temperature of fermentation by cooling devices, postponement of fermentation until winter and the transportation of grapes or must to a cool locality, and controlling the kind of fermentative agents present by sterilization and the use of pure and selected yeasts.

While the bulletin is based upon observations made by the author in a visit to some of the chief vine-growing regions of Europe and Algeria, it contains also some experimental work conducted in California.

"The main lesson of immediate practical importance to California wine makers to be learned from these observations and experiments is the oft-repeated one of cool fermentation." The experiments at the station have shown that good, sound dry wines can be made from grapes grown on rich irrigated soils in central California. So far such wines have not been made successfully.

The following method is believed to offer an almost practical certainty of attaining this object: "(1) Heating the crushed grapes to a temperature and for a time sufficient to extract the necessary color, tannin, and body; (2) immediate separation of the must and cooling to 85° F.; (3) immediate fermentation of the must at a temperature not exceeding 90° F." This method is not recommended for immediate introduction; but in view of the results that have been obtained when working with small quantities in California and of its successful employment in France it is considered very desirable that the method should be given a thorough trial.

Contribution to the study of wine making in Algeria, J. BERTRAND (*Bul. Agr. Algérie et Tunisie, 11* (*1905*), *No. 13, pp. 285-292*).—Notes are given on wine making in Algeria, and experiments in the manufacture of both red and white wines are reported.

Orange wine, PAIRAULT (*Bol. Cámara Com. Asunción, Paraguay, 1904, No. 15* (*Abs. in Mo. Consular Rpts.* [*U. S.*], *1904, No. 289, pp. 69, 70*).—The author has made a special study of fermentation as applied to the production of orange wine.

The usual way of making orange wine in the Antilles is to peel the oranges, press out the juice, add sugar to it, and then place it in a glass or earthenware vessel and subject it to spontaneous fermentation. This fermentation proceeds slowly on account of the low nutrition of the medium in which the yeast works, consequently an acid fermentation sets in and the result is a poor product.

To overcome this difficulty the author states that after the orange juice has been sterilized sufficiently there should be added to every quart of the liquid 12.25 to 14 oz. of sugar, 0.175 oz. of brewer's yeast, and 2 oz. of a mixture made of the following proportions: Ammonium phosphate 30, calcium phosphate 40, potassium bitartrate 40, magnesium sulphate 3. "When the mixture is cooled fermentation proceeds, and in a few days there results an excellent product. A sweet or dry wine may be made by increasing or diminishing the amount of sugar added."

In Consular Reports No. 297, page 9, two corrections to the above article are made. Instead of brewer's yeast it should be "maltopeptone," and "instead of 2 ounces of a mixture of ammonium phosphate, etc., 23 grains should be added."

Review of viticultural reviews, E. H. TWIGHT (*Bul. Cal. Vit. Club, 1905, No. 1, pp. 7-16*).—This number contains about 20 abstracts of articles on wine making appearing in French journals.

Preparation of practically sterile apple must, G. PERRIER (*Compt. Rend. Acad. Sci.* [*Paris*], *140* (*1905*), *No. 5, pp. 324, 325*).—Many methods of sterilizing apple must have been suggested, but for the most part they bring about some undesirable

change in its composition. Experiments have therefore been made during a period of 3 years with formaldehyde to preserve must.

In this work the apples are first washed and then put into a solution of formaldehyde in the proportion of 8 to 1,000 and left there for from 5 to 10 minutes. They are then washed in clean water, and crushed and pressed. The crushing and pressing apparatus is also sterilized with formaldehyde used in the proportion of 4 parts to 1,000. It has been found that the must of apples thus treated does not ferment. Such must was sent from Rennes to Buenos Ayres and back again without any fermentation whatever taking place.

The must thus obtained contains only small traces of formaldehyde, and this disappears at the end of several days. The taste and the composition of the must are identical with that of must prepared from apples which have been subjected to no treatment whatever. When the musts are seeded with yeast they ferment regularly, producing normal cider of high quality containing no traces of formaldehyde.

Directions for the manufacture of olive oil in Algeria, P. DUMAS (*Bul. Agr. Algérie et Tunisie, 11 (1905), No. 13, pp. 292-302*).—This is an account of methods employed in olive-oil making in Algeria.

Cotton-seed products, L. L. LAMBORN (*New York: D. Van Nostrand Co., 1904, pp. XIII+240, figs. 79, map 1*).—It is stated that "the purpose of this book is to supply a demand for a treatise on the subject of cotton seed which should deal not only with the extraction of the oil from the seed, but with the utilization of the products of the seed as well. With this purpose in view, this book is submitted to a clientele which includes the technical student, the practical man in the fat and oil industries, the cotton-seed oil miller and, last but in no wise least, the consumer of the products of cotton seed."

Different chapters deal with the cotton plant, the cotton-seed industry, summary of procedure in utilizing of cotton seed, cotton seed, cotton-seed products, manufacture of oleomargarine and lard compound, manufacture of soap and soap powder, cotton-seed meal and cotton-seed hulls for cattle food and fertilizer, and rules for the government of transactions in cotton-seed products.

Reports of the Twelfth Census and publications of this Department were drawn on in the preparation of the book.

VETERINARY MEDICINE.

The evolution of immunity, G. R. LEIGHTON (*Jour. Compar. Path. and Ther., 17 (1904), No. 4, pp. 287-295*).—In this article particular attention is given to a discussion of immunity as a problem of heredity.

Several examples are cited of animal and human diseases in which a resistance to the disease is gradually being developed among races which are subject to the infection. The author believes that innate immunity and the power of acquiring immunity to a disease are evolved in the same manner as other characters, and that the whole process is due to natural selection. The prevalence of disease is considered one of the most important factors by which the process of natural selection is influenced.

The fundamental laws of immunity, A. WOLFF (*Centbl. Bakt. [etc.], 1. Abt., Orig., 37 (1904), Nos. 3, pp. 390-397; 4, pp. 566-576; 5, pp. 684-706*).—This is a general article in which the author discusses the nature of toxins, endotoxins, bacteriolysis, agglutination, hemolysin, precipitins, cytotoxins, the relationship of leucocytes to immunity, and other subjects related to this problem.

The intrauterine and extrauterine transmission of antitoxins from mother to offspring, P. H. RÖMER (*Beitr. Expt. Ther., 1905, No. 9, pp. 18-41, pls. 5*).—These experiments were carried out on guinea pigs, rabbits, sheep, cattle, and human beings.

The antitoxins employed were those of tetanus and diphtheria. In guinea pigs and rabbits it was found that no diphtheria antitoxin could be demonstrated in the blood of the young, although the antitoxin was present in the mother's blood at the time of parturition. Similar results were obtained with tetanus antitoxin. In the experiments with cattle and sheep it was shown definitely that the antitoxin could be transmitted in considerable quantities in the milk of the mother. In such cases the amount of antitoxin found in the blood of the young and the amount in the milk of the mother corresponded quite closely.

Annual report on the distribution of animal plagues in the German Empire (*Jahresber. Verbr. Tierseuch. Deut. Reiche, 18 (1903), pp. VI+222, pls. 4*).—As in previous reports, a general account is presented of the health of animals in Germany and of the prevalence of anthrax, black leg, rabies, glanders, foot-and-mouth disease, pleuro-pneumonia, sheep pox, scabies of horses and sheep, swine erysipelas, swine plague, fowl cholera, fowl plague, cerebro-spinal meningitis, influenza of horses, tuberculosis, and trichinosis. The greater portion of the report is occupied with a detailed account of the distribution of these diseases in different parts of the German Empire.

Diseases due to streptococci and their preventive and curative treatment, THOMASSEN (*Rev. Gén. Méd. Vét., 3 (1904), No. 30, pp. 289–302*).—It is believed that in cases of infectious pleuro-pneumonia of horses a streptococcus is associated with the pathogenic pasteurella. Various other diseases of the nature of erysipelas and with similar symptoms are shown to be due to streptococci. Notes are given on the classification of these organisms according to the animal which was affected and according to the nature of the disease produced. In treating the diseases caused by streptococci success has been had in the use of serum. The administration of drugs has not given very satisfactory results except in the case of ichthargan and collargol. The various pathogenic streptococci of man and animals seem to be identical in their pathogenic properties.

Pathogenic mucors and mucormycoses in animals and man, G. J. BARTHELAT (*Thesis, Univ. Paris, 1903, pp. 128, figs. 13*).—In general mycoses may be divided into 2 groups according as they are produced by species of Aspergillus or Mucor.

According to the author's experience, the most virulent species of Mucor are *Mucor corymbifer*, *M. ramosus*, *M. truchisi*, *M. regnieri*, *M. pusillus*, *Rhizomucor parasiticus*, etc. Numerous observations were made on spontaneous cases of mucormycoses affecting different parts of the body of animals and man. As a rule, pathogenic mucors become established more readily in tissues which are already altered in a pathological manner.

The introduction of spores of mucors into the veins of rabbits, guinea pigs, and chickens, causes the death of these animals after a period which varies according to the quantity of spores inoculated. Spontaneous cases of mucormycoses may be advantageously treated by means of arsenic and iodid of potash.

Tuberculosis of cattle, D. E. SALMON and T. SMITH (*U. S. Dept. Agr., Bur. Anim. Indus. Circ. 70, pp. 28*).—This is a revision by D. E. Salmon and J. R. Mohler of an article in the Special Report on the Diseases of Cattle (E. S. R., 16, p. 708).

The frequency of bovine tuberculosis in abattoirs and dairies in the department of Herault, A. CONTE (*Rev. Gén. Méd. Vét., 4 (1904), No. 41, pp. 224–227*).—The official reports in France concerning the prevalence of tuberculosis are believed to be somewhat defective and greater thoroughness along this line is recommended. Certain French races of cattle appear to be greatly afflicted with tuberculosis, infection varying from 9.55 to 35.83 per cent. In one instance 199 out of 518 animals reacted to the tuberculin test.

Experiments concerning tuberculosis, III, E. C. SCHROEDER and W. E. COTTON (*U. S. Dept. Agr., Bur. Anim. Indus. Bul. 52, pp. 95–125*).—In continuing their experiments along this line the authors found that numerous injections of attenuated cul-

tures did not give so much protection as a single injection of a more virulent culture. The highest degree of immunity is produced by cultures of a virulence just insufficient to cause progressive tuberculosis. With such cultures subcutaneous injection is as effective as the intravenous method.

An attempt to obtain an antitoxic blood serum from the donkey, mule, and horse by inoculation with tuberculin and attenuated tubercle bacilli was only partly successful. The serum of treated animals appeared to have some antituberculous power.

The persistence of tubercle bacilli in the tissues of animals after injection was studied, especially in cattle. Virulent tubercle bacilli were found in all lesions of whatever age. It appears, therefore, that bacilli may retain their virulence long after they cease to multiply and perhaps indefinitely. Dead bovine tubercle bacilli inoculated into a sheep caused quite extensive disease and persisted in the tissues for nearly 6 months. Tubercle bacilli of such low virulence as to be perfectly innocuous for guinea pigs remained in the tissues of cattle for 10 months. On account of the long persistence of tubercle bacilli in the tissues, the method of immunization by attenuated cultures is condemned as somewhat dangerous to man.

Lesions in the kidneys caused by intravenous inoculation with tubercle bacilli, L. BERNARD and M. SALOMON (*Compt. Rend. Soc. Biol.* [*Paris*], *57* (*1904*), *No. 35, pp. 526–528*).—Five rabbits were inoculated with an emulsion of tubercle bacilli directly into the left ventricle, and also 3 dogs were inoculated intravenously. These animals were killed from 20 days to 3 months after inoculation and the kidneys were studied for the purpose of determining the lesions produced by such infection. These lesions were found to be chiefly of 3 sorts, viz, tuberculous follicles, chains of lymphocytes, and epithelial lesions.

The dangerous properties of tuberculous meat and prophylactic measures, VALLÉE and VILLEJEAN (*Rev. Gén. Méd. Vét.*, *3* (*1904*), *No. 29, pp. 233–245*).—According to the majority of investigators at the present time, tubercle bacilli of bovine origin are the most virulent of all forms of these organisms.

Notes are given on the distribution of tuberculous lesions in adult cattle, calves, sheep, and goats, together with statistics on the relative frequency of the occurrence of this disease in slaughtered animals. The permanent French commission for the study of tuberculosis recommends that tuberculosis of hogs should be added to the list of diseases which must be passed upon by the sanitary police.

The value of the study of tuberculin reaction, S ARLOING (*Jour. Méd. Vét. et Zootech.*, *56* (*1905*), *Jan., pp. 1–5*).—A brief criticism is presented of the recent work of Vallée on the subject of a precocious reaction to a second tuberculin inoculation.

In the author's opinion the rapidity with which reaction to tuberculin manifests itself is not much greater at the second test than at the first test. In 40 cases of cattle and goats experimentally inoculated with tuberculosis and subsequently tested with tuberculin for the first time the maximum temperatures were presented in 2 cases within 2 hours, in 2 cases within 4 hours, in 2 cases within 5 hours, and in 9 cases within 6 hours.

In only 1 case did the maximum temperature occur as late as 14 hours after inoculation. The author suggests, therefore, the desirability of taking the temperatures in all cases much sooner after inoculation with tuberculin than has generally been recommended.

Two ways of treating tuberculosis in herds, H. L. RUSSELL (*Wisconsin Sta. Bul. 126, pp. 15, figs 4*).—In 1 herd of 70 cows, the milk of which was used for city supply, 57 reacted to tuberculin, and of the 57 reactors 32 were so badly affected as to require total condemnation of the carcass. In many the udder was affected. In another herd of 72 animals 69 reacted.

In both these cases negligence and unsanitary surroundings were responsible for the heavy losses and the danger to human health. Notes are given on other instances in which the first case of tuberculosis in a herd was promptly detected by

the tuberculin test and the further spread of the disease thus prevented. The importance of the lesson taught by these examples is pointed out.

Immunization against tuberculosis, P. BAUMGARTEN (*Berlin. Klin. Wchnschr., 42 (1905), No. 3, pp. 55, 56*).—The author carried on a number of experiments in testing serum immunization of calves against tuberculosis. Good results along this line had already been obtained in experiments with guinea pigs and rabbits.

The serum used in the experiments came from an animal which had previously received inoculations of human tubercle bacilli and subsequently virulent bacilli from a case of pearl disease in cattle. The animal used for the production of serum had been repeatedly tested with tuberculin without reaction. For the immunization experiment 3 calves were used about 3 months old. One of these received 82 cc. of bovine immune serum within a period of 16 days. At the end of that period the calf was inoculated with 5 cc. of virulent bovine tubercle bacilli. One of the 3 calves served as a control animal, while the third calf was inoculated with virulent bovine bacilli and also received serum as a curative treatment

The control calf became affected with generalized tuberculosis and showed great emaciation. After slaughter abundant evidence was obtained of general infection. The calf which was treated in a prophylactic manner with immune serum when slaughtered at the same time showed no swelling of the lymphatic glands or other alteration which could be attributed to tuberculosis. In the prescapular-lymphatic gland a few yellowish tubercles were found of doubtful nature. The calf which received immune serum for curative purposes was by no means so seriously affected as the control animal and the results obtained with it indicate that an immune serum may be of considerable value for curative purposes.

Experiments in protective vaccination of cattle against tuberculosis according to the method of von Behring, F. HUTYRA (*Beitr. Expt. Ther., 1905, No. 9, pp. 1–17*).—The experiments reported in this paper were carried out on young cattle which received vaccine according to the method of von Behring. The animals were subsequently subjected to intravenous or subcutaneous injections of virulent bovine tubercle bacilli or such bacilli were added to the food. The results of these experiments are presented in great detail in a tabular form.

The author's experiments agree with those of von Behring in showing that human tubercle bacilli, when injected intravenously into young cattle were capable of conferring upon the cattle a high resistance to virulent cultures of tubercle bacilli. Von Behring's method is considered as based upon a solid foundation. It is suggested that further experiments are desirable for the purpose of learning the duration of immunity produced by this method.

Combating bovine tuberculosis according to the method of von Behring, EBELING (*Berlin. Tierarztl. Wchnschr., 1905, No. 1, pp. 1–5*).—The author's observations along this line were made on 1,100 vaccinated cattle, of which 759 received a second vaccination. The nature and theory of von Behring's method are described, and notes are given on the author's method of procedure in making vaccination. The temperatures of animals are taken morning and evening for 2 days before and for 8 days after vaccination.

Among the 1,126 calves vaccinated by the author, 37 were subsequently slaughtered and carefully examined. Of this number, 36 were absolutely free from tuberculous alterations, while in the one remaining animal slight alterations were observed in the right mediastinal and left bronchial glands. The method of von Behring is recommended as practical and efficient.

Anthrax in cattle, horses, and men, D. E. SALMON and T. SMITH (*U. S. Dept. Agr., Bur. Anim. Indus. Circ. 71, pp. 10*).—This is a revision by D. E. Salmon and J. R. Mohler of articles in Special Report on the Diseases of Cattle (E. S. R., 16, p. 708) and in Special Report on the Diseases of the Horse (E. S. R., 15, p. 620).

Alterations in the character of the anthrax bacillus, G. SCAGLIOSI (*Centbl. Bakt.* [*etc.*], *1. Abt., Orig., 37* (*1904*), *No. 5, pp. 649–654*).—Anthrax bacilli and spores have been preserved by the author on sterilized threads since 1894.

The action of diffused light upon the anthrax organism was found to be very slight, even after a lapse of 10 years. The agglutinative action was also little affected. Inoculation experiments showed that the virulence of the bacilli is almost as great as that of fresh cultures. From the author's experiments it appears that changes of temperature are more important than any other factors in modifying the virulence and other characters of anthrax cultures.

Texas fever, or Southern cattle fever, D. E. SALMON and T. SMITH (*U. S. Dept. Agr., Bur. Anim. Indus. Circ. 69, pp. 13*).—This is a revision by D. E. Salmon and J. R. Mohler of an article in the Special Report on the Diseases of Cattle (E. S. R., 16, p. 708).

Texas fever cattle tick: Pasture methods of eradication, H. A. MORGAN (*Tennessee Sta. Bul., Vol. XVIII, No. 1, pp. 10*).—A general account is given of the distribution of the cattle tick, immunity to Texas fever, and the national quarantine. The life history of the tick is carefully described with special reference to methods of its eradication. In eradicating the ticks a pasture rotation system may be used, excluding cattle, horses, and mules from pastures from June to October, inclusive, and thus starving out the ticks, or the feed lot system may be adopted.

Experimental transmission of African coast fever by means of ticks, A. THEILER (*Fortschr. Vet. Hyg., 2* (*1905*), *No. 10, pp. 257–268*).—An elaborate account is presented of the appearance, development, and habits of various ticks which occur in South Africa. Experiments were made to determine the possible agency of these ticks in different stages in transmitting African coast fever.

In these experiments *Rhipicephalus decoloratus*, *R. simus*, *R. appendiculatus*, *R. evertsi*, and *Hyalomma ægyptium* were used. From a result of the author's experiments it is concluded that African coast fever is transmitted by *Rhipicephalus appendiculatus* and *R. simus*. The first species is the most important, and adult ticks, of which the nymphs sucked virulent blood, are chiefly concerned in carrying infection. The other species of ticks may be disregarded, with the possible exception of *Amblyomma hebræum*, with which the author made no experiments.

It appears that a tick can produce infection only once. African coast fever is to be expected throughout South Africa wherever the intermediate host of *Piroplasma parvum* is found.

Some diseases complicating rinderpest among cattle of India, J. D. E. HOLMES (*Jour. Compar. Path. and Ther., 17* (*1904*), *No. 4, pp. 317–326, pl. 1*).—As a rule, rinderpest runs a regular course and offers little difficulty in diagnosis. It is often complicated, however, by the simultaneous occurrence of Texas fever, trypanosomiasis, echinococcus disease, distomatosis, or foot-and-mouth disease. Notes are given on the symptoms and pathological anatomy observed in such cases.

The prophylactic treatment of rinderpest by means of preventive inoculation, more especially in the conditions prevailing in India, G. K. WALKER (*Jour. Compar. Path. and Ther., 17* (*1904*), *No. 4, pp. 326–343*).—Considerable difficulty has been experienced in inducing the natives of India to apply any curative or preventive remedies against rinderpest. The disease is enzootic in India, and the mortality is not as high as that observed in South Africa and elsewhere. The virulence of the disease is greatest during the cold season, particularly at the commencement of an outbreak.

The various methods used in treating this disease are carefully outlined and their advantages and disadvantages are described. These methods include Koch's bile method, the glycerin bile method of Edington, the use of a mixture of bile from different sources, the use of serum alone, and the method of simultaneous inoculation

of serum and virulent blood. The advantages of the serum method are that it affords immediate and full immunity and may cure the disease if applied during the period of incubation. The serum may be stored and kept ready for use. It may also be readily transported in bottles. Only one inoculation is required and there is practical certainty of securing good results if proper care is taken.

Notwithstanding the many good points of various methods of treatment, it is believed by the author that there is still room for improvement in the practical and safe treatment of rinderpest.

Inflammation of the udder in cows, M. G. DE BRUIN (*Schweiz. Arch. Tierheilk., 47 (1905), No. 1, pp. 12–24*).—The literature relating to this subject is briefly discussed. Notes are given on a number of different forms of inflammatory conditions of the udder. These conditions may be due to streptococci, tubercle bacilli, and other causes.

In preventing the development of infectious mastitis it is recommended that the straw or litter be furnished in a clean condition, that the cows' tails be prevented from coming into contact with the filth, and that particular attention be given to the feeding and management of cows for the purpose of preventing contamination with bacteria. Attention should also be given to the health of the attendants and to the temporary exclusion from the herd of all animals suffering from the retention of the afterbirth, mastitis, wounds, and other diseases in the case of which bacteria might gain entrance to the milk.

Diseases of the stomach and bowels of cattle, A. J. MURRAY (*U. S. Dept. Agr., Bur. Anim. Indus. Circ. 68, pp. 10*).—This is a revision by L. Pearson of an article in the Special Report on the Diseases of Cattle (E. S. R., 16, p. 708).

Intestinal coccidiosis of young cattle, L. DEGOIX (*Rev. Gén. Méd. Vét., 3 (1904), No. 28, pp. 177–186, figs. 8*).—This disease is also known under the names hemorrhagic enteritis, bloody dysentery, etc.

The first noticeable symptom is the sudden appearance of dysentery with a slight fever, the appetite is lost, and rumination ceases. Emaciation takes place rapidly, and is accompanied with considerable fever during the latter stages of the disease. The duration of the disease is from 5 to 10 days, when recovery or death takes place. In favorable cases recovery takes place rapidly. The author made a study of coccidia in the alimentary tract of affected cattle. These organisms were never found in the epithelial cells of the mucous layer of the intestines, but rather in the deeper lying tissue.

The pathological lesions of the disease were found throughout the whole extent of the large intestines. The organism is described in detail. In controlling this disease the author recommends the disinfection of excrement from diseased cattle and the administration of salol, creolin, or other substances as intestinal disinfectants.

Abortion, or slinking the calf, J. LAW (*U. S. Dept. Agr., Bur. Anim. Indus. Circ. 67, pp. 11*).—This is reprinted from the Special Report on the Diseases of Cattle (E. S. R., 16, p. 708).

Osteomalacia, or creeps, in cattle, J. R. MOHLER (*U. S. Dept. Agr., Bur. Anim. Indus. Circ. 66, pp. 2*).—This is reprinted from the Special Report on the Diseases of Cattle (E. S. R., 16, p. 708).

Ophthalmia in cattle, M. R. TRUMBOWER (*U. S. Dept. Agr., Bur. Anim. Indus. Circ. 65, pp. 2*).—This is a revision by L. Pearson of an article in the Special Report on the Diseases of Cattle (E. S. R., 16, p. 708).

Cattle poisoned by fresh paint, E. H. JENKINS (*Connecticut State Sta. Rpt. 1904, pt. 5, p. 448*).—Mention is made of the poisoning of 2 cows by paint which had been consumed with the grass upon which the paint had been spilled, or licked from freshly painted boards.

The symptoms and development of experimental sheep pox, F. J. BOSC (*Rev. Gén. Méd. Vét., 4 (1904), Nos. 42, pp. 273–283; 43, pp. 337–348*).—In the author's

experiments lambs were selected about 4 months of age and coming from herds which were free from the disease. These animals were inoculated cutaneously, subcutaneously, and also into the peritoneum and trachea. The period of incubation and symptoms of the disease from these various forms of inoculation were studied, and a general classification is presented of the symptoms which assist in the diagnosis of the disease and the determination of the period of its development.

Serum treatment of sheep pox, F. J. Bosc (*Compt. Rend. Soc. Biol.* [*Paris*], *57* (*1904*), *No. 37, pp. 647–649*).—During the author's investigation of this disease a study was made of the action of various mixtures of virus and the serum of hyperimmunized animals in treating sheep pox.

The curative action of the mixture of virus and the serum was practically nil. Its preventive action, however, was striking. The technique of this treatment is comparatively simple. Animals are inoculated with virulent virus in the ear. Subsequently a hypodermic injection of 10 to 15 cc. of the serum of hyperimmunized animals is given. This method yielded excellent results, not only in the laboratory but also in field work under unfavorable conditions.

New facts concerning the etiology of hog cholera, E. A. de Schweinitz and M. Dorset (*U. S. Dept. Agr., Bur. Anim. Indus. Circ. 72, pp. 157–162*).—This is reprinted from the Twentieth Annual Report of the Bureau of Animal Industry, 1903 (E. S. R., 16, p. 724).

Glanders, J. McFadyean (*Jour. Compar. Path. and Ther., 17* (*1904*), *No. 4, pp. 295–317*).—A historical statement is given concerning the exact knowledge of the nature of glanders. The glanders bacillus is described, and notes are given on its behavior upon different culture media.

Particular attention is given to an account of the methods of infection of glanders. The author succeeded in artificially infecting 4 horses with glanders by adding glanders bacilli to the feed. Detailed notes are given on the distribution of the glanderous lesions in these 4 cases. As a result of this study it is believed that ingestion may be the common natural method of infection with glanders. This belief is at least strengthened by the evidence which the author presents, showing that the lesions in spontaneous cases of glanders and in those due to artificial infection through the alimentary tract are very similar.

The etiology of contagious pleuro-pneumonia and related diseases in the horse, M. G. Tartakovski (*Arch. Vet. Nauk* [*St. Petersb.*], *34* (*1904*), *Nos. 10, pp. 765–787; 11, pp. 875–933, figs. 8*).—The literature of this disease is critically discussed in connection with bibliographical references.

The author carried out numerous experiments in the treatment of the disease, with especial reference to the determination of its etiology. As a result of these experiments it is concluded that contagious pleuro-pneumonia of horses is a specific disease belonging to the group of hemorrhagic septicemia. It closely resembles, in many respects, swine plague and septicemia of rabbits. It usually occurs in the form of an epizootic and may be complicated with a number of other diseases. All affected animals should be closely quarantined, and exposed animals should be given serum treatment.

The forms of pneumonia in the horse, V. Drouin (*Rev. Gén. Méd. Vét., 5* (*1905*), *No. 49, pp. 1–16*).—Statistical data are presented showing the number of deaths in horses from pneumonia from 1897 to 1903, as well as the percentage of pneumonia among the total number of deaths in horses during the same period. The various forms of traumatic and infectious pneumonia are described in considerable detail with notes on the usual methods of treatment.

The trypanosoma of dourine and its life history, A. Lingard (*Centbl. Bakt.* [*etc.*], *1. Abt., Orig., 37* (*1904*), *No. 4, pp. 537–547*).—This organism varies in size according to the age of the parasite. The disease is transmitted chiefly during

coitus. The cutaneous plaques or nettle-rash eruptions which appear during the course of this disease are described in detail. The trypanosomes are always found in connection with the plaques.

The biology of trypanosomes of nagana and mal de caderas, W. L. JAKIMOFF (*Centbl. Bakt.* [*etc.*], *1. Abt., Orig., 37* (*1904*), *No. 5, pp. 668-678*).—The author discusses in a detailed manner the morphology and biology of *Trypanosoma brucei* and *T. elmassiani.*

It was found in inoculation experiments that the trypanosomes of nagana and mal de caderas cause an acute infection in mice and rats which lasts not longer than 1 week. In dogs, foxes, guinea pigs, rabbits, and cats the disease shows a slower course, while in goats it assumes a chronic form. Outside of living animals trypanosomes remain alive and maintain their virulence longest in defibrinated blood at a living temperature. Trypanosomes were found to be exceedingly susceptible to heat and disinfection.

Nagana infection in guinea pigs, MARKL (*Centbl. Bakt.* [*etc.*], *1. Abt., Orig., 37* (*1904*), *No. 4, pp. 530-537*).—*Trypanosoma brucei* was used in these experiments and was found to produce death after the inoculation of guinea pigs within from 11 to 80 days. Detailed notes are given on a number of cases. The incubation period varied from 3 to 8 days. In almost all cases the progress of the disease appeared to be without striking symptoms, but ultimately death occurred very suddenly.

Trypanosomiasis and tsetse-fly disease in French Guiana, A. LAVERAN (*Compt. Rend. Acad. Sci.* [*Paris*], *140* (*1905*), *No. 2, pp. 75-78*).—Brief notes are given on the distribution of tsetse flies and other biting insects in French Guiana and on the relation between these insects and trypanosomiases.

Equine piroplasmosis or "biliary fever," T. BOWHILL (*Jour. Hyg.* [*Cambridge*], *5* (*1905*), *No. 1, pp. 7-17, pls. 3*).—This disease is of great importance in certain parts of Cape Colony for the reason that recently imported horses may develop an acute and fatal form of the disease. The distribution of the disease is briefly discussed and notes are given on the pathogenic blood parasite which occurs in various forms. Apparently, the range horses of South Africa are somewhat immune to the disease, and the author believes that animals which have recovered from one attack are immune. A number of secondary affections may follow upon the occurrence of the disease.

The diagnosis of rabies, L. LUZZANI (*Ztschr. Hyg. u. Infectionskrank., 49* (*1905*), *No. 2, pp. 305-324*).—During the author's observations and experiments with this disease results were obtained which indicate that Negri's corpuscles may be connected with the etiology of the disease.

The author's observations were made on 179 cases, of which 165 were in dogs, 12 in cats, 1 in a beef animal, and 1 in a horse. Among this number 107 were examined for the presence of the parasite and it was found in 102 cases. The author believes, therefore, that in suspicious cases a positive diagnosis may be reached if the endocellular form of the protozoan is found in the nervous system.

The action of centrifugation of rabies virus, P. REMLINGER (*Compt. Rend. Soc. Biol.* [*Paris*], *58* (*1905*), *No. 1, pp. 27, 28*).—In experiments carried out by the author it was found that emulsions of rabies virus, diluted at the rate of from 1 to 50 and 1 to 100 and maintained in the centrifuge revolving at the rate of 100 times per minute, showed a loss of virulence in the supernatant portion after a period of 1 hour. The virulence in this portion of the material was diminished gradually. The author believes that these experiments show that rabies is due to a micro-organism, but that this organism is probably ultra-microscopic in size.

Fowl plague, E. LECLAINCHE (*Rev. Gén. Méd. Vét., 3* (*1904*), *No. 26, pp. 49-54*).—This disease, which is also called bird pest, belongs with the group of hemorrhagic septicemia. Notes are given on the symptoms, diagnosis, pathological lesions, and

prophylaxis of the disease. In controlling fowl plague, it is recommended that the shipment of living or dead birds from infected localities be absolutely prohibited and that thorough disinfectant measures be put in operation.

RURAL ENGINEERING.

Irrigation work in cooperation with the Office of Experiment Stations, United States Department of Agriculture, 1903 and 1904, J. G. HENRY and O. H. ELLING (*Kansas Sta. Bul. 128, pp. 279-286, 307-315*).—An account is given of prospecting for underground water at the Fort Hays Substation, the sinking of wells, the installation of a 4-in. vertical centrifugal pump, and the utilization of the water supply thus secured in the irrigation of a variety of crops, including corn, Kafir corn, sorghum, potatoes, cabbage, soy beans, cowpeas, mangels, and sugar beets, with observations on the cost of sinking the well and irrigating by this means.

The experiments in 1903 were of a preliminary character and were rendered inconclusive by the heavy rains during the growing season. In 1904 "the irrigation work was considerably extended and good results were obtained. However, it appears that the method of pumping water is too expensive to warrant irrigating the common crops. Potatoes and other vegetables, and perhaps alfalfa, will give profitable returns for irrigation."

Conference on water conservation and irrigation (*Sydney: Gov. Printer, 1905, pp. XXIX+277, maps 3*).—This is an account of the proceedings of a conference of delegates from different parts of New South Wales, called by the prime minister of the colony to consider mainly the legal rights of the colony in the water of the Murray River and its tributaries, particularly with the view to making an effective agreement among the three states interested regarding the utilization of these waters for purposes of water conservation, irrigation, and navigation. The draft of a proposed law covering the case is given.

Water conservation and the equitable distribution of water for irrigation and other purposes, H. G. MCKINNEY (*Jour. and Proc. Roy. Soc. N. S. Wales, Engin. Sect., 37 (1903), pp. V-XIV*).—A brief preliminary discussion of this subject as applied to New South Wales conditions.

Property in water, G. CHAMIER (*Jour. and Proc. Roy. Soc. N. S. Wales, Engin. Sect., 37 (1903), pp. XIV-XXIII*).—A discussion of riparian rights as affecting use of water in irrigation in New South Wales.

Irrigation geologically considered with special reference to the artesian area of New South Wales, E. F. PITTMAN and T. W. E. DAVID (*Jour. and Proc. Roy. Soc. N. S. Wales, Engin. Sect., 37 (1903), pp. CIII-CLIII, pls. 2*).—The present state of knowledge is explained and the desirability of more accurate information is pointed out. A list of papers bearing on the subject, compiled by W. S. Dun, is given.

Artesian water supply, W. G. COX (*Agr. Gaz. N. S. Wales, 16 (1905), No. 3, pp. 253-257, fig. 1*).—The author states that "the mechanical power derivable from the pressure given in the outflow from artesian wells, although it varies in different bores, is a constant mechanical asset, the value of which is little understood in Australia, and its prospective value, when the bores become multiplied over the face of the land, can scarcely be estimated or realized." A statement is given of the pressure and resultant horsepower of a number of artesian wells in New South Wales and Queensland, and the utilization of this power in hydraulic turbines is briefly discussed.

A review of water conservation in New South Wales, L. A. B. WADE (*Jour. and Proc. Roy. Soc. N. S. Wales, Engin. Sect., 37 (1903), pp. LXVI-LXXXV, fig. 1*).

Reservoir outlets, M. RINGELMANN (*Jour. Agr. Prat., n. ser., 9 (1905), No. 20, pp. 638-642, figs. 8*).

Relation of electricity to irrigation works and land development, T. ROOKE (*Jour. and Proc. Roy. Soc. N. S. Wales, Engin. Sect., 37 (1903), pp. XCII–CII*).—The possibilities of the application of electricity in irrigation are discussed, examples of successful use being cited.

Irrigation, R. LUNA (*Heraldo Agr., 4 (1904), No. 12, pp. 10, 11; 5 (1905), Nos. 1, pp. 17, 18, fig. 1; 2, pp. 9, 10, figs. 2; 3, p. 9, fig. 1; 4, pp. 19, 20*).—Notes are given on irrigation in Mexico and other countries.

Filtration of public water supplies, R. W. PRATT (*Ohio Sanit. Bul., 10 (1905), No. 1–3, pp. 65–76*).—Various methods which have been used for this purpose are discussed.

Sewage disposal, G. A. JOHNSON (*Ohio Sanit. Bul., 10 (1905), No. 1–3, pp. 23–38*).—This article contains statements regarding the number and size of sewage purification works in Ohio, the reasons for sewage purification, methods of sewage disposal, including dilution, broad irrigation and sewage farming, intermittent sand filtration, treatment of sewage in coarse-grain beds, and notes on preparatory treatment of sewage and disposal of sludge. The Columbus sewage testing station and the methods used there are described in some detail.

The septic tank for the disposal of sewage, F. T. SHUTT (*Canada Expt. Farms Rpts. 1904, pp. 194–197, fig. 1*).—This system of sewage disposal is described and its installation is explained.

Land disposal of garbage: An opportunity for engineers and contractors (*Engin. News, 53 (1905), No. 14, pp. 367–369*).—The successful experience of the city of St. Louis in disposing of garbage by burial on agricultural lands is described, and the system is commended on account of its simplicity and efficiency. "From the economic point of view, it saves from destruction all the fertilizing elements in the garbage, and would enable barren sandy wastes to be converted into market gardens."

Eleventh annual report of the commissioner of public roads for the year ending October 31, 1904, H. I. BUDD (*Paterson, N. J.: News Printing Co., 1905, pp. 220, pls. 39*).—This report includes statements regarding costs of roads constructed in New Jersey during the year; descriptions of the improved roads; an account of the New Jersey good roads exhibit at the St. Louis Exposition; articles on oiled roads, road maintenance, permanence of roads, meadow roads, bitulithic pavement, and facts and fallacies of road construction and repair; a list of quarries and gravel pits in the State; and appendixes containing forms of specifications, etc., and the text of the State road law approved April 1, 1903, with regulations adopted in accordance with this law.

The campaign for good roads (*Wallaces' Farmer, 30 (1905), No. 15, pp. 544, 545, figs. 11*).—This is in large part a description of King's method of keeping roads in condition by dragging.

Road improvement in South Carolina, P. T. BRODIE (*Clemson Agr. Col. Ext. Work, 1 (1905), No. 1, pp. 18–43, figs. 11*).—A general discussion of this subject illustrated by local examples of road construction, particularly the object lesson road constructed at Clemson Agricultural College.

Practical road building in Madison County, Tennessee, S. C. LANCASTER (*U. S. Dept. Agr. Yearbook 1904, pp. 323–340, pls. 5, figs. 5*).—"The purpose of this article is to give the plain facts relating to the construction, cost, and maintenance of first-class stone roads in a county of west Tennessee, where it was necessary to transport all material by rail; and in order that the reader may be able to comprehend these facts more fully, a few statistics are given regarding area, population, taxable values, etc."

Road building in the far North, C. W. PURINGTON (*Engin. and Min. Jour., 78 (1904), Nos. 21, pp. 828, 829, figs. 4; 22, pp. 869–871, figs. 4*).—Road building in Alaska and the Yukon Territory of Canada is discussed, and work undertaken is described.

A treatise on concrete, plain and reinforced, F. W. TAYLOR and S. E. THOMPSON (*New York: John Wiley & Sons; London: Chapman & Hall, Ltd., 1905, pp. XXXV+585, figs. 176*).

Reinforced concrete (*New York: Engin. News Pub. Co., 1904, pp. X+434, figs. 311*).—Part 1 of this volume deals with Methods of Calculation, by A. W. Buel, and parts 2 and 3 Representative Structures, and Methods of Construction, by C. S. Hill.

The modern asphalt pavement, C. RICHARDSON (*New York: John Wiley & Sons; London: Chapman & Hall, Ltd., 1905, pp. VII+580, figs. 32*).

Lime, cement, and gypsum: Their preparation and use for building, technical, and agricultural purposes, R. TORMIN (*Kalk, Zement und Gips, ihre Bereitung und Anwendung zu bauliche, gewerbliche, und landwirtchaftliche Zwecken. Leipsic: B. F. Voigt, 1905, pp. VIII+188*).

Automobiles and agriculture, FINK (*Deut. Landw. Presse, 32 (1905), No. 29, pp. 254, 255, figs. 5*).

The use of the windmill in draining soils, J. FARCY (*Jour. Agr. Prat., n. ser., 9 (1905), No. 4, pp. 117-122, figs. 4*).

The Griffin mill, F. KRULL (*Ztschr. Angew. Chem., 18 (1905), No. 4, pp. 137-139, fig. 1*).—The construction and operation of this mill are described. The essential feature of the mill is a rotating pestle.

Silo construction, G. N. KNAPP (*Wisconsin Sta. Bul. 125, pp. 92, figs. 44*).—This bulletin describes in detail, with numerous illustrations, the construction of the 7 distinct types of silos in general use in Wisconsin, viz, the King, Gurler, stave, Minneapolis, Christensen, stone, and brick silos. The bulletin deals chiefly with problems in silo construction, but considers such questions as how to fill the silo, how to take silage out, how to prevent freezing, what crop to use for silage, what machinery to use to fill silo, etc., in so far as they have a direct bearing on these problems.

Modern silage methods, T. CHERRY (*Jour. Dept. Agr. Victoria, 3 (1905), No. 1, pp. 29-40, pls. 3, fig. 1*).—This is an illustrated description of methods of building silos, particularly the overground silo, and of machinery and methods used in filling the silo, with brief notes on silage crops and the value of silage as a feeding stuff.

The construction of pigsties (*Bd. Agr. and Fisheries [London], Leaflet 121, pp. 5*).

The evolution of the plow, T. H. FOSTER (*Transvaal Agr. Jour., 3 (1905), No. 10, pp. 232-236*).—A brief history of the development of the plow.

Grading of the experimental plats at the Hawkesbury Agricultural College, C. POTTS (*Agr. Gaz. N. S. Wales, 16 (1905), No. 3, pp. 278-285, figs. 10*).—The methods and implements used in this work are fully described.

An implement for the simultaneous plowing under of manures and subsoiling, E. BIPPART (*Deut. Landw. Presse, 32 (1905), No. 26, pp. 231, 232, fig. 1*).—An implement which plows under manure to a shallow depth and at the same time breaks up the subsoil is described.

Lightning report, J. B. REYNOLDS (*Ann. Rpt. Ontario Agr. Col. and Expt. Farm, 30 (1904), pp. 23-25*).—A record is given of damage done by lightning to trees of various kinds, animals, and farm buildings during the 4 years 1901-1904. An analysis of the figures shows strong presumptive evidence as to the efficiency of planting trees about farm buildings as a means of protection from lightning. "The planting of trees, such as spruce, elm, or maple, near enough to buildings to protect them, but not so near as to endanger them, is strongly recommended. The trees should be planted at such distance that when full grown their branches will not touch the buildings."

AGRICULTURAL EDUCATION.

Industrial education in schools for rural communities, L. D. HARVEY ET AL. (*Winona, Minn.: Nat. Ed. Assoc., 1905, pp. 92*).—This is a report presented at the meeting of the National Educational Association at Asbury Park, July 3, 1905, by a committee appointed at the Boston meeting of the association in 1903, to investigate and report to the association conclusions as to what should be undertaken in the field of industrial education in schools for rural communities. The members of the committee, which has been continued, are L. D. Harvey, of Wisconsin, chairman; L. H. Bailey, of Cornell University; Alfred Bayliss, of Illinois; W. T. Carrington, of Missouri; and W. M. Hays, of this Department.

The report includes a summary of conclusions regarding industrial education (agriculture, domestic science, and manual training) in rural schools; an argument for such education; a discussion of what in the field of industrial education should be undertaken in rural schools of different grades, namely, one-room rural schools, consolidated schools, rural high schools, and secondary schools of agriculture and domestic economy, with suggestive outlines for courses in nature study and agriculture for elementary and secondary schools, suggestions for eliminating part of the unnecessary work now undertaken in rural schools to make room for industrial subjects and for the training of teachers to give instruction in these subjects, and an account of boys' experiment clubs and other agencies available for cooperation in the development of industrial education.

Information regarding the organization and courses of study of the existing and proposed schools discussed by the committee is given in four appendixes, Appendix A, treating of the Dunn County (Wisconsin) School of Agriculture and Domestic Economy; B, of the Minnesota School of Agriculture; C, of "articulated courses in industrial subjects in the consolidated rural school, the agricultural high school, and the agricultural college, as prepared by W. M. Hays, at the request of the committee;" and D, the syllabus of an elementary course in agriculture, quoted from Circular 60 of this Office.

The general conclusions of the committee are (1) that in existing one-room district schools a limited amount of nature study, elementary agriculture, and hand work for both boys and girls may be undertaken, but that in these schools little can be expected from this work except where enthusiastic and well qualified teachers are in charge; (2) "that in the consolidated school having at least four teachers, one of whom is prepared to teach the elements of agriculture and manual training, and another domestic science, very much more in the field of industrial education may be attempted than in the one-room school, and with far better results;" (3) "that in the township or other distinctively rural high school, and in the village high school attended by a considerable number of pupils from the country" elementary agriculture, domestic science, and other lines of industrial education should be taught by teachers specially prepared for the work; (4) that in view of the success of agricultural or industrial high schools in this country and abroad, such schools should be organized in large numbers in agricultural communities; (5) "that the agricultural colleges and experiment stations have already done much in the formulation of a body of knowledge essential in the field of industrial education, but that more yet remains to be done in putting this body of knowledge into available form for use in elementary and secondary schools, and that effort in this direction should be made a prominent feature in the work of the agricultural colleges of the country;" (6) "that the mastery of such parts of this rapidly developing body of knowledge as is within the capabilities of elementary and secondary school pupils furnishes a mental training unsurpassed in extent and quality by the mastery of any other body of knowledge now regarded as essential in our common school courses and requiring an equal amount of time, and that for utility value it is not equaled by any other

body of knowledge at present acquired through the expenditure of the same amount of time and effort;" (7) that much needs to be done to educate the people in rural communities to see and appreciate the value of industrial education; (8) "that the courses of study in rural schools should be framed with reference to meeting the needs of the children in those communities, and not with reference to preparing a small percentage of these children to enter higher schools whose courses of study are formulated, not to meet the needs of the great majority of those who attend them, but to prepare the remaining small minority to enter some still higher school;" (9) that it is possible and desirable, without detriment to the present school system, to organize for rural people an articulated series of schools from the elementary school to, and including, the agricultural college; (10) that special opportunities and inducements must be offered to teachers to prepare themselves for giving instruction in industrial subjects; (11) that the organization of boys' and girls' clubs, reading courses, granges, and farmers' institutes should be promoted; and (12) that under existing conditions as to the preparation of teachers for this work "any law making mandatory the teaching of the elements of agriculture, manual training, or domestic science in the entire body of rural schools within a State is unwise, in that the lack of correct information and consequent faulty teaching on the part of the great mass of country school-teachers will tend to bring the whole subject into disrepute and cause a reaction which will postpone the proper development of industrial education."

Lady Warwick's farming college for girls, H. SPENDER (*Cent. Mag., 70 (1905), No. 4, pp. 548–553, figs. 4*).—This is a popular account of Lady Warwick's efforts to provide such training for middle class girls in England as will enable them to earn a living from the land.

The school she opened in Reading in 1895 is described as preparing the way for her more commodious farm school at Studley Castle, or Warwick Castle, as it is sometimes called. The latter school was opened in 1901 and has an attendance of about 40 students, who are given both theoretical instruction and practical work in horticulture, dairying, beekeeping, canning, pickling, and other related subjects. The author states that Lady Warwick announces that she will gladly welcome American girls to her school.

Agricultural education in Porto Rico, F. M. PENNOCK (*South. Workman, 34 (1905), No. 8, pp. 433–438, figs. 6*).—The writer, who is director of agriculture in the University of Porto Rico, gives an account of the development of agricultural education in Porto Rico since the close of the Spanish-American War.

The first step in this development was the organization of 19 agricultural schools, 10 of which, owing to failures due largely to lack of trained teachers, have since been discontinued. The remaining 9 schools are now said to be doing successful work. The next step was the organization of the University of Porto Rico, the charter of which provides that an agricultural and mechanical department shall be organized and that this institution shall be the recipient of any funds which the United States Government may appropriate for agricultural and mechanical education under the provisions of the Morrill Act, in case its benefits are extended to Porto Rico.

A farm of 100 acres has been purchased at Rio Piedras for the agricultural department, and here an agricultural school of secondary grade was started in February, 1905, in connection with the normal school of the university. The students devote the morning hours to practical work in the fields and the afternoon hours to class work at the normal school and the agricultural college.

The annual report of the Boston school-garden committee, 1905 (*Boston, 1905, pp. 7, pls. 2, fig. 1*).—This is a report of progress by the committee which has had charge of school-garden work in Boston for 4 years. Children's gardens have been maintained during the past year in connection with 9 schools, and in numerous places throughout the city not connected with schools.

Outlines of nature studies, W. Lochhead (*Ont. Agr. Col. and Expt. Farm Bul. 142, pp. 48*).—This bulletin is published for the use of teachers, and includes suggestive outlines for nature-study work on a large number of common subjects in plant and animal life, weather, water, and soils. A classified list of helpful books in nature study is appended.

Boys' agricultural clubs, D. J. Crosby (*U. S. Dept. Agr. Yearbook 1904, pp. 489–496, pls. 3*).—The author gives a brief account of the origin and progress of boys' agricultural clubs in Illinois, Ohio, Iowa, and Texas, and comments on the influence of this work upon the boys and the other members of the communities in which such clubs have been organized.

Hints for the guidance of exhibitors at school shows (*Bot. Dept. [Trinidad], Bul. Misc. Inform., 1904, No. 44, pp. 128–131*).—Directions are given for preparing, exhibiting, and judging over 30 different varieties of vegetables and fruits for school shows.

MISCELLANEOUS.

Yearbook of the Department of Agriculture, 1904 (*U. S. Dept. Agr. Yearbook 1904, pp. 776, pls. 76, figs. 64*).—The Yearbook for 1904 has been prepared on the same general plan followed in previous years. It contains a report of the Secretary on the work of the Department during the year, 31 miscellaneous articles noted elsewhere in this issue, and an appendix consisting of a summary of information on various subjects of agricultural interest.

Report of Connecticut State Station, 1904 (*Connecticut State Sta. Rpt. 1904, pt. 5, pp. XV*).—These pages appended to part 5 of the annual report contain the organization list, an announcement concerning the work of the station, a report of the board of control, a financial statement for the year ended September 30, 1904, and a table of contents to the different parts of the report, which have been noted elsewhere.

Experiments at Fort Hays Branch Station, 1902–1904, J. G. Haney and O. H. Elling (*Kansas Sta. Bul. 128, pp. 251–329, pls. 11*).—This includes a history of the branch station and reports and summaries of experiments along several lines which have been conducted during 2 years. The experimental work is noted elsewhere in this issue.

Seventeenth Annual Report of Tennessee Station, 1904 (*Tennessee Sta. Rpt. 1904, pp. 93–107*).—This contains the organization list; brief reports by the president of the university and the botanist, chemist, dairyman, horticulturist, and librarian of the station; a list of the bulletins issued by the station; and a financial statement for the fiscal year ended June 30, 1904.

Experiment Station Work, XXIX (*U. S. Dept. Agr., Farmers' Bul. 225, pp. 32, figs. 6*).—This number includes articles on the following subjects: Injury by smoke and gases, fertilizer mixtures, flint varieties of corn, buying and judging seed corn, tobacco seed, cowpea seed, treating seed oats for smut, potato culture, tomato growing, influence of feed on milk, protecting cows from flies, experiments with turkeys, mineral matter for chickens, brooder house, American Camembert cheese, and swelling in canned peas.

Proceedings of the second annual reunion of the Ohio State Board of Agriculture; the College of Agriculture, Ohio State University; the farmers' institute lectures of Ohio; and the Ohio Agricultural Experiment Station (*Ohio Sta. Bul. 151, pp. 147–194*) —This contains the addresses and discussions on the various subjects considered at the meeting, which was held at the experiment station in June, 1904.

Consumers' fancies, G. K Holmes (*U. S. Dept. Agr. Yearbook 1904, pp. 417–434*).—The author mentions various whims or fancies of consumers in the purchase of butter, cheese, fruits, meats, and other products. As an illustration, it is mentioned

that for city trade the appearance of an apple is of much more importance than quality. It is believed that farmers should learn the whims and fancies of the markets and endeavor to meet those fancies.

An agricultural tour in British Columbia, F. T. SHUTT (*Canada Expt. Farms Rpts. 1904, pp. 197–203*).—Notes are given on the more important agricultural districts visited by the author in May and June, 1904.

Agricultural development in Argentina, F. W. BICKNELL (*U. S. Dept. Agr. Yearbook 1904, pp. 271–286, pls. 4*).—This is a description of the progress being made along agricultural lines in Argentina.

Agricultural conditions in Argentina, C. D. GIROLA (*An. Min. Agr. Argentina, Secc. Agr. (Agron.), 1 (1904), No. 1, pp. 407, pls. 6, map 1*).—Results of studies with reference to the different crops produced in each of the provinces of the country, together with the various agricultural industries, transportation, ports, markets, colonization, immigration, capital, and credit are presented. The publication discusses in particular the cereals, fruits, forage plants, species of forest trees, oil-producing plants, textile crops, dye plants, and plant diseases.

Agricultural conditions in the Province of Entre Rios, Argentina, E. S. RAÑA (*An. Min. Agr. Argentina, Secc. Agr. (Agron.), 1 (1904), No. 4, pp. 326, figs. 59, maps 7*).—Agricultural conditions in general, and the culture of wheat, flax, corn, forage plants, peanuts, and miscellaneous crops are described. Statistics with reference to agricultural production in the province, and estimates of the cost of producing different crops are given.

State publications on agriculture, C. H. GREATHOUSE (*U. S. Dept. Agr. Yearbook 1904, pp. 521–526*).—This deals with State publications other than those of the experiment stations. Some of the more important series of publications are enumerated and notes are given on the nature of the reports and the distribution of the publications.

Accessions to the Department Library, January–March, 1905 (*U. S. Dept. Agr., Library Bul. 54, pp. 59*).

NOTES.

Arizona Station.—A. E. Vinson has been appointed associate chemist to succeed H. B. Slade, who died in the spring.

Colorado College and Station.—J. A. McLean, a recent graduate of Iowa State College, has been appointed assistant in animal husbandry, vice C. J. Griffith, resigned.

Connecticut State Station.—B. F. Walden has entered the service of the station as assistant to the entomologist, and J. L. Kreider and Edward J. Shanley, assistants in chemistry.

Connecticut Storrs Station.—Arthur W. Dox has been appointed chemist in connection with the cheese investigations which are being conducted in cooperation with the Dairy Division of this Department. A flock of 65 Maltese milch goats, imported by the Bureau of Animal Industry, have been received at the station, where they will be used in experiments in the breeding, feeding, and care of milch goats, in cooperation between the station and the Bureau.

Florida Station.—F. M. Rolfs, botanist and horticulturist, has resigned to accept a position at the Missouri Fruit Station. H. S. Fawcett succeeds F. C. Reimer, resigned, as assistant botanist and horticulturist, and Leonard Haseman has become assistant in zoology and entomology.

Hawaiian Sugar Planters' Station.—This station has recently organized a division of pathology and physiology under the directorship of N. A. Cobb, late pathologist for the department of agriculture of New South Wales. L. Lewton-Brain, late mycologist and agricultural lecturer of the Imperial Department of Agriculture for the West Indies, is assistant director of the new division, and E. M. Grosse assistant. W. E. Chambers, late of the *Agricultural Gazette of New South Wales*, has been appointed general illustrator for experiment station publications.

Idaho Station.—The department of entomology has been discontinued, and the work in that line placed in the hands of the plant pathologist, L. F. Henderson. J. S. Burd, station chemist, has resigned to pursue postgraduate work at Yale University.

Indiana Station.—G. I. Christie, recently of the Iowa Station, has been appointed assistant in the agricultural department, to take part in the extension work in agronomy under the recent State appropriation; and W. A. Cochel, of the Missouri Agricultural College, has been appointed assistant in animal husbandry, also in the State work. R. A. Craig has been appointed veterinarian, vice A. W. Bitting, resigned. H. E. Van Norman has resigned to accept a position in the Pennsylvania State College.

Iowa Station.—E. B. Watson has succeeded G. I. Christie as assistant in soils.

Kentucky College and Station.—The trustees of the college have recently created the position of assistant professor of agriculture and animal husbandry, and have elected J. J. Hooper to the position. Mr. Hooper is a graduate of the Texas Agricultural College and for the past two years has been taking postgraduate work at

the Iowa State College. G. N. Keller, assistant entomologist and botanist, has resigned his position and is now connected with the department of agriculture of Ireland, assisting in housing and curing tobacco.

Louisiana University.—E. L. Jordon, of Madison, Wisconsin, has been elected assistant professor of agriculture, and entered upon his duties with the beginning of the college year.

Maryland College and Station.—B. E. Porter, a graduate of the Iowa State College, has been appointed instructor in animal husbandry. S. B. Shaw, assistant horticulturist in the station, has resigned to accept a position with the Baltimore and Ohio Railroad.

Massachusetts Station.—Albert Parsons, assistant chemist, has resigned to accept a position as assistant superintendent of the Hood Farm, at Lowell, Mass. He is succeeded by F. G. Helyar, of the University of Vermont. Joseph G. Cook, assistant in feeds and feeding, has resigned to become superintendent of a large dairy and vegetable farm in the vicinity of Boston, and is succeeded by R. F. Gaskill, a recent graduate of the college dairy course. E. S. Fulton, assistant chemist, has accepted an appointment in connection with the nutrition investigations at Middletown, Conn., and is succeeded by A. C. Whittier, of the University of Maine.

Michigan College and Station.—Horace W. Norton, assistant in animal husbandry, has resigned to engage in dairy farming at Howell, Michigan.

Minnesota University.—William Robertson, instructor in agricultural physics in the school of agriculture, has been appointed superintendent of the substation at Crookston. He will also have charge of organizing the new agricultural school to be built at that place, provision for which was made by the last legislature.

Missouri University and Station.—Dean and Director H. J. Waters, J. W. Connaway, and C. H. Eckles, who spent last year in Europe on leave of absence, have returned and resumed their respective duties. President R. H. Jesse, B. M. Duggar, and W. L. Howard have been granted leave of absence and will spend the year in study in Europe.

Montana College and Station.—E. P. Tannatt has been appointed professor of civil engineering in the college and irrigation engineer in the station.

Nebraska Station.—George R. Chatburn has been added to the station staff as highway engineer.

Nevada University and Station.—President J. E. Stubbs will be absent on leave for six months, beginning November 1. Dean N. E. Wilson will act as president and director during his absence.

North Carolina Station.—Franklin Sherman, jr., has resigned his position as State entomologist to accept the chair of entomology and zoology in the Ontario Agricultural College. R. S. Woglum, a graduate of Cornell University, has been appointed assistant State entomologist. G. M. MacNider and W. G. Haywood have been added to the station staff as assistant chemists. The State department of agriculture has located a branch station for the fruit and trucking interests at Willard, in Pender County.

Ohio Station.—O. E. Bradfute, president of the board of control, has been transferred by the Governor to the board of trustees of the Ohio State University, and John Courtwright, of Ashville, appointed in his place, D. L. Sampson being elected president of the board. B. E. Carmichael, a graduate of the University of Illinois, has been appointed chief in animal husbandry. The station's exhibits at the Ohio State Fair are attracting more and more attention each year. This year the fair management assigned to the station 2,000 sq. ft. of floor space, which was all occupied, and was constantly crowded with visitors. The station has also made exhibits at several county fairs.

Pennsylvania Station.—Percy W. Flint, of Charleston, South Carolina, has been appointed assistant chemist, vice Arthur W. Clark, resigned.

Rhode Island Station.—M. A. Blake, assistant horticulturist, has resigned to accept a similar position at the Massachusetts Agricultural College, vice George O. Greene, resigned.

Tennessee Station.—The station forces have just finished, in cooperation with the commissioner of agriculture of the State, a campaign of farmers' institute work in western Tennessee. In the general educational campaign now being conducted in east Tennessee, the director has been making addresses upon agricultural education. A new silo and a modern manure shed with cement floors have been constructed for experimental work. The botanical department has undertaken an investigation of so-called clover-sickness in the State. A number of fungus diseases have been found, and what appears to be the chief cause of the trouble is assigned to a new anthracnose, caused by an apparently undescribed species of Colletotrichum.

Texas College.—H. H. Harrington, for many years professor of chemistry in the college and chemist to the station, has been elected to succeed D. H. Houston as president of the college. Dr. Houston has, as previously noted, gone to the State University as president of that institution.

Utah College and Station.—The shops of the mechanic arts department of the college were almost totally consumed by fire on the night of September 11. The fire was apparently of incendiary origin. The bench rooms, planer and lathe room, forge room, foundry and carriage rooms, with all their contents, were almost complete losses. Some valuable testing machines in the mechanical engineering laboratory were saved. The total loss is estimated at $40,000, with an insurance amounting to $7,100. It is expected that the shops will be speedily rebuilt and reequipped. J. Willard Bolte, of the Michigan Agricultural College, has been appointed poultryman in the station.

The Agricultural Colleges.—The following is taken from *The Breeder's Gazette:* "Practically without exception American agricultural colleges recently opened their fall terms with increased attendance. In some instances the enrollment has been almost doubled. Altogether the increase has been marked, indicating wonderful growth and distribution of interest in agricultural education. It is a good token. Nothing is more significant as showing the trend of the times. It requires but ordinary mental penetration to see the day when the largest success in agriculture as a business will depend upon technical training and commercial sagacity. The colleges ought to be overflowing, every one of them. Their mission is to shape the destiny of agriculture, and hence of the nation, through their students. Their responsibility is tremendous, but they are equal to it. What they have accomplished within a few years, in the face of a disappearing prejudice, is a trustworthy earnest of great service in future."

Manitoba College of Agriculture.—Buildings are being erected for a new college of agriculture for Manitoba, established by a recent session of the provincial legislature, which appropriated $200,000 for the purpose. The college is located at Winnipeg, and its principal is W. J. Black, a graduate of the Ontario Agricultural College, who will have charge of the work in animal husbandry. The principal buildings consist of a main building, 131 ft. long by 67 ft. wide, and 3 stories in height above a high basement; and a science and dairy building, 64 by 66 ft., and 2 stories in height above a high basement.

The main building is of stone and white brick, and the science and dairy building of brick with a stone foundation. The main building, in addition to providing laboratories, class rooms, a library, and an auditorium with a seating capacity of upward of 500, will afford temporary accommodations for about 60 students, the intention being to erect a dormitory building when the increase in attendance warrants. The basement and first floor of the science and dairy building will be used for butter and cheese making, milk testing, home dairying, etc., and the upper floor for laboratory and class room purposes.

In addition to these two buildings, a power house, principal's residence, live-stock auditorium, and horse and cattle barns are being provided. The horse and cattle barns are of modern design, and the live-stock auditorium, which connects them, will afford seating capacity for about 300. The college farm consists of 117 acres, and is immediately outside the city limits of Winnipeg, on the Assiniboine River. The college buildings are located on the banks of this stream, about 4 miles from the center of the city. A part of the farm will be used for experimental work in agriculture, horticulture, and forestry.

The regular college course will extend over two years, and will open immediately after the fall work on Manitoba farms has been completed, and close in time to allow students to reach home before the spring work begins. There will be no rigid entrance examinations, the main requirement being sufficient knowledge of the English language to benefit by the lectures, and practical experience upon a farm covering at least two summers. A tuition fee of $10 per annum will be charged, and board will be furnished at actual cost. There will be special dairy courses in butter and cheese making, to cover from 10 to 14 weeks. "The college in its teaching will be practical in the highest possible degree. It will train practical farmers, not educate them along lines calculated to lead young men from the farm."

It was expected to open the college to students in the regular course in January, but owing to the delay in building, this has been abandoned. It is planned, however, to carry on the dairy school and to offer short courses in animal husbandry and agronomy. W. J. Carson has been elected professor of dairying.

Agricultural High School in Kansas.—A four-year agricultural course is offered this fall in the Norton County High School, at Norton, Kans. The course of study will follow closely the outline suggested by the committee on methods of teaching agriculture in its ninth report (Circ. 60 of this Office), and it is planned to lay especial emphasis upon farm crops, animal production, and farm machinery, all of which are items of great importance in farm practice in Norton County.

Arrangements have been made with the three implement dealers of Norton to assist the teacher of agriculture in giving courses in farm machinery, by taking the agricultural classes into their warehouses under the direction of an expert, who will instruct them in the structure, manipulation, and care of the different machines. It is planned also to take the classes on numerous trips to leading farms in the vicinity of the school to study farm management, domestic animals, and types of farm buildings.

The course is in charge of A. F. Turner, a graduate of the Kansas Agricultural College. It starts out with an enrollment of 9 boys out of a total of 70, and Mr. Turner writes that most of the first-year boys will take up agriculture when they get to it in the course. Arrangements are being made for a grain-judging contest to be held in January, which will be open to all young men in the county. The implement dealers of Norton have offered prizes of farm machinery aggregating in value over $100 for this contest.

A Centralized Agricultural School.—Farragut School, located near Concord, Tenn., is a centralized school comprising within its territory most of the area of three former school districts. It was opened in September, 1904, and its first year was a successful one. The school is supported jointly by the Southern Education Board, which has contributed about $3,500, the State tax levy for the salaries of teachers, and local contributions. The funds thus raised, exclusive of teachers' wages, amount to $8,000, of which $6,000 was expended for a school building and equipment. The building is 54 by 80 ft., 2 stories high, and contains 6 well-lighted schoolrooms and a large assembly room. One of the abandoned schoolhouses has been moved to the site of the new building and is used for domestic science and manual training class rooms.

A small poultry house with incubator and brooder, a two-frame hotbed, and a shed for horses comprise the major portion of the farm equipment. The school has

12½ acres of land, 3 of which are used for horticulture, 6 for farm crops, and the remaining 3½ acres for campus and farmyard. It is the plan to make this a model rural school in which agriculture, domestic science, and manual training shall be leading features. There are at present 5 teachers, including the superintendent and the teacher of agriculture, the latter a graduate of the University of Tennessee. The school is under the control of a local board of 9 members.

Agriculture in New Missouri Normal Schools.—Two new normal schools are to be established in Missouri next year, each to have, among others, an industrial department, in which instruction will be given in agriculture, horticulture, domestic art, domestic science, and manual training and drawing. One-third of the time of each student will be devoted for two years to preparation for teaching industrial subjects in the rural and village schools.

Agriculture in Wisconsin Public Schools.—According to a recent note in the *Journal of Education*, Wisconsin now requires the elements of agriculture to be taught in every rural school in the State, and no diploma can be issued to any pupil graduating from a rural school unless he has had instruction in agriculture.

Agriculture at the College of Science, Poonah, India.—The following facts regarding agricultural instruction in this institution are furnished by Prof. J. B. Knight, a graduate of the Massachusetts Agricultural College and at present professor of agriculture in the college at Poonah. It appears that the College of Science was originally a college of engineering, but in 1879 provision was made for a class in agriculture and forestry and 72 acres of land for a college farm were bought. In 1884 an herbarium and a botanical garden were added, and in 1885 a chemical laboratory.

Two years later a veterinary hospital and operating rooms were provided, and in 1890 graduates from the agricultural class were given a diploma in agriculture. A lecturer in agricultural chemistry was appointed in 1898, and the following year the standard of the agricultural work was raised and the degree changed to licentiate of agriculture. The course given at present covers 3 years and includes theoretical instruction in agriculture, agricultural chemistry, botany, veterinary science, etc. There are at present 77 students taking the agricultural work, by far the larger proportion being first-year men.

Agricultural Instruction in the Transvaal.—According to the last annual report of the Transvaal Department of Agriculture, there is no agricultural school in that country, but the Transvaal Technical Institute has recently been established, and it is expected that this will form the nucleus of a future university, which will include a college of agriculture. In the meantime some instruction in agriculture is provided by making arrangements to receive students or apprentices at the veterinary experiment station and the different government laboratories, experiment farms, fruit gardens, poultry yards, etc. School gardens are maintained in connection with most of the schools in the Marico and North Lichtenburg districts.

Agricultural Schools in the West Indies.—The agricultural schools conducted under the Imperial Department of Agriculture for the West Indies, which are now in operation in St. Lucia, St. Vincent, and Dominica, were established for the special purpose of affording practical training in agriculture to a selected number of boys of about 15 years of age who have passed the fourth standard in the public schools. After passing a probationary period of 3 months, boys are formally admitted into the schools on an agreement being signed by their parents or guardians to allow the boys to remain undisturbed at the school for a period of 3 or 4 years, during which time they not only receive free instruction but are lodged, boarded, and clothed free of expense to their parents.

Winter Schools in the Rhine Province.—There are now 31 winter schools under the control of the Rhine Province Chamber of Agriculture, 4 of which last year completed their twenty-fifth year. At that time the total attendance at the winter schools

had been 11,467 pupils, 3,993 of whom had attended 2 winter terms. A feature of these schools is the variety of special courses, which include horticulture, the utilization of fruit, vine culture, bee culture, feeding, fertilizers, bookkeeping, and domestic economy.

Algerian School of Agriculture.—A school of agriculture with a farm school attached has been organized at Maison-Carrée, which it was expected to open to students on October 9. The number of students is limited to 25, and these will be chosen from candidates 17 years old or older who pass satisfactory examinations in mathematics, chemistry, and natural science.

An Agricultural School in Turkey.—The *Southern Workman* records the organization of the Thessalonica Agricultural and Industrial Institute at Salonica, Turkey, under the control of an undenominational board of 12 directors, incorporated under the laws of the State of New York. The school is on a 52-acre farm, 5 miles from Salonica, and has been in operation about a year and a half. Its work is similar to that of the Hampton and Tuskegee institutes.

Experiment Station Apprentices in Ireland.—The Department of Agriculture and Technical Instruction for Ireland has recently opened three experiment stations located respectively at Clonakilty, County Cork; Ballyhaise, County Cavan, and Athenry, County Galway. In addition to conducting experiments in animal husbandry, dairying, and other branches of agriculture, these stations will admit a limited number of young men as apprentices. These apprentices will be given practical instruction in the work of the farm, shop, and garden, as well as class-room instruction in English, arithmetic, bookkeeping, and technical agriculture in the evenings, and at other times when outdoor work is not pressing. There is a sliding scale of fees ranging from $15 to $16 per session, based on the aggregate valuation of the holdings of the parents of the apprentices.

New Experiment Station in South Australia.—The government of South Australia has set apart 1,000 acres of the Kybybolite Estate, in the southeastern part of the colony, for an experiment station under the control of the Department of Agriculture. The climate at this place is much more humid than at Roseworthy, and a greater variety of crops can therefore be tested. Provision has been made for accepting farm pupils at Kybybolite, who will have an opportunity to take lectures under the professor of agriculture of the Roseworthy Agricultural College.

New Board of Agriculture in India.—The Government of India has recently constituted a board of agriculture, the duties of which are the improvement of agricultural methods by the introduction of better quality of seed grains and roots, by the adoption of up-to-date machinery and implements, by experimenting with soils and fertilizers, and by the study of plant diseases and economic insects. "The board has also under consideration a system of agricultural tuition, with a view to a distribution throughout the country of men trained in the science of the subject." It has been decided to publish a quarterly journal on agricultural subjects, and also to issue separate scientific publications.

New Fertilizer Law in Porto Rico.—The legislative assembly of Porto Rico at its last session passed an act to regulate the registration and inspection of commercial fertilizers, fertilizer materials, and chemicals in Porto Rico, to take effect July 1, 1905. The Commissioner of the Interior is charged with the inspection, and all dealers in fertilizers are required to register their goods with the commissioner, to pay an inspection fee of 25 cents per ton, and to secure from the commissioner tags to be attached to each package setting forth the name of the fertilizer, the name and address of the manufacturer, and guaranteed analysis, including minimum percentages only of available phosphoric acid, nitrogen, and potash. Pulverized leather, raw, steamed, roasted, or in any other form, is barred from use in fertilizers without a full and explicit statement of the fact. Violation of the provisions of the act will be considered a misdemeanor, the penalty on conviction being a fine of not less than

$200 nor more than $500, or imprisonment not to exceed six months in default of payment.

Meeting of Agricultural Implement Manufacturers.—The Twelfth Annual Convention of the National Association of Agricultural Implement and Vehicle Manufacturers, held at Niagara Falls, New York, September 27–29, was a meeting of general interest to American farmers, both because farm machinery is one of the most vital factors in the success of American agriculture and because of the interest which the Association showed at the meeting in methods for the further perfection of its products so as to make them more effectively do the work of the American farm. About 250 members were present. The sessions were well attended, and the reports of the different committees show that the Association, as a whole, is doing much practical work for its members. Among the reports was one from the attorney of the Association, the committees on transportation, legislation, patents, and a lengthy and interesting report on irrigation in arid lands.

On the first day of the session Judge Grosscup, of Chicago, delivered an able address on The Transportation Problem. A representative of the International Harvester Co. also presented a paper on The Necessity for Tax-Free Alcohol for Industrial Purposes.

The literary feature of the second day's session, September 28, was a series of papers by representatives of the Department of Agriculture and the agricultural colleges, the gentlemen submitting papers having been invited by the Association to explain the work done by these agencies to secure the improvement and better use of farm machinery. The first of these addresses was on Practical Farm Mechanics, by Prof. J. W. Gilmore, professor of farm mechanics at Cornell University. This paper dealt with the methods of teaching farm mechanics at Cornell, and explained some of the investigations which that institution is making of farm machinery. Dr. Elwood Mead, Chief of Irrigation and Drainage Investigations of this Office, read a paper on The Applications of Power to Farm Work, showing the importance of a proper adjustment of machines to the power which operates them and the strength of the man that controls them. It also called attention to the evolution now taking place in farm machinery, in which steam, gas, wind, and electricity are displacing both man and animals in operating. Prof. C. J. Zintheo, who has charge of the investigations of farm machinery in this Office, explained some of the studies now being made by the Office, paying especial attention to the work being done to determine the value of denaturized alcohol and of wind as power agents in the operation of farm machinery. Prof. G. N. Knapp, professor of agricultural engineering in the University of Wisconsin, was present and participated in the discussion.

The work of the Agricultural Department and of the various stations which have taken up studies of farm machinery was warmly commended in the discussions of the convention, and the following resolutions were unanimously adopted by the association:

Resolved, That we indorse and commend the agricultural engineering investigations of the United States Department of Agriculture, and believe their extension will benefit both the users and makers of farm machinery.

Resolved, That a committee of three be appointed by the president to confer and advise with the proper governmental authorities about the conduct and extension of these investigations.

We also recommend as a feature of these investigations the establishment of a laboratory and museum for testing and illustration of principles in farm mechanics.

Resolved, That we indorse and commend the teaching of farm mechanics and agricultural engineering in the various agricultural and other colleges, and that we pledge to all of this work our cooperation and support.

Mr. H. E. Miles, of Racine, Wisconsin; Mr. J. Butterworth, of Moline, Illinois; and Mr. Newell Sanders, of Chattanooga, Tennessee, were appointed as a committee

to confer with the U. S. Department of Agriculture on the conduct and extension of investigations of farm implements and machinery.

Suggestions were made by manufacturers that at least half of the men sent abroad to foreign countries by the Bureau of Commerce and Labor, to study the requirements of American commerce, should have a knowledge of farm implements and agricultural practice, as farm implements represent one of the largest lines of American exports. These men should study soils and farm crop conditions, in order that they might report intelligently the character of farm implements which would meet the demands of different localities.

The convention adjourned on the 28th, and on the 29th, at the invitation of Canadian manufacturers, they took a trip to Hamilton, Ontario, where they visited the International Harvester Company's factory, and to Toronto, where a banquet was given in their honor. On the latter occasion addresses on commercial relations and reciprocity were made by prominent men from both the Canadian and American Manufacturers' Associations.

Personal Mention.—Dr. D. E. Salmon, for twenty-one years Chief of the Bureau of Animal Industry of this Department, resigned his position, to take effect October 1.

J. B. Dandeno, assistant professor of botany at the Michigan Agricultural College, and S. F. Edwards, instructor in bacteriology in the same institution, have been appointed to the chairs of botany and bacteriology, respectively, in the Ontario Agricultural College at Guelph.

C. W. Howard, a graduate of Cornell University, and for the past year laboratory assistant in entomology, has been appointed assistant entomologist under the Transvaal Government. The entomologist is C. B. Simpson, also a graduate of Cornell University.

George L. Clothier, formerly of the Forest Service of this Department, has become instructor in forestry in the Mississippi College, a new department having been recently established in that institution. In addition to his instruction in the college, he will carry on propaganda work in forestry in the State, and will conduct some special studies of forest problems in cooperation with the Forest Service.

A press notice states that Don Enrique Fynn, an agricultural engineer of some prominence in South America, has been appointed chief of the division of agriculture in the Argentina Government, which undertakes to provide instruction for farmers and others interested in agriculture, and to generally stimulate efforts for agricultural improvement and development.

Prof. Julius Kühn, of Halle, widely known for his agricultural writings, especially upon feeding animals, celebrated his eightieth birthday October 23.

Dr. H. Fischer has been appointed director of the bacteriological station in the agricultural high school at Berlin.

Prof. W. Hoffmeister, director of the experiment station at Insterburg, Germany, retired October 1. He is succeeded by Dr. W. Zieldorff, chemist of the Hohenheim station.

Miscellaneous.—The late Major Henry E. Alvord bequeathed to the Massachusetts Agricultural College a large collection of agricultural books, pictures, and museum articles. He also left a bequest of "not less than $4,000 nor more than $5,000, preferably the latter," to found a scholarship to be known as the Alvord Dairy Scholarship. The income of this fund is "to be applied to the support of any worthy student at said college, graduate or postgraduate, who may be making a specialty of the study of dairy husbandry (broadly considered) with intentions of becoming an investigator, teacher, or special practitioner in connection with the dairy industry." The bequest is subject to the life interest of Mrs. Alvord.

The Geological Survey of Ireland has recently been transferred from the charge of the board of education to the department of agriculture and technical instruction. In connection with an article on the transference, by Grenville A. J. Cole, describing the survey's work and published in the department's journal, it is mentioned that a laboratory for the examination of soils was established in Belfast in 1837 as a part of the geological survey, and a soil survey projected. "The scheme was unfortunately regarded by the authorities as either immaterial or inopportune, and it was left for Germany, the United States, Japan, and other nations to develop agricultural geology as a branch of organized research." In connection with the accounts of recent drift surveys, chapters on the soils have been included, and now that the geological survey has been transferred to the department of agriculture it is suggested that these drift surveys will be supplemented by the preparation of soil maps for districts of special agricultural interest.

It is learned from *Nature* that the late John Innes, of Merton, Surrey, left his house, the Manor Farm, and two acres of ground, to establish thereon a school of horticulture for giving technical instruction in the science and art of horticulture and the necessary physical and mental training incidental thereto.

It is reported that the Long Island Railroad has located an experimental farm on Long Island, N. Y., to determine the possibilities of bringing the land into productive condition. The land is overgrown with scrub oak and pine, and is typical of large tracts which have never been cultivated, although lying at the very doors of a great market.

The University of Melbourne has received a largely increased endowment from the government of Victoria on condition that a degree course in agriculture be established. It is understood that the necessary arrangements for such a course have been completed.

A monument to the late Max Maercker, director of the agricultural experiment station at Halle, was unveiled in Halle October 24.

The name of the Durham College of Science, Newcastle-upon-Tyne, England, has been changed to Armstrong College. The agricultural department of the college remains in charge of Prof. Douglas A. Gilchrist.

The secretary of state for the British Colonies has appointed Gerald Dodgeon to examine and report upon questions relating to the development of the agricultural resources of British West Africa.

O

EXPERIMENT STATION RECORD.

VOL. XVII. NOVEMBER, 1905. No. 3.

The statement has recently been made that scientists often retard the progress of general and industrial science by their impractical views of practical affairs. The idea was not that investigation should be confined to utilitarian lines, or that research in pure science should be restricted—for what is pure science in one connection becomes applied science in another, but rather that in various lines of research more rapid and surer progress would be made if investigators brought to their work more practical knowledge of its economic relations. This appears to be a reasonable deduction, and there is much evidence to bear it out. Granting that all knowledge is useful, its useful aspects must be brought out, and there must be intelligence in its application.

In olden times men of science recognized that to secure support for their investigations they must "disguise their work under a utilitarian cloak." As time has gone on the world has become more sympathetic toward science and less exacting in its demands to be assured of its immediate application. This is a result of education and its broadening influence, which has spread by contact to people of all classes; but nevertheless a large body of people continue to distinguish between what to them is theoretical or pure science, and what is applied science. To such, Doctor Jordan's estimate of the value of science that it "lies in its relation to human conduct," and the value of knowledge that it "lies in the use we can make of it," will come as a vindication of a possibly unformulated conviction. As a matter of fact, institutions of research supported by public funds have gained popular support largely because they succeeded in devising helps in economic and utilitarian affairs.

The public expectations of practical results vary somewhat with the character of the investigation and of the institution. In the case of agricultural investigation the expectations have come to run very high, largely as a result of past experience and the confidence which has been inspired in this line of work. The experiment station is an institution for investigation in science as applied to agriculture. It is regarded as a utilitarian institution. Its purpose is the attainment of

results which will have a direct application to one of our fundamental industries—direct in the sense that the gulf which often intervenes between abstract research and its application will be bridged over.

Definite practical knowledge is at a higher premium than ever before. The scientist who is carrying out investigations is more and more expected to develop the economic relations of his work. While we are more and more patient in awaiting conclusions, we expect that a definite ultimate aim will be kept constantly in view, which centers about some phase of agricultural production. This will constitute the real purpose of the undertaking, and will distinguish it in general character from research in pure science.

Furthermore, the final results and suggestions must not only be practical in their relations, but they must be practicable as well. Certain practices which might be suggested are not practicable because they can not be fitted into farm operations, which have to be governed by certain conditions of first importance.

The ability to see clearly the practical bearings of his work and to make its application is not given to every investigator. There are still some evidences of this in our experiment stations, although as a class our station workers possess this ability in probably a greater degree, and are closer in their contact and relations with agricultural practice, than any similar class of workers in the world. The most successful of them have made a study of the farmer's methods and shown a close sympathy with his needs.

We still need in some directions more of intelligent, well-aimed investigation, which will be started right and pursued with a clear purpose to the very end. Our work in some lines is not carefully enough planned. It is fragmentary and not thorough. It needs systematizing, and to have supervision which will stimulate it while giving general direction. This need is enhanced by the division of the men's time between college and station duties, and the interruptions which come from other causes. It is one of the arguments for a director and for a closer organization.

One of the chief criticisms made upon our experiment station work has been the striving to secure practical applications too rapidly, and not giving time enough for the fundamental research on which these applications must rest. It has been asserted that "the proportion of applied science in agriculture is too great in this country," and that "while we do not need fewer workers in applied agricultural science, we do need more workers who would devote themselves to fundamental research"—with an outlook to practical agriculture, doubtless.

No one will dispute the need of more investigation of a fundamental character. The experiment stations themselves have demonstrated this, and their work has led up to it. Before their advent the limita-

tions of our knowledge of agricultural science were not realized, and the gaps which we now perceive were not apparent. As the work has advanced the problems have become more intricate and the call more imperative for systematic and thorough investigation. To realize its importance we have only to remember how the work upon silage preservation was promoted by the discovery of the real nature and cause of the changes, and the influences governing them. Immediately the way was open for more intelligent understanding of the problems. And in cheese making the fundamental investigations which showed the character of the compounds formed, the nature of the changes, and the influence of conditions clarified the whole subject of manufacture and ripening, and simplified the solution of minor problems.

We are approaching the point in a number of departments of the work where there will be much waste of effort and much delay in reaching the final conclusions unless some classic fundamental investigations can be carried out. To enable this will require some relief from the routine of the class room and the laboratory, and from the various forms of extension work. There is a very perceptible movement to free certain of the station experts from heavy teaching duties, which is already affording some measure of relief; but the demands of the farmers' institute upon the station staff show no general diminution.

Last year the station men in forty-three States and Territories took a prominent part in the institute work. This involved three hundred and sixty men, who devoted to it an aggregate of over twenty-six hundred days. In one State alone the station specialists delivered two hundred and twenty-three addresses at institutes and similar farmers' gatherings. This shows a just appreciation of station men as institute workers. They have a message for the farmers, and are in position to give advice upon a wide range of practical questions. This work has increased in dignity and importance, as the great majority of farmers now go to the institutes to be instructed, and these meetings afford opportunity for the oral presentation of the station's work and results. But important as the relation is, it is becoming more and more evident that to a large extent a separate staff of workers will have to be provided for the institutes.

Too much of our work is done under pressure. This applies not only to the experiments themselves, but to the preparation of matter for publication. This seems inevitable under our present system, and where such a mass of material is published some of it is bound to be immature. But the matter might be much improved by more careful editing and supervision.

The lack of editing impairs the usefulness and effectiveness of these writings, especially in the case of stations where little attention is

evidently paid to the matter. In reviewing publications we are not infrequently misled or in doubt as to some important points, owing to the way in which the matter is presented. The data should be carefully computed and compared, and summaries of the more important results given in the clearest manner. A table is a difficult thing for many people to understand, but the difficulties are greatly enhanced if the table is improperly constructed.

There is often a feeling that the publications must be the complete record of the station's work, and hence publications are loaded down unduly with data which adds to the expense of publication and are of interest to only an occasional reader. Ultimately the station's publications should give the permanent record of their work, as far as the important results and application are concerned; but much, if not most, of the data should be retained in the station's unprinted records.

The question may well be asked whether, considering its real purpose, a bulletin should be published for general distribution until it has a definite message to carry. Bulletins which merely record data are of very doubtful value to the general public, and hence their publication in large editions is an unnecessary expense. We still have meteorological bulletins, although not as many as formerly, which give only a record of the weather conditions, with no possible means of comparing them with the crop conditions of the season, and no attempt to trace any relationship. We likewise have soil temperatures reported without reference to anything else, so that they can be of very little value to anyone except the writer, who presumably has other observations related to them. We have descriptions of flora, though fewer than formerly, which stop just short of the vital point to agriculture; and we have weed studies which give the botanical relationships, distribution, and habits of the plant, but only an imperfect method of eradication or subjection, if indeed an attempt is made in that direction.

In the preparation of matter for popular distribution the point of view of the reader should be kept constantly in mind. In a weed bulletin, for example, unless it be merely a preliminary warning, the vital thing to the farmer is a method for eradication, and he has a right to expect when he picks up a bulletin that this has been studied in a thorough manner, and will be presented to him along with the more technical part in a clear, straightforward way. To nearly eradicate a weed is only to reduce its quantity, and the partial remedy will be only temporary. Furthermore, the farmer is encouraged to believe a halfway method will do. If the plant reproduces by rootstocks, the scattering joints, if allowed to remain, will rapidly produce more rootstocks and seeds and the difficulty will continue, often in more serious form.

Instead of being content with a halfway method the author should endeavor to work out and present a thorough method of eradicating

the pest, even though it involve some added labor on the part of the farmer. If the weed is a sufficiently troublesome pest to command attention it is worth serious study, and the attempt should be to prescribe an effective and practicable method of ridding fields of it.

Unfortunately, not all investigators are good writers. They do not have the ability to present what they report in a logical, orderly sequence, so that one can follow clearly step by step and understand without a partial rereading of the article. This lack of coordination is the most serious editorial fault of our station literature, and the inference from it often is the serious one that the writer has not analyzed his subject and coordinated its different parts. The subject is frequently befogged by bringing a side issue into the discussion, and suggestions often lose their force from the manner in which they are presented. Clearness and simplicity of presentation are of far greater importance than form and style, and are especially desirable in publications intended for popular consumption, like the majority of the station bulletins.

There should be some person connected with each station whose business it is to edit the station publications—to read them critically and see that the text and tables are clear and logical. He may not be a special officer, but he should represent the director in this important function. While this work calls for great tact, a discreet and conscientious editor may exert great influence on the character of the literature of a station. This has been demonstrated at several stations where more attention is given to these matters. The investigator should welcome the editor who can suggest some more effective and attractive form for presenting his ideas.

The text should be edited for fact as well as for clearness, and in this the scrutiny of specialists in a number of lines will often be helpful. It will prevent narrowness, and will make the bulletin the product of the constructive and critical skill of a number of minds. It were well for every station man to regard the publication of his bulletin as the culmination of his work upon the subject up to that point, the product by which his colleagues and the world will judge him. His real interest lies in that which will endure, will serve as a basis for science, or will at once serve an economic end. And the people's real interest is that the economic relations of scientific work be so clearly developed that their application can be made in everyday affairs.

The exercises connected with the installation of Dr. Edmund Janes James as president of the University of Illinois occupied most of the week beginning October 15, and were of an unusually interesting character because of the large number of administrative officers and

professors connected with foreign and American universities and colleges who were in attendance, the variety and scope of the papers read, and the subjects discussed at the meetings held during the week.

The wonderful growth of the university in the past ten years, both in material equipment and in the number of its faculty and students, afforded a splendid demonstration of the possibilities of the development of the institutions founded on the Morrill Acts of 1862 and 1890 and the Hatch Act of 1887, when once the people of a State are thoroughly aroused to the importance of maintaining and extending higher education on a National and State basis. This university is directly the outcome of the National land-grant act of Congress for higher education, and has been maintained wholly by State and National funds.

In 1895 the University of Illinois had four colleges in six buildings, less than fifty members on its faculty, and about six hundred students. In 1905 it has eleven colleges in twenty-five buildings, four hundred and eighty-seven members on its faculty, and nearly four thousand students. In the same period the legislative appropriations have increased from $295,000 to $1,500,000.

Among the subjects most prominently and thoroughly discussed on this occasion were the relations of the State to education in both higher and lower schools, and the best methods of administration for American universities. The functions of the university or college president and the relations of the faculty to the president and board of trustees were most earnestly discussed, and a marked divergence of opinion regarding the authority which the president should possess was brought out. It was evident that while university development in this country in recent years has been in the direction of the centralization of authority in the president, there was a strong feeling in the minds of many of the eminent educators gathered on this occasion that this tendency had gone too far, and that in some ways the boards of trustees and the college faculty should be brought closer together and exert more influence in determining the educational policy of the institution.

In the conference of college and university trustees, the first of its kind held in this country, much attention was given to questions relating to the management of finances and accounting for funds. The desirability of stricter accounting and more intelligible and accurate financial reports was strongly insisted on.

Agriculture as a subject on which has been based one of the main divisions of the university, and which in recent years has fully shared in the general prosperity of the institution, was given full recognition in the programme of the installation exercises. In his inaugural address, in which great stress was laid on the importance of maintaining the courses of instruction in the university on a high grade and

increasing research work, President James used the college of agriculture as an illustration of a university department which had developed so rapidly in number of students that it was evident the day was not far distant when it would be impracticable for the university to care for all the students in agriculture who would come for instruction on the present basis. He was therefore in favor of raising the requirements for entrance to the college of agriculture, and at the same time seeking to provide for the secondary education of thousands of students in special public schools to be established in different parts of the State.

The degree of doctor of agriculture was conferred upon former Secretary of Agriculture Norman J. Colman and Hon. A. H. Sanders, editor of *The Breeders' Gazette*, as distinguished leaders of agricultural progress in this country; and at the assembly of the college of agriculture the services of Doctor Colman to agriculture were set forth in addresses by Col. Chas. F. Mills and the Director of this Office. In the response to these addresses made by Doctor Colman, as well as in the remarks of other speakers, the history of the Hatch Act and the consequent development of agricultural education and research in this country were described in outline. In this way attention was drawn to the fact that the National Government, through its Department of Agriculture and Congress, had been largely instrumental in laying the foundations of our present system of agricultural education and research, and had cooperated with the colleges and stations during all the stages of their development.

Last year the trustees of Cornell University passed a resolution creating what is virtually a board of visitors for the college of agriculture, composed of representatives of the State and district agricultural societies. The trustees invited each of these societies to send a delegate annually, at the expense of the university, to visit the college of agriculture and make an inspection of its work.

In accordance with this provision, delegates from a large number of these societies visited the college early in October of this year. An opening talk was given by President Schurman, and Director Bailey spoke to the delegates on the purpose for which the college farm should be utilized. A tour was made of the farms, laboratories, and other buildings of the college and the experiment station, and the work was described. The delegates formed a permanent organization, called the New York State Committee for the Promotion of Agricultural Education and Research, adopted a constitution, and elected officers. The president of the State Breeders' Association was elected president of the new organization, the president of the State Fruit Growers' Association was elected secretary, and the secretary of the Western New York Horticultural Society, treasurer.

The committee will meet at the college in October each year. The authorities look for very good results from this organization. It is

official and representative. It will bring all the farmers of the State into more intimate knowledge and touch with the work of the college and station, and will help to give the various agricultural organizations an individual interest in the institution. It is a recognition of the relation of the college of agriculture to the farmers of the State, and of the fact that the college to be most effective should understand and appreciate the agricultural needs, problems, and aims of that class of people.

Professor Bailey's remarks to the delegates upon the purpose of the college farm are of interest as representing the prevailing views of agricultural educators upon this point and as showing the gradual evolution of ideas which has taken place. The purpose of the farm in connection with collegiate instruction in agriculture has been a fruitful topic of discussion ever since the establishment of agricultural colleges, and the prevalent notion regarding its relation to instruction has undergone many changes.

Professor Bailey presented abstracts of letters bearing upon this point from deans and professors in some of the leading agricultural colleges. The general consensus of opinion was that the college farm should be looked upon as an outdoor laboratory for instruction in those things which require contact with practical things, rather than as a model farm or one for growing maximum crops or for giving students a large amount of practical training.

"It seems to me," Professor Bailey said, "that we have now come to the final and proper stage or idea, that the college or university farm must be a laboratory. The pattern farm, model farm, commercial farm, and illustration farm are all incidental and secondary to this general purpose. . . . A college farm is a means to an end. The end is the teaching of students; the growing of maximum crops may or may not be the best way of attaining this end. We hope to conduct our farms on the best business principles and in conformity with the very best farm practices; we expect to make them interesting and attractive to students and visitors; nevertheless, the laboratory utilization of these areas is to be our first consideration. If we are not using farms as a means of training men, then we are not using them for pedagogical purposes, and the future will not justify our possession of them."

RECENT WORK IN AGRICULTURAL SCIENCE.

AGRICULTURAL CHEMISTRY.

The determination of phosphoric acid by means of ammonium phosphomolybdate, G. P. Baxter and R. C. Griffin (*Amer. Chem. Jour., 34 (1905), No. 3, pp. 204–217*).—This is a second paper on this subject and deals especially with the nature and amount of the occluded substances in the ammonium phosphomolybdate precipitate.

The results of the investigation confirm the conclusion reached in the previous paper "that it is possible to obtain ammonium phosphomolybdate constant in composition and in a state suitable for weighing, so that it may be used for the accurate estimation of phosphoric acid." The precipitation should be performed at room temperature by pouring the phosphate solution into the molybdic acid. "If the precipitation is performed in the reverse manner the composition of the precipitate varies considerably."

The precipitate is the diammonium salt which when heated to a high temperature with ammonium nitrate is converted almost completely into the triammonium phosphomolybdate. "The ammonium in the precipitate is readily replaced by potassium, in the presence of a high concentration of potassium salts, but the reverse change takes place if the potassium phosphomolybdate is then treated with concentrated ammonium salts." It was found that the precipitate occludes varying amounts of both molybdic acid and ammounium molybdate, according to the conditions of precipitation.

The Pemberton method of determining phosphoric acid by titration of ammonium phosphomolybdate with standard potassium hydroxid is condemned as inaccurate because (1) the precipitate occludes varying amounts of molybdic acid; (2) 24 molecules of alkali are required for the neutralization of 1 molecule of ammonium phosphomolybdate and not 23 as commonly assumed; and (3) titration with phenolphthalein in the presence of ammonia always yields uncertain results.

"No method for estimating phosphoric acid, which depends upon the determination of the molybdic acid in ammonium phosphomolybdate, is accurate unless allowance is made for the occluded ammonium molybdate and molybdic acid."

Determination of citrate-soluble phosphoric acid in superphosphate, O. Seib (*Ztschr. Analyt. Chem., 44 (1905), No. 6–7, pp. 397, 398*).—The following quick method is proposed as a substitute for the official Petermann method used in Belgium:

To 2½ gm. of the superphosphate in a small mortar add in 10 cc. portions while still warm a mixture of 20 cc. of concentrated sulphuric acid and 80 cc. of water, grinding the superphosphate with the acid mixture and pouring off the solution into a ½ liter flask. The operation is repeated 3 times, when the residue is washed into the flask with the remaining acid solution and the flask is shaken for half an hour in a rotary apparatus. The solution is cooled and the flask filled to the mark with water. The solution is filtered and 50 cc. of the filtrate is used for the determination of phosphoric acid by means of magnesia mixture. Comparative tests by the author and others of this method and Petermann's method show closely agreeing results.

On the determination of phosphoric acid, F. RASCHIG (*Ztschr. Angew. Chem., 18* (*1905*), *No. 24, p. 953*).—A reply to Hlavnicka's criticism of the author's method previously noted (E. S. R., 17, p. 6) in which the reliability of the method is maintained and the use of a clear blue glass is recommended to increase the sharpness of the reaction in titrating with methyl orange.

Detection of natural phosphates in phosphatic slags, L. LEDOUX (*Cong. Chim. Pharm. Liège, 1905, pp. 129–134; abs. in Jour. Soc. Chem. Indus., 24* (*1905*), *No. 16, p. 904*).—"The method consists in extracting the phosphate, first with citric acid, which dissolves all the phosphoric acid of the slag, and then with nitric acid. The latter extract only gives a precipitate with ammonium molybdate when mineral phosphates have been added to the slag."

A new reagent for potassium, E. P. ALVAREZ (*Chem. News, 91* (*1905*), *p. 146; abs. in Analyst, 30* (*1905*), *No. 352, pp. 254, 255*).—The reagent proposed is "iconogene," sodium amidonaphthol sulphonate, which it is claimed in 5 per cent solution gives in neutral solutions of potash compounds a white, very brilliant, crystalline precipitate of potassium amidonaphthol sulphonate which is slightly soluble in water and insoluble in alcohol. Ammonia salts are not precipitated and magnesia compounds do not interfere with the reaction, if sufficient ammonium chlorid is present. Nickel, cobalt, and bismuth give precipitates insoluble in excess of the reagent.

Contribution to the analysis of nitrate of soda, R. BENSEMANN (*Ztschr. Angew. Chem., 18* (*1905*), *Nos. 24, p. 939; 31, pp. 1225–1228*).—The method proposed (a preliminary note on which was referred to in E. S. R., 17, p. 7) is as follows:

Dissolve 80 gm. of the nitrate in water, making the volume 1,000 cc., dilute 50 cc. of this solution with water, acidify with nitric acid, and add silver nitrate. The silver chlorid precipitated multiplied by 10.192 gives the per cent of sodium chlorid. Dilute a second portion of 50 cc., acidify with hydrochloric acid, and add barium chlorid. The barium sulphate obtained multiplied by 15.236 gives the per cent of sodium sulphate. Evaporate to dryness 100 cc. of the solution with 16 gm. of crystalized oxalic acid, take up in water, and evaporate to dryness again, repeating this operation 5 times.

Ignite the residue, heating gently at first, and maintaining at a red heat for 15 minutes. Dissolve the ignited mass in water, making the volume 250 cc. Dilute 125 cc. of this solution with water, acidify with nitric acid, and add silver nitrate. The weight of silver chlorid obtained multiplied by 24.146 gives the per cent of potassium perchlorate. Titrate 100 cc. of the solution with standard sulphuric acid (80 gm. of SO_3 per liter), or nitric acid (108 gm. of N_2O_5 per liter), or hydrochloric acid (73 gm. per liter). The acid required, less 0.2735 cc. for each per cent of sodium chlorid and 0.1305 for each per cent of potassium chlorate, multiplied by 3.375 gives the per cent of nitric acid (N_2O_5).

The chlorate is determined by the Gilbert method, as follows: Mix 20 gm. of the nitrate with pyrolusite and some sodium carbonate solution; dry the mixture, melt, and ignite; dissolve the ignited mass in a liter of water; acidify 200 cc. of this solution with nitric acid, and add silver nitrate. The silver chlorid obtained multiplied by 21.359 gives the per cent of potassium chlorate. Tests of the method on a number of samples of nitrate are reported.

The analysis of cyanamid, R. PEROTTI (*Rend. Soc. Chim. Roma, 1904, p. 192; abs. in Ztschr. Angew. Chem., 18* (*1905*), *No. 23, pp. 906, 907*).—In the method proposed cyanamid is dissolved in water, and an excess of ammoniacal silver nitrate is added, the excess being determined by the ordinary potassium sulphocyanate method.

The quantitative estimation of nitric acid and nitrates, W. H. EASTON (*Chem. Engin., 1, pp. 142–145; abs. in Jour. Amer. Chem. Soc., 27* (*1905*), *No. 7, Rev., p. 394*).—An electrolytic method of reducing nitric acid or nitrate to ammonia in a copper solution acidified with sulphuric acid and distilling the ammonia into standard acid is

described. The method of Vortmann based on the use of known amounts of copper sulphate and sulphuric acid and the titration of the excess of sulphuric acid after the reduction of the nitrate is also described.

Determination of nitrites in waters, W. P. MASON (*Jour. Amer. Chem. Soc., 27 (1905), No. 5, p. 614; Chem. News, 91 (1905), No. 2379, p. 299*).—A brief note calling attention to the considerable amounts of nitrites which may get into distilled water in the laboratory from the presence of burning Bunsen lamps.

The rapid analysis of cream of tartar and tartaric acid baking powders, R. O. BROOKS (*Pennsylvania Sta. Rpt. 1904, pp. 141–145*).—This description of a method suggested for the examination of baking powders was presented at the meeting of the Association of Official Agricultural Chemists in 1904 (E. S. R., 16, p. 327).

Analysis of formaldehyde sold in North Dakota, E. F. LADD (*North Dakota Sta. Rpt. 1904, pt. 1, pp. 18–20*).—Analyses of a large number of samples of formaldehyde are reported. The data for the different samples are grouped according to the drug companies from which they were reported by retail druggists as having been purchased.

Forty-one samples showed a maximum, minimum, and average formaldehyde content of 42.41, 36.78, and 39.72 per cent respectively; 34 samples maximum, minimum, and average percentages of 41.40, 34.87, and 38.82; 19 samples maximum, minimum, and average percentages of 39.82, 25.42, and 33.75; 41 samples maximum, minimum, and average percentages of 39.37, 21.60, and 35.12; and 81 samples maximum, minimum, and average percentages of 41.28, 14.17, and 37.40. Experiments made at the station showed that formaldehyde does not lose strength upon standing.

The results indicate that commercial formaldehyde is adulterated to a considerable extent, which is believed to be the main reason why formaldehyde has not given more general satisfaction in the treatment of wheat smut. It is reported that retailers have been found guilty of selling short weight or measure, and it is believed that the price at which formaldehyde has been retailed is out of proportion to its cost.

Detection of adulteration in maple sugar and sirup, C. H. JONES (*Vermont Sta. Rpt. 1904, pp. 446–457*).—This is a preliminary report on studies which are being made at the station on the detection of cane sugar when added to maple products.

The amount and character of the ash is considered of special importance in differentiating pure from adulterated products. On the basis of numerous analyses the minimum ash content of pure maple sirup weighing 11 lbs. to the gallon is placed at 0.5 per cent and of maple sugar at about 0.6 per cent, which minimum figures it is stated are rarely attained even with far more thorough filtration than factory equipment affords. The methods employed and the results obtained in the analysis of the ash of 24 samples of pure and 8 of adulterated maple products, and of 8 commercial samples of brown sugar, raw cane sugar, and glucose are reported. The determinations to which particular importance is attached are the total ash and the amount and alkalinity of the soluble and insoluble ash.

The determination of the volume of the precipitate produced in the sugar solution by lead subacetate, while having its limitations, is considered of great value and capable of practical application. This test as used by the author is made by dissolving 5 gm. of the sample in 10 cc. of water, transferring to a graduated sedimentation tube, adding 2 cc. of standard lead subacetate solution, and centrifuging for 4 minutes at a speed of 1,400 revolutions per minute. Pure maple products of average quality show a reading varying from 1.5 to 3 cc. A similar test has been worked out and used by Hortvet (E. S. R., 16, p. 846).

The author also discusses the reliance that may be placed upon the aroma and color of maple products, and the ratio of lime to potash. The limited number of analyses reported show a much higher ratio of lime to potash in brown sugar than in maple products and also a higher sulphate content. Further investigations are to

be made along these lines, and also concerning the organic acids normally present in pure maple products.

On the determination of fat in milk poor in fat, T. S. THOMSEN (*Landw. Vers. Stat., 62 (1905), No. 4-5, pp. 387-399*).—Experiments were made with buttermilk, skim milk, and various mixtures and dilutions of these with water. The Gottlieb method gave higher and, according to the author, more reliable results than the extraction method. The results of fat determinations on buttermilk and skim milk before and after peptonizing led to the conclusion that the impurities in the fat obtained by the Gottlieb method are very slight.

A study of the Hübl, Hanus, and Wijs methods of iodin absorption, H. L. WILSON (*Pennsylvania Sta. Rpt. 1904, pp. 146-150*).—The work here reported was done in cooperation with the associate referee on fats and oils of the Association of Official Agricultural Chemists, the results of which have already been noted in the report of the referee (E. S. R., 15, p. 438).

Some notes concerning Halphen's test for cotton-seed oil, E. FULMER (*Washington Sta. Bul. 67, pp. 3-10*).—Noted from another publication (E. S. R., 14, p. 836).

Reaction of lard from cotton-seed meal fed hogs with Halphen's reagent, E. FULMER (*Washington Sta. Bul. 67, pp. 11-27*).—Noted from another publication (E. S. R., 16, p. 226).

The precipitation limits with ammonium sulphate of some vegetable proteins, II, T. B. OSBORNE and I. F. HARRIS (*Amer. Jour. Physiol., 13 (1905), No. 5, pp. 436-447*).—The present paper is a continuation of work previously noted (E. S. R., 15, p. 222). The principal conclusions drawn from the investigations are as follows:

"Hofmeister's method of fractional precipitation of proteins from their solutions by ammonium sulphate affords, in most cases, a valuable and ready means for the separation of such substances when associated in the same solution.

"The precipitation limits are not characteristic for each individual protein substance, as is commonly assumed, but appear to depend on the conditions existing in the solution at the time of precipitation. . . .

"Vegetable globulins can not be distinguished from vegetable albumins by means of their precipitation limits with ammonium sulphate, since many of these globulins are not precipitated until the concentration in ammonium sulphate is raised well above one-half saturation, while leucosin, the best characterized albumin of vegetable origin now known, is almost completely precipitated at one-half saturation."

The glycocoll content of different proteids, F. DUBROWIN (*Inaug. Diss., St. Petersburg, 1902; abs. in Physiol. Russe, 3 (1904), Nos. 48-60, p. 184*).—Cleavage was induced in a large number of proteids by treatment with sulphuric acid. No glycocoll group was found in the vegetable proteids examined. On the other hand, the proteids of connective and skeletal tissue gave large quantities of glycocoll. Judged by the glycocoll content of their cleavage products collagen, ossein, chondin, and elastin are closely related. The proteid of the crystalline lens of the eye was found to contain 4.5 per cent tyrosin and 0.7 per cent glycocoll. No glycocoll was found in the cleavage products of myosin.

Determination of hippuric acid in urine, R. E. STALLINGS (*Pennsylvania Sta. Rpt. 1904, pp. 151-154*).—Using a modification of König's method, hippuric acid, uric acid, and benzoic acid were determined in samples of urine of a steer, and also to test the method in an artificial mixture of these acids to which a small amount of sodium hydroxid had been added. In the case of the artificial mixture, the results obtained for hippuric and uric acids were too low. The greatest discrepancy was observed with the uric acid, while the benzoic acid was too high. In the case of urine, fairly concordant results were obtained.

Ten lectures on biochemistry of muscle and nerve, W. D. HALLIBURTON (*Philadelphia: P. Blakiston's Son & Co., 1904, pp. XVI+160, pls. 8, figs. 17; rev. in Jour. Amer. Chem. Soc., 27 (1905), No. 4, pp. 448–450*).—The topics considered have to do with muscle ferments, pigments, glycogen, lactic acid, creatinic, and phosphocarnic acid, the chemical changes accompanying contraction, muscle proteids, the metabolism of nerve, coagulation of nerve proteids, the chemical changes in nerve during degeneration and regeneration, and related topics. The volume embodies the author's opinions based on the results of his investigations.

Miscellaneous analyses, C. H. JONES and F. M. HOLLISTER (*Vermont Sta. Rpt. 1904, pp. 457–461*).—Analyses are reported of 20 samples of materials furnishing nitrogen, phosphoric acid, and potash, 15 samples of wood ashes, 2 samples of home-mixed fertilizers, 2 samples of Peruvian guano, 4 samples of muck, and 1 sample each of barley and weed silage, oats and pea silage, foul seed, bone and lime, dry waste and greasy waste from a woolen mill, hen manure, weed killer, and maple sugar.

Report of the chemist: Division of foods and feeding, J. B. LINDSEY (*Massachusetts Sta. Rpt. 1904, pp. 37–44*).—In this part of the report statements are made concerning the extent and character of the work done during the year. Of 2,026 pieces of glassware examined in the execution of the dairy law, 200 were found inaccurately graduated.

Report on general work in the chemical laboratory, C. A. GOESSMANN (*Massachusetts Sta. Rpt. 1904, pp. 104–110*).—Brief notes on the examination of wood ashes, lime ashes, and miscellaneous material, and on phosphatic slag and experiments with native phosphates.

By fusing 1 part of Canadian apatite, containing 31.22 per cent of phosphoric acid, with 4 parts of a mixture of 23 parts of sodium carbonate and 39 parts of potassium carbonate, 3.68 per cent of the phosphoric acid was made soluble in water and 26.78 per cent soluble in neutral ammonium citrate, leaving only 0.76 per cent insoluble. By fusing 1 part of the apatite with only 1.15 parts of the carbonate mixture (the theoretical amount required to convert the phosphate into soluble form), 2.56 per cent of the phosphoric acid was made soluble in water and 15.96 per cent soluble in citrate solution. Boiling the phosphate in solutions of the carbonates of various strengths showed little effect in rendering the phosphoric acid soluble.

Proceedings of the twenty-first annual convention of the Association of Official Agricultural Chemists, held at St. Louis, Mo., September 26, 27, and 28, 1904, edited by H. W. WILEY (*U. S. Dept. Agr., Bur. Chem. Bul. 90, pp. 254*).—This is the official report of the proceedings of the convention. A summarized account of the meeting has been given (E. S. R., 16, p. 320), and a circular of the Bureau containing extracts from the proceedings noted (E. S. R., 16, p. 539).

METEOROLOGY—WATER.

Monthly Weather Review (*Mo. Weather Rev., 33 (1905), Nos. 4, pp. 127–182, figs. 6, charts 13; 5, pp. 183–232, figs. 16, charts 10*).—In addition to the usual reports on forecasts, warnings, weather and crop conditions, meteorological tables and charts for the months of April and May, 1905, recent papers bearing on meteorology, recent additions to the Weather Bureau library, etc., these numbers contain the following articles and notes:

No. 4.—Special contributions on Studies on the Diurnal Periods in the Lower Strata of the Atmosphere—III, The Diurnal Periods of the Vapor Tension, the Electric Potential, and Coefficient of Dissipation, by F. H. Bigelow; The Observations with Kites at the Blue Hill Observatory, 1897–1902, by F. H. Bigelow; Mathematical Theory of the Nocturnal Cooling of the Atmosphere (illus.), by S. T. Tamura; The

Influence of Small Lakes on Local Temperature Conditions (illus.), see p. 224, by J. L. Bartlett; The Great Indian Earthquake of April 4, 1905, as Recorded at the Weather Bureau (illus.), by C. F. Marvin; Rhododendron Leaves as Thermometers, by J. F. Johnson; Fake Rainmaking, by W. L. Moore; Wind Velocities for Different Altitudes and Exposures, by A. J. Mitchell; Tornadoes of March 17, 1905, in Western Oklahoma, by C. M. Strong; Some Temperatures Taken on Lakes Huron and Superior in July and August of 1904, by F. L. Odenbach; A Cold Weather Dust Whirl, by F. W. Proctor; Note on the Winds of the Region Adjacent to the Gulf of California, by G. H. Stone; A Heavy Deposit of Hoarfrost and its Effect in Retarding Nocturnal Cooling (illus.), by D. A. Seeley; and Tornado of April 14 near Pensacola, Fla., by W. F. Reed, jr.; and notes on unusual weather at Dodge, Kans., snow and frost crystals, tidal phenomena, and meteorological course at Williams College.

No. 5.—Special contributions on Studies on the Diurnal Periods in the Lower Strata of the Atmosphere—IV, The Diurnal Periods of the Terrestrial Magnetic Field and the Aperiodic Disturbances (illus.), by F. H. Bigelow; Proposed Observations in Meteorology to be Undertaken during the Expedition to Observe the Total Eclipse of the Sun in Spain and Tunis. August 30, 1905 (illus.), by F. H. Bigelow; Snowfalls, Freshets, and the Winter Flow of Streams in the State of New York (illus.), by R. E. Horton; The Rainfall of the Drainage Area of New Orleans, La. (illus.), by F. S. Shields; Canadian Seismographic Records (illus.), by R. F. Stupart; and Supplying Moisture in Connection with Artifical Heating, by G. A. Loveland; and notes on meteorology and the teachers of physics, sounding balloons at St. Louis, Mo., atmospheric explorations in the Tropics, atmospheric electricity, notes on earthquakes by Weather Bureau observers, and storm warnings at wireless telegraph stations.

Summaries of temperatures, rainfalls, and sunshines, E. F. LADD (*North Dakota Sta. Rpt. 1904, pt. 1, pp. 12–17*).—Tables are given which show the monthly and annual temperature and rainfall for 1904, the annual rainfall since 1892, monthly and annual rainfall since 1895, monthly and annual sunshine record for 1904 and for each year since 1899, and daily observations on evaporation from a water surface, May to September, 1904, with monthly summaries of evaporation and rainfall for the same period during the years 1902 and 1903.

The mean temperature as recorded at Fargo for the year 1904 was 37.05° F.; the maximum temperature 91, in August; the minimum —39, in January. The annual rainfall was 20.26 in. as compared with 20.83 in. for the previous 13 years. The averages for a series of years show that the larger proportion of the rainfall occurs during the growing period, the total rainfall or snow calculated as rain for the 5 months, November to April, being less than 2 in.

"There has been since 1901 a regular decrease in the per cent of sunshine recorded from 49.43 per cent to 39.04 per cent. There has been also an increase in cloudy weather but a decrease in evaporation from a water surface and generally an increase in rainfall."

The total amount of water evaporated from a water surface during May to September, 1904, was 6.09 in. per month or 0.215 in. per day, the total amount evaporated during the period being 30.44 in. as compared with 28.12 in. in 1902 and 41.87 in. in 1903. "In 1902 the evaporation was 1.96 times the rainfall for the same period. In 1903 it was 2.58 times as great, and in 1904 it was 2.47 times as great. Or, in other words, the evaporation from a water surface is from 2 to 2.5 times the amount of the rainfall for the months under consideration."

Meteorology, T. M. CARPENTER (*Pennsylvania Sta. Rpt. 1904, pp. 155–169, 269–291*).—The observations here recorded are of the same character as those reported in previous years (E. S. R., 16, p 750). Monthly summaries of observations are given in the body of the report and the detailed record in an appendix. The summary for 1903 is as follows:

Summary of meteorological observations, 1903.

	1903.	Growing season (Apr.-Sept.).
Barometer (inches): [a]		
Mean	30.051	
Highest	30.758 (Nov. 21)	
Lowest	29.237 (Apr. 3)	
Temperature (° F.):		
Mean	48.4	61.4.
Highest	89 (July 3, 10)	89 (July 3, 10).
Lowest	−6 (Feb. 19)	18 (Apr. 5).
Mean daily range	17.5	19.2.
Greatest daily range	45 (Apr. 4)	45 (Apr. 4).
Least daily range	3 (Mar. 7, Aug. 28, Oct. 5, Dec. 9).	
Mean daily relative humidity (per cent)	79.6	79.2.
Rainfall (inches):		
Total	44.09	25.73
Greatest monthly	7.25 (June)	
Greatest daily	3.12 (Aug. 28)	3.12 (Aug. 28).
Number of days on which 0.01 in. or more of rain fell.	131	69.
Mean percentage of cloudiness	56.5 [b]	57.4.
Number of days on which cloudiness averaged 80 per cent or more.	114	57.
Average hours of sunshine per day		6 h. 18 m.
Last frost in spring		May 9
First frost in fall		Sept. 19.

[a] January and February not included. [b] January not included.

Weather of 1904, S. Blore (*Year Book Col. Agr. and Hort. Holmes Chapel, 1904, pp. 23–28, charts 2*).—Weekly averages of barometer readings, temperature, and precipitation at the College of Agriculture and Horticulture, Holmes Chapel, Cheshire, England, are recorded in tables and diagrams, and the general weather conditions of the year are discussed.

"The total rainfall for the year, 24.03 in., is the lowest since 1887, when 20.42 in. was registered. July and August were the wettest months with 2.83 and 3.73 in., respectively. March and June were the driest with 1.17 and 0.94 in. There were only 174 days on which a recordable amount of rain fell as compared with last year's 204. . . . The chart of the weekly barometric reading . . . shows clearly the steadiness of the barometer during the periods when little or no rain fell and also the great fluctuations from drought to rain and vice versa. . . . The chart of weekly average temperatures, maximum and minimum, shows a gradual rise from the beginning of the year to the middle of July, and then a similar fall to the end of the year, with some few variations. The highest temperature of 85° F. was reached on August 3, and the lowest was 22 degrees of frost registered during . . . November."

Climatological data for the year 1904 (*Rpt. Bur. Agr., Labor and Indus. Mont., 9 (1904), pp. 388, 389*).—A compilation of observations at 45 places in the State on temperature, precipitation, cloudiness, and direction of wind, with data for elevation and the number of years records have been kept.

Results of meteorological observations in the year 1902 (*Ber. Met. Com. Naturf. Ver. Brünn, 22 (1902), pp. XIV+170, charts 6*).—This is the twelfth report of the meteorological commission of the Society of Naturalists of Brünn, Austria, giving detailed tabular summaries of observations at a large number of stations under the direction of the central office of Brünn.

Meteorology, P. Bonâme (*Rap. An. Sta. Agron. Mauritius, 1904, pp. 1–9*).—A record is given of observations during 1904 at the agricultural experiment station of Mauritius on atmospheric pressure, temperature, precipitation, humidity, and evaporation.

The weather 1904–5, F. J. Plymen (*Jour. Southeast. Agr. Col. Wye, 1905, No. 14, pp. 262, 263*).—The general weather conditions at the Southeastern Agricultural College at Wye during the 17 months ended May 31, 1905, are described.

Notes on the difference of temperature, McGill College grounds and Mount Royal, Montreal, Canada, C. H. McLeod and H. T. Barnes (*Proc. and Trans. Roy. Soc. Canada, 2. ser. 10 (1904), Sec. III, pp. 71-125, pls. 25*).—Comparative observations on the college grounds, 180 ft. above sea level, and on Mount Royal, 800 ft. above sea level, are reported in tables and diagrams and briefly discussed.

The curves show "that any marked change in temperature at the lower station has been heralded by a change in the same direction at the higher station by an interval of time, sometimes as great as 24 hours. This interval, which seems to be very variable, depends probably upon wind conditions. . . .

"No attempt has been made to trace the connection between wind or general weather conditions and the differential curves. Without consideration of such effects it would appear that the following relations hold: (*a*) Normal differences in temperature vary with the average air temperature, increasing negatively as temperature falls. (*b*) Departure from normal differences in a negative direction indicates lower air temperatures, and in a positive direction change to warm weather."

Reprints of papers and charts relating to meteorology and terrestrial magnetism, G. Hellmann (*Neudrucke von Schriften und Karten über Meteorologie und Erdmagnetismus. Berlin: A. Asher & Co., 1904, vol. 15, pp. 328; rev. in Science, n. ser., 22 (1905), No. 552, p. 116*).—This is the fifteenth and final volume of this bibliographical work, including the more important papers relating to meteorology and terrestrial magnetism.

The influence of small lakes on local temperature conditions, J. L. Bartlett (*Mo. Weather Rev., 33 (1905), No. 4, pp. 147, 148, fig. 1*).—A comparison is made of observations on temperature at Washburn Observatory, University of Wisconsin, which is located on a ridge between Lakes Mendota and Monona, and at Harvey, Portage, Beloit, and Dodgeville, located respectively to the east, north, south, and west of Madison, within a radius of 45 miles from that city.

The results, which are shown diagrammatically, make it clear that the lakes have a considerable influence on the temperature conditions. This influence is exerted in preventing the occurrence of killing frosts in the late spring and early fall. The range of temperature at Madison during January and February, when the lakes are almost invariably thickly coated with ice, averages over 2 degrees less than at the other points. During August the minimum curve reaches its extreme positive departure and the daily range of temperature averages 6 degrees less than that of neighboring purely continental exposures.

"While the exposure at Madison especially favors the influence of the lakes on the observed temperatures, yet it is believed that wherever small lakes are found the temperature conditions in their vicinity will show departures from the purely continental type of their section much resembling those given above, though not so marked."

The sun and nature, C. Flammarion (*Separate from Bul. Soc. Astron. France, 1905, July, pp. 10, figs. 3*).—A report on observations at the Paris observatory on the relation between variations in sun spots and the leafing and flowering of trees.

The farmer and the weather map, H. H. Lyon (*Country Gent., 70 (1905), No. 2745, pp. 809, 810*).—This article advises farmers to study the daily weather map more closely, especially the position and movement of the high and low areas. It suggests that "it would be a great help to the farmer and would tend to popularize the Weather Bureau" if, in addition to the daily forecasts published in the daily papers, the forecast official would state in simple language "the position of the 'low' areas, indicate their probable or possible course, and the rapidity of their movement. He could state the chances of their containing large or small quantities of moisture and something regarding their probable time and manner of exit from any given area."

Weather forecasts in the service of agriculture, GROHMANN (*Mitt. Deut. Landw. Gesell., 20 (1905), No. 29, pp. 225–227, fig. 1*).—The postal-card method of distributing forecasts practiced by the Royal Saxon Meteorological Institute is described and commended.

Fake weather forecasts, F. J. WALZ (*Pop. Sci. Mo., 67 (1905), No. 6, pp. 503–513*).—A review of various popular and fallacious methods of weather forecasting.

On the significance of Bacillus coli in potable waters, H. VINCENT (*Ann. Inst. Pasteur, 19 (1905), No. 4, pp. 233–248*).—The author refutes Löffler's contention that it is not possible to judge of the value of a water by the number of micro-organisms present and that special methods for determining simply *Bacillus coli* or the bacilli of putrefaction are not necessary. He maintains, on the contrary, that bacteriological analysis is of great value in determining the quality of water.

The delicate methods which have been devised for the numerical determination of *B. coli*, the organisms of putrefaction, or pathogenic germs, particularly the typhoid bacillus, have been of great importance in determining the efficiency of methods of purification of waters, in improving sanitary conditions of cities, and in preventing or arresting epidemics, especially those of typhoid fever.

SOILS—FERTILIZERS.

The principal soil areas of Iowa, W. H. STEVENSON, G. I. CHRISTIE, and O. W. WILLCOX (*Iowa Sta. Bul. 82, pp. 373–394, figs. 3, map 1*).—This bulletin gives the results of investigations of the principal soil areas of Iowa, based upon the work of the Iowa Geological Survey on the glacial geology of the State.

It is stated that "all the soils of Iowa without exception are, in respect to their origin, referable to one or the other of four easily distinguishable classes, which are to be found in plainly marked areas." These classes, which are mapped and fully described in the bulletin, include (1) geest, or soils resulting from the secular decay of indurated rocks; (2) soils of fluviatile origin, or stream-made soils (alluvium); (3) soils of æolian origin, or wind-made soils (loess); and (4) soils of glacial origin, or ice-made soils (drift or till); or, more briefly, geest, alluvium, loess, and till.

The loess and till are the most important of these classes. "Geest occurs chiefly in Winneshiek, Allamakee, Fayette, Clayton, Delaware, Dubuque, and Jackson counties, and only very rarely and in trivial amounts in other parts of the State." Alluvial soils or "bottom lands" "occur all along the courses of every important stream in Iowa. The Missouri, Big Sioux, Nishnabotna, Nodaway, Grand, Chariton, Des Moines, Skunk, Iowa, Cedar, Wapsipinicon, and Mississippi rivers and their tributaries have bottoms of varying widths." They occupy not over 6 per cent of the total area of the State and when properly drained are generally highly productive.

Practically all of the remaining area of the State is occupied by loess and drift (till) soils. "There are three distinct areas of loess soils, the Missouri loess in western Iowa, the Mississippi loess in eastern Iowa, and the loess of southern Iowa." The loess soils as found in Iowa are generally light colored (various shades of buff and yellow, sometimes becoming whitish), fine-grained, but porous and as a rule fertile.

"There are three distinct areas of glacial till, the Wisconsin, the Iowan, and the Kansan. In their relations to agriculture these are typically characteristic of the age of the till." The drift (till) soils differ somewhat with their age. The Wisconsin drift "is principally a black loam, sandy in some places and clayey in others. It is generally rich in the elements of plant food and frequently contains small bowlders of various materials, including granite. . . . The soils of the Iowan drift sheet do not differ very much from those of the Wisconsin; peat bogs and alkali are very much rarer." The Kansas drift occurs in only limited areas on hillsides and

slopes in western and southern Iowa and is uniformly unproductive. In the older drift areas the soils have undergone more complete weathering and leaching than in the more recent areas, and consequently are as a rule lighter in color, poorer in soluble constituents, and contain less undecomposed rock.

The geological origin and general properties of the different classes of soils are discussed and some of the problems which need investigation in connection with each are pointed out.

Soils, H. INGLE (*Transvaal Agr. Jour., 3 (1905), No. 12, p. 731*).—Averages of 11 samples of virgin soils collected along the banks of the Vaal River are reported, which show nitrogen 0.075 per cent, lime 0.94, phosphoric acid 0.045, and potash 0.27. The average of 10 samples collected in the White River Settlement, Transvaal, shows nitrogen 0.093, lime 0.048, phosphoric acid 0.051, and potash 0.20 per cent.

Some soil analyses, A. PARDY (*Natal Agr. Jour. and Min. Rec., 8 (1905), No. 6, pp. 573, 574*).—Analyses with reference to total and available constituents, water capacity, etc., of 3 samples of soils from different parts of Natal are reported.

These analyses show that, "compared with the rich fertile soils of other countries, these are poorly supplied all round with the ingredients desirable in a highly productive soil. They are deficient in organic matter and are liable to be quickly affected by atmospheric influences—temperature, rain, and drought. The soils are only capable of holding a limited supply of moisture." The use of lime, barnyard manure, and green manures to improve the fertility of the soils is suggested.

Results obtained in examination of thin layers of soil, A. DELAGE and H. LAGATU (*Compt. Rend. Acad. Sci. [Paris], 140 (1905), No. 23, pp. 1555–1558*).—A reply to criticisms of previous notes on this subject (E. S. R., 16, p. 756), explaining the practical application of the method as a supplement to mechanical and chemical analyses and in helping to explain the varying assimilability of the potash and phosphoric acid in different soils.

Classification and nomenclature of soils according to mineralogical constitution, H. LAGATU (*Compt. Rend. Acad. Sci. [Paris], 141 (1905), No. 6, pp. 363–366, fig. 1*).—Applying the method of mineralogical examination (referred to in the last article), the author describes more in detail a graphic method of interpreting the results and classifying soils on the basis of their content of lime, clay, and sand.

Soil temperatures, S. BLORE (*Year Book Col. Agr. and Hort. Holmes Chapel, 1904, p. 29, chart 1*).—Weekly averages of soil temperature at the surface and at depths of 3, 6, 9, and 18 in. and 3 and 6 ft. at the College of Agriculture and Horticulture, Holmes Chapel, Cheshire, are recorded. Observations on soil temperature are a new feature of the work of the college observatory. It is proposed to trace the relation of soil temperature at varying depths with that of the air above, as well as its bearing upon plant growth.

The percolation of rain water through soils, W. F. SUTHERST (*Chem. News, 92 (1905), No. 2384, p. 49*).—The author records the results of observations on the rate of percolation of water through sandy loam, loam, clay loam, heavy clay soil, and garden soil which had been subjected to prolonged drought. For the purpose of the observations the soils were packed in glass tubes 1$\frac{3}{8}$ in. in diameter and water was poured on them from time to time in amounts equivalent to 0.1 to 1 in. The slowness of percolation in case of the clay soils indicates that with such soils more than 50 per cent of the rainfall (the proportion given by Lawes and Gilbert) would be lost by evaporation and surface drainage.

The alkali soils of Montana, F. W. TRAPHAGEN (*Montana Sta. Bul. 54, pp. 91–121, pls. 5*).—This bulletin gives a summary of investigations on alkali soils in Montana and elsewhere, largely from a previous bulletin of the station (E. S. R., 11, p. 223), and reports results of pot experiments with alfalfa, oats, wheat, barley, and timothy on soils containing varying amounts and combinations of alkali salts. Analyses with reference to chlorin, sodium sulphate, and sodium carbonate of 358 samples of

alkali soils from different parts of the State are reported. No data are reported for the experiments, but the following summary of general results is given:

"The presence of magnesium sulphate—Epsom salt—in quantity up to 1 per cent has apparently no ill effect upon the growth of alfalfa.

"The limiting quantity of sodium sulphate—Glauber's salt—for alfalfa seems to be about seven-tenths of 1 per cent.

"With a mixture of two-thirds sodium sulphate and one-third magnesium sulphate, which represents very closely the composition of Montana alkali, the limiting quantity appears to be about the same as with sodium sulphate alone.

"It should be said that these experiments were conducted with great care, the purpose being to eliminate every adverse condition except that imposed by the presence of the 'alkali.' Especially was it provided that a sufficient quantity of water should always be present.

"In this connection it may be stated that the presence of alkali was observed, in another series of experiments, to very materially increase the drought-resistant powers of the plants under investigation.

"The results of experiments with oats, wheat, barley, and timothy tend to show that the danger limit for alkali of the character of that found in Montana is above 1 per cent."

The nature and treatment of alkali spots, L. E. KELSEY (*Iowa Agr.*, *6* (*1905*), *No. 1, pp. 12, 13*).—The small alkali areas occurring in the Wisconsin glacial drift soils of the west-central part of northern Iowa are described, as well as the various methods of reclamation which have been proposed for such soils. Underdrainage with liberal applications of coarse manure is considered the most effective and practical means of reclamation yet proposed.

Ant heaps, H. INGLE (*Transvaal Agr. Jour.*, *3* (*1905*), *No. 12, pp. 729–731*).—Analyses of ant heaps and of surrounding soil are reported which "indicate much greater fertility in the ant heap material than in the soil on which it occurs. The organic matter and nitrogen are particularly noticeable, the latter being more than four times as abundant in the ant heap, while the 'available' potash and phosphoric acid are also much higher." These analyses, as well as the experience of a number of practical farmers which is recorded, indicate that "pulverized ant heaps might with advantage be used as a manure on poor soils, and should be of great value in gardens, for seed beds, etc., provided that their physical properties—fine texture, etc.—do not render them too close and impervious."

On the accumulation of fertility by land allowed to run wild, A. D. HALL (*Jour. Agr. Sci.*, *1* (*1905*), *No. 2, pp. 241–249*).—The article records observations on 2 plats of land, one of which was originally in wheat, the other in leguminous plants (beans and clover), which have been allowed to run wild, the first since 1882, the second since 1885.

Examination of the soils at the beginning of the experiment and in 1904 shows a marked increase of carbon and nitrogen in the surface, the rate of increase of nitrogen in the wheat soil being 100 lbs. per acre annually, in the other soil 25 lbs. The mechanical composition of the 2 soils is shown to be very similar, and it is thought that their difference in behavior under cultivation and in natural vegetation (that of the one being nearly free from leguminous plants, that of the other containing considerable of such plants) may perhaps be due to absence of calcium carbonate in the former, while the latter is well supplied with this substance as a consequence of liberal application of chalk in former period (the eighteenth century).

Manurial requirements of the Leonardtown loam soil of St. Mary County, Md., F. D. GARDNER (*U. S. Dept. Agr., Bur. Soils Circ. 15, pp. 13*).—Tests by the "wire-basket" method of the manurial requirements of "good" and "poor" samples of this soil, which is a light-colored silt loam of varying fertility, are reported. The soils were treated with organic manures (barnyard manures of various kinds, organic

matter from city dump, and green manures), lime, and chemical fertilizers (sodium nitrate, potassium sulphate, and tricalcium phosphate). Wheat plants were grown on the soils by the wire-basket method as follows:

"Five small wire baskets 3 in. in diameter by 3½ in. in depth are used for each treatment. After the soil has been treated with its respective fertilizer and brought up to the optimum water content with distilled water, the equivalent of about 325 gm. of dry soil is placed in each basket. The soil is firmly packed, and 6 germinated kernels of wheat are planted in each basket. During the process of packing a small portion of the soil presses out through the wire mesh, but this is brushed off and returned to the interior of the basket, after which the basket is at once dipped into melted paraffin, which not only forms an intimate contact with the soil, but also produces a water-tight covering.

"An eighth to a quarter of an inch of washed quartz sand is now placed over the soil of each basket, and its contents at once weighed and the weight recorded. In from 3 to 5 days the wheat plants will have emerged from the soil and have a height of approximately 1 in., at which time the surface of the basket is sealed—that is, it is covered with a piece of paper having a small opening in the center sufficiently large to permit the plants to pass through. The paper is dipped in melted paraffin just before placing it over the soil, and then a small amount of paraffin is run around the outer edge of the paper, thus forming contact with the side of the basket.

"In this way all evaporation from the soil is prevented, excepting the minute amount which may pass through the small opening immediately around the plants. The loss from this source is so slight in comparison to that which is transpired by the plants that no account is taken of it, but even if the loss were considerable it should be practically the same from all baskets. The weight of the basket is taken immediately before sealing and immediately afterwards, in order to ascertain the weight which has been added to it in the process of sealing. This increase is now added to the original weight of the basket, and the result is what is known as the 'optimum weight,' or that weight at which the contents of the basket contain the most favorable amount of moisture for the growth of plants.

"During the growing of the plants, which usually continues from 18 to 21 days from the date of sealing, the baskets are weighed at intervals of 2 or 3 days and watered with distilled water, in order to retain a favorable moisture content for plant growth. By this method the loss of water or the amount transpired by the plants is ascertained periodically, and at the end of the experiment the total amount of water given off through the plants of each basket is obtained for comparison with the growth and green weight of the plants, which is ascertained by cutting and weighing the plants at the time the experiment is concluded. All conditions of the experiment are so carefully controlled that the average result of 5 baskets rarely differs more than 5 per cent from the average result of any other 5 baskets that have been treated throughout in precisely the same manner. Differences which occur beyond this amount may therefore safely be attributed to the different manurial treatments which have been given."

From the results obtained by this method the conclusion is drawn that "both barnyard manure and green manure are beneficial to this soil when in a run-down condition, but that the effects from applications of green manure are decidedly more beneficial in that they are more lasting than for equal amounts of barnyard manure. The benefits from liming are so obvious that they need no comment, while potash and nitrogen in combination with manure are sufficiently beneficial to justify their application, at least in amounts not to exceed 250 lbs. per acre, but the results do not seem to indicate that when applied alone they are of enough effect to warrant their use."

These results "appear to be in harmony with the actual field experience of successful farmers in the locality."

How can we maintain the fertility of our Colorado soils? W. P. HEADDEN (*Colorado Sta. Bul. 99, pp. 16*).—The purpose of this bulletin is stated to be "to present to the farmers of Colorado some of the most patent facts relative to the maintenance of the productiveness of their lands." It discusses in a brief popular way the origin of Colorado soils, their deficiences and the extent to which they have been exhausted, and various means of restoring and maintaining fertility, including the use of commercial fertilizers, barnyard manure, and green manures.

It is stated that the soils of the eastern slope of the Rocky Mountains in Colorado are for the most part light sandy loams derived from the disintegration of the mountain rocks, which are essentially granitic in character. They are not particularly rich in potash and phosphoric acid, but nearly all of them contain as much as 0.1 per cent of nitrogen, which is considered the standard for a fairly productive soil. The climatic conditions, however, are not especially favorable to the formation of humus, the tendency being toward a burning up of the organic matter rather than its humifaction.

Considering the geographical position of the State and its remoteness from supplies of the chemical fertilizers (potash salts, nitrate of soda, etc.), there is serious doubt whether these materials can be profitably used for maintaining or increasing the fertility of the soils. The use of barnyard manure "is one of the most important and at the same time available means for the maintenance of the productiveness. . . . The next best method is probably that of green manuring, and for this purpose we have no better plant than alfalfa."

Soil fertility, W. C. WELBORN ([*Philippine*] *Bur. Agr. Bul. 6, pp. 13*).—A popular discussion of means of maintaining soil fertility, with suggestions as to the specific fertilizer requirements of the principal Philippine crops and the need of fertilizer laws in the Philippines.

Fertilizers registered for sale in Arkansas during 1905, A. M. MUCKENFUSS (*Arkansas Sta. Bul. 86, pp. 53–57*).—Actual and guaranteed analyses of 72 samples of fertilizers examined by the State chemist are reported.

Analyses of fertilizers, C. A. GOESSMANN (*Massachusetts Sta. Bul. 103, pp. 20*).—This bulletin includes directions for sampling fertilizers; instructions to manufacturers, agents, etc.; a discussion of trade values of fertilizing ingredients for 1905; and analyses of miscellaneous fertilizing materials, including wood ashes, nitrate of soda, cotton-seed meal, dried blood, sulphate of ammonia, clover roots, potash salts, acid phosphates, fish fertilizers, oyster-shell lime, paper-mill dustings, wool dustings, wool waste, cotton waste, cotton-waste compost, sewage-bed sludge, sewage, sheep manure, tobacco stems, tobacco dust, wood charcoal, salt-marsh mud, muck, peat, and soils (18 miscellaneous samples).

Analyses of commercial fertilizers and manurial substances, C. A. GOESSMANN (*Massachusetts Sta. Bul. 104, pp. 28*).—Analyses are reported of licensed fertilizers and miscellaneous fertilizing materials, including wood ashes, potash salts, German peat moss, river mud, wool-mill refuse, charcoal, boneblack, nitrate of soda, cotton-seed meal, barnyard manure, hen manure, and soils (19 miscellaneous samples).

Report on official inspection of commercial fertilizers and agricultural chemicals during the season of 1904, C. A. GOESSMANN (*Massachusetts Sta. Rpt. 1904, pp. 94–103*).—The results of examinations of 525 samples representing 295 brands are summarized. Tables show the average composition of the different classes of all fertilizers analyzed, and the maximum, minimum, and average composition of special crop fertilizers. A schedule of trade values of fertilizing constituents and a list of licensed manufacturers and dealers are given.

Analyses of miscellaneous fertilizer materials, M. S. MCDOWELL (*Pennsylvania Sta. Rpt. 1904, pp. 124–136*).—Analyses of the following materials are reported and discussed: Muriate of potash, sulphate of potash, kainit, sylvinit, wood ashes, nitrate of soda, nitrate of potash, sulphate of ammonia, dried blood, ground bone,

tankage, boneblack, rock phosphate, basic slag, Peruvian guano, tannery ashes, flue dirt, land plaster, mixed fertilizers, and garbage ashes.

Commercial fertilizers, J. L. HILLS, C. H. JONES, and F. M. HOLLISTER (*Vermont Sta. Bul. 112, pp. 71–92*).—This bulletin contains analyses of samples of 57 brands of fertilizers, representing 1905 shipments in the hands of local dealers. A schedule of trade values to be used in Vermont in 1905 is also given.

Commercial fertilizers, J. L. HILLS, C. H. JONES, and F. M. HOLLISTER (*Vermont Sta. Bul. 116, pp. 143–244.*)—This bulletin reports and discusses analyses of 137 brands of fertilizers, representing the output of 13 companies, examined during 1905.

Only 71 per cent of the brands met their guaranties, 7 failed to give a commercial equivalent of their guaranteed composition, and 1 was far below its guaranty. The average composition of all of the fertilizers showed 8 per cent more plant food than was guaranteed. The crude stock used in the preparation of the fertilizers was found to be on the whole of good quality. The average selling price was $29.62, the average valuation $19.04. It is estimated that 56 cts. worth of plant food was bought for a dollar in average low-grade goods, 64 cts. worth in medium-grade goods, and 73 cts. worth in high-grade fertilizers, thus showing the economy of buying high-grade goods.

A table is given which shows the composition of different brands during the past 5 years. The purchase of fertilizers, systems of fertilization, methods of application, and kinds of plant food best suited to different purposes are discussed, and 80 formulas for different crops and crop conditions are given with suggestions as to their use.

Commercial fertilizers, J. H. STEWART and B. H. HITE (*West Virginia Sta. Bul. 95, pp. XIV+15–68*).—This is a complete report of analyses of fertilizers inspected during 1904, including also information regarding the conduct of the fertilizer inspection, valuation of fertilizers, availability of nitrogen in fertilizers, etc., and the text of the State fertilizer law.

Manures, F. T. HOLBROOK and E. J. RUSSELL (*Jour. Southeast Agr. Col. Wye, 1905, No. 14, pp. 159–169*).—Analyses and descriptions are given of a number of samples of typical fertilizers available for use in the region of Wye, Kent, including guanos, fish manures, bones and bone products, meat fertilizers and other waste animal products, shoddy, hoof meal, lime and chalk, kainit, silicate residue, and mixed fertilizers.

On the relationship between the amount of oil in cake and the farmyard manure produced, G. J. GOODWIN and E. J. RUSSELL (*Jour. Southeast. Agr. Col. Wye, 1905, No. 14, pp. 187–207*).—This article reviews experiments made elsewhere which bear on this subject, and reports results of digestion experiments made at the Southeastern Agricultural College at Wye with 2 steers, to determine the influence of the quality of the oil cake fed upon the manure produced. The analytical results are reported in this paper. The results of field tests on potatoes of the manures produced are to be embodied in a future report.

The conclusions reached are that "(1) [the] analyses fail to reveal any difference between dung made from rich oil cake and that from poor oil cake, the rest of the ration being the same in both cases. . . .

"(2) When the dung, mixed with sufficient litter, was left under the bullocks and thoroughly trampled, the loss of nitrogen amounted to 15 per cent, a value closely in accord with the results of other English and of German investigators. . . .

"(3) The loss is more serious than it appears, for, in addition to the 15 per cent mentioned, a certain amount of the easily available ammoniacal nitrogen is converted into slowly available insoluble bodies. . . . The exact percentage changed can not be stated with accuracy. . . .

"(4) From the standpoint of the value of manure produced, peat moss is much better than straw as litter, owing to its higher nitrogen content and its greater power of absorbing ammonia. It contains, however, very much less potash, and, as farm-

yard manure has hitherto furnished the farmer's chief supply of this fertilizer, substitution of peat moss for straw would in many cases involve dressing the land with potash. Such dressings cost little, and would be more than paid for by the saving of nitrogen."

Utilization of blood in agriculture, A. GRAU (*Jour. Agr. Prat., n. ser., 10 (1905), No. 32, pp. 177, 178*).—It is pointed out that since each sheep yields about 2 kg. of blood and each head of cattle about 20 kg. of blood, which in the fresh condition contains 3 per cent of organic nitrogen, the importance of utilizing this by-product is obvious. Various methods which are applicable on the farm, such as absorption in peat, straw, etc., and treatment with about 3 per cent of lime are referred to and the method of commercial treatment of precipitation by heating and the addition of dilute acid and drying is described. Brief general directions regarding the use of this dried material as a fertilizer are given.

Lime nitrogen (*Jour. Bd. Agr.* [*London*], *12 (1905), No. 2, pp. 101, 102; Jour. Dept. Agr. So. Aust. 8 (1905), No. 12, p. 742*).—The method used by Frank in preparing this material is briefly described, with his directions regarding the use of it as a fertilizer. The experiments by Gerlach, Wagner, and others to determine the fertilizing value of the material are briefly referred to. The general conclusion drawn from these experiments is "that lime nitrogen is likely to prove a satisfactory nitrogenous manure."

Comparative experiments with lime nitrogen, nitrate of soda, and burnt lime on fodder beets, C. ASCHMAN (*Landwirt, 1905, No. 37; abs. in Chem. Ztg., 29 (1905), No. 42, Repert. No. 11, p. 156*).—In the experiments here reported nitrate of soda gave the largest yield. The lower yields resulting from applications of lime nitrogen are thought to have been due to the fact that the material was not worked into the soil to a sufficient depth. The crops grown with nitrate of soda contained the largest amount of dry matter but those grown with lime nitrogen contained the highest percentage of nitrogen compounds. The lime of the lime nitrogen was apparently not as effective in increasing the sugar content as burnt lime.

New land, lime, and litmus, W. A. SHERMAN (*Country Gent., 70 (1905), No. 2746, pp. 833, 834*).—An account is given of the use of lime (600–800 lbs. per acre) in restoring the productiveness of recently cleared acid pine land. Tests of the soil with litmus paper are reported, which indicate that the acid character of the soil was not overcome by the liming.

Liming experiments of the agricultural society of Saxony (*Deut. Landw. Presse, 32 (1905), No. 42, p. 361*).—A brief description is given of the plan of simple experiments with lime, which have been carried on in cooperation with farmers since 1899.

On the retrogression of soluble phosphates in mixed manures, G. GRAY (*Trans. Austral. Assoc. Adv. Sci., 1904, p. 157; Chem. News, 92 (1905), No. 2386, pp. 77–79*).—Experiments are reported in which a well-made superphosphate containing 17.74 per cent of soluble phosphoric acid was mixed with equal parts of bone dust, guano, basic slag, kainit, slaked lime, and ground limestone, and the amounts of water-soluble, citrate-soluble, and insoluble phosphoric acid determined from time to time.

The results show that with bone dust the amount of retrogession was small and the rate of change slow. The citrate soluble phosphoric acid increased at the expense of the insoluble. With a guano containing a small percentage of calcium carbonate the reversion was slow, only 7 per cent of the soluble phosphoric acid being reduced after 18 days. As in case of the bone dust citrate-soluble phosphoric acid was formed at the expense of the insoluble phosphoric acid. With a guano containing a high percentage of calcium carbonate the retrogression was considerable and proceeded not only to the stage of dicalcium phosphate but beyond this to form insoluble tricalcium phosphate.

With basic slag the reversion was rapid, over 50 per cent of the acid being in an insoluble form within 3 hours. Only about 7 per cent of the phosphoric acid was reverted in 18 days in the kainit mixture. In the slaked lime mixture 94 per cent of the soluble phosphoric acid was reverted within 3 hours and the whole amount present within 24 hours. Reversion was not so rapid with calcium carbonate as with slaked lime, but 80 per cent of the water-soluble phosphoric acid was converted into citrate-soluble acid in 24 hours.

Plant peculiarities as shown by the influence of sodium salts, H. J. Wheeler. (*Rhode Island Sta. Bul. 104, pp. 49-92, pls. 8, dgms. 12*).—This is a report on a continuation of observations and experiments, previous accounts of which with a partial résumé of literature are given in earlier reports of the station (E. S. R., 11, p. 915).

The experiments have been conducted since 1894 on 48 sixtieth-acre plats, one series of which was fertilized with various combinations of sodium chlorid and muriate of potash, another with sodium carbonate and potassium carbonate. One subseries with each of these fertilizer combinations was limed in 1894 at the rate of 2 tons of slaked lime per acre. The experiments reported in this bulletin were made in 1899 with certain plants which it was thought might perhaps be helped by soda and with others which seemed doubtful.

"The work of the first 5 years demonstrated conclusively that soda could not perform all of the functions possibly attributable to potash, for where soda was substituted entirely for potash the crops became poorer from year to year. During the earlier years also few reliable indications were afforded that sodium salts were of benefit so long as a full ration of potassium salts was used. One of the chief objects attained in the first 5 years was the exhaustion to a striking degree of the assimilable potash, thus preparing the soil for use in making more satisfactory trials of sodium salts than were possible before."

In 1899 each plat was manured as follows: Dried blood 1,020, dissolved boneblack 600, floats (finely pulverized phosphate rock) 480, and magnesium sulphate 420 lbs. per acre. Sodium and potassium salts were each substituted for the other upon some one or more of the 48 plats in "quarter," "half," "three-quarter," and "full" rations. The full rations of the sodium and potassium salts used were as follows: Sodium chlorid (common salt) 231.6, sodium carbonate (soda ash) 202.2, muriate of potash (80 to 85 per cent potassium chlorid) 331.8, and potassium carbonate (pearl ash) 300 lbs. per acre. Spring rye, golden millet, chicory, Bloomsdale spinach, white Strasburg radish, flat turnip, Mansbury barley, Norbiton Giant beet, Danvers carrot, Iceberg lettuce, white pea-bean, and Budlong turnip (ruta-baga) were used in the experiment.

The results without exception indicate that soda is not as efficient as potash as a plant nutrient. "It can not be disputed, however, that soda is of some use in some manner with many varieties of plants, when the supply of potash is quite limited, and also with at least a few varieties of plants even in the presence of a fairly abundant supply of potash. Whether sodium salts would be rendered useless with all varieties of plants if the supply of potassium salts were greatly increased is a point which is not as yet fully proved, nor is it fully clear as yet in just what manner the sodium salt has been helpful in this particular experiment. This is a question which will be considered later in connection with the chemical analyses of the crops.

"It may, however, be stated here that sodium salts seem to liberate at least phosphoric acid and potash, so that under certain circumstances they may act as indirect manures. They also appear under certain conditions to prevent plants from assimilating large amounts of potash in excess of their needs, thereby conserving the potash supply within the soil. It does not appear unlikely, when the supply of potash is limited, that sodium salts may aid in some degree in performing some function of potassium."

On those crops which were particularly benefited by liming (barley, beets, turnips) the alkaline carbonates, as a rule, proved more effective than the neutral salts, probably on account of their action in neutralizing the acids of the soil.

AGRICULTURAL BOTANY.

Quack and wheat grasses, L. H. PAMMEL (*Iowa Sta. Bul. 83, pp. 397-416, figs. 7*).—The author describes quack grass (*Agropyron repens*), giving an account of its history and distribution and notes on its character as a weed plant.

Its value as a forage plant is shown by tables giving the results of analyses of the plant cut at different periods of growth, and suggestions are given regarding the methods of extermination. The author claims that quack grass can be exterminated by proper methods of culture, which include early plowing, thorough harrowing, the removal of rootstocks, and the prevention of growth throughout one or more seasons. If this treatment is persisted in it is said that the grass may be entirely eradicated.

Notes are given on a number of species of Agropyron which are commonly called wheat grasses, together with descriptions of the plants and statements regarding their forage value. Among the species described are *Agropyron pseudo-repens*, *A. occidentale*, *A. tenerum*, *A. richardsoni*, and *A. caninum*.

Soil-binding grasses, L. H. PAMMEL (*Iowa Sta. Bul. 83, pp. 417-421, figs. 2*).—An account is given of investigations carried on along the line of the Chicago and Northwestern Railroad to protect embankments from washing.

Quack and wheat grasses were tested, together with a number of other plants which were believed to have some value in this respect. Quack grass proved well suited to use as a soil-binder, but its character as a weed makes it objectionable for some localities. Brome grass and blue grass planted on the north side of embankments, if properly handled, will produce a good sod in a few years.

For the south side the author recommends the planting of western wheat grass and Canadian blue grass. For binding shifting sands the author recommends the use of a number of native species of plants, some of which succeed very well for the purpose indicated.

Studies of Mexican and Central American plants—No. 4, J. N. ROSE (*U. S. Nat. Mus., Contrib. Nat. Herbarium, vol. 8, No. 4, pp. 281-339, pls. 10, figs. 6*).—Notes are given on a number of hitherto undescribed plants, many of the specimens having been obtained by the author in Mexico. A number of the species recorded are of some economic importance, and their value as ornamentals, etc., is indicated. The author presents synopses of several genera of Mexican plants, and gives technical descriptions of the species.

The useful plants of the island of Guam, W. E. SAFFORD (*U. S. Nat. Mus., Contrib. Nat. Herbarium, vol. 9, pp. 416, pls. 70*).—This publication is an elaboration of notes made by the author during a series of cruises while connected with the United States Navy. After describing the early history of the island, previous scientific explorations, and its physical conditions, an account is given of the vegetation of the island, the author grouping the different plants according to formations.

Notes are also given on the people inhabiting Guam, and the agricultural and other industries. The principal plants used for food, fiber, oil, starch, forage, etc., are described, and the distribution of these plants not only in the islands of the Pacific Ocean but in other tropical regions is indicated. Particular attention is given to the method of cultivating and propagating the more important species, and also the means adopted for the preparation of their products, such as arrowroot, copra, cacao, etc.

A descriptive catalogue is given of all the plants, the arrangement being alphabetical and the native names, as applied in Guam, Hawaii, the Philippines, and elsewhere, indicated.

The respiration of plants, H. Marshall Ward et al. (*Rpt. Brit. Assoc. Adv. Sci., 1904, pp. 344, 345*).—A report is given by a committee of the British Association upon investigations by F. F. Blackman and Miss G. L. C. Matthaei dealing with the effect of temperature and light upon the photosynthesis of leaves.

It was found that one of the important considerations of the experiments was that the leaves should all be kept under similar conditions of illumination and temperature for some time before the beginning of the experiment, and that the real internal temperature of the leaf should be definitely known. With these precautions, a series of experiments was conducted in which the temperatures ranged from −6° C. to 45° C., and it was found that for each temperature a maximal assimilation exists specific to that temperature.

The amount of light required to produce the specific maximal assimilation varies directly with the magnitude of the maximum. When the maximum is reached no further increase in illumination or in the amount of carbon dioxid supplied will augment the assimilation by the plant. The amount of assimilation is just determinable at −6° C., from which temperature it rises rapidly toward the maximum. At temperatures of about 38° C. the leaves are incapable of maintaining their high initial rate of assimilation for any considerable time. The higher the temperature the shorter the duration of the period of maximal assimilation, and it was found impossible to obtain the maximal value at temperatures close to 45° C., which was a fatal temperature for the plants under observation.

The relation between the carbon dioxid assimilation and various intensities of natural illumination was also investigated, determinations being made of the assimilatory value of natural illumination at dawn, midday, in sun and shade, during rain and storms, and at dusk, and it is shown that the diffuse light of the whole heaven compares favorably with feeble direct sunlight as an illuminant.

FIELD CROPS.

Report of the agriculturists, W. P. Brooks, F. R. Church, and S. B. Haskell (*Massachusetts Sta. Rpt. 1904, pp. 115–153, dgm. 1*).—During this season the general lines of investigation previously described were again followed (E. S. R., 16, p. 350). The experiments this year included 220 plats in the open field, 150 closed plats, and 278 pots in vegetation tests. The grass garden of the station includes 48 species and 7 varieties, most of them occupying 1 sq. rod of land.

Potatoes were grown this year in connection with the comparative test of different sources of nitrogen, and on the basis of yield secured the materials ranked as follows: Barnyard manure, nitrate of soda, dried blood, and sulphate of ammonia. Based on the increase in all the crops since the beginning of the experiment, as compared with the check plats, the relative rank of the different fertilizers was: Nitrate of soda 100, barnyard manure 83.6, dried blood 66.9, and sulphate of ammonia 56.9. The growing of soy beans has so far shown but little effect on the succeeding crop.

This year high-grade sulphate of potash appeared considerably superior to the muriate for rhubarb and cabbage. Silicate of potash gave a relatively very low yield of cabbage and of field and silage corn, while the nitrate and carbonate of potash gave relatively high yields. Results with different phosphates for corn indicated, as in previous years, a very low degree of availability for Florida soft phosphate.

The soil test with corn has now been in progress for 16 years, and during this time the land has been in corn 8 years and in grass 4 years. Corn was grown in succession the last 3 years, and the past year was excellent on all plats receiving potash every year. The plat receiving muriate of potash alone continuously yielded 47 bu. per acre, and the one receiving dissolved boneblack in addition yielded 53 bu., being a better yield than was obtained on the plat treated annually with 5 cords of barnyard

manure per acre. The importance of a liberal supply of potash in fertilizers for corn is pointed out by these results.

In the soil tests with grass and clover nitrate of soda, either alone or in combination, gave a large increase in the first crop. Potash without lime had but little effect. The use of potash continuously for 15 years, with a ton of lime per acre in 1899 and 1904, produced a marked effect on the proportion of clover and also on the total yield. The plat receiving dissolved boneblack and muriate of potash continuously produced the most profitable crop. The annual cost of fertilizers for the limed portion of this plat was about $7.50 per acre, and the yield of hay was 6,160 lbs.

This year the yields obtained where a fertilizer mixture rich in potash and a special corn fertilizer were used were practically equal, but the cost of production with the mixture rich in potash was a little over $5 per acre less than with the special corn fertilizer. In comparing the value in corn production of a moderate application of barnyard manure alone and of a small application used in connection with the application of sulphate of potash, the crops obtained under the 2 systems were equal in amount of stover, but the plats receiving manure alone gave an average of about 5 bu. of grain per acre more than the combination of manure and potash. The use of barnyard manure alone, however, proved the more economical.

On the grass lands receiving different fertilizer treatment in rotation, the average yield of hay was at the rate of 8,050 lbs. per acre for all 3 systems of manuring. The average yield in this test from 1893 to 1904, inclusive, was 6,718 lbs.

Spreading barnyard manure as hauled from the stable during winter was again compared with placing it in a large heap to be spread in spring. In 3 out of 5 tests the results were in favor of the winter application, but the difference in yield was insufficient to cover the difference in the cost of hauling, which amounted to $4.80 per acre. An application of nitrate of soda after harvesting the first crop of grass did not sufficiently increase the crop of rowen to make the practice profitable, possibly on account of a somewhat deficient rainfall.

The 49 varieties of potatoes under test ranged in yield from 104 bu. of merchantable potatoes per acre for the Clinton to 319 bu. per acre for Simmon Model. Given in the order of productiveness, the following varieties yielded over 260 bu. per acre: Simmon Model, Extra Early White Rose, Great Divide, Steuben, 1904, and Mills New Rose Beauty.

Field experiments for 1903, W. R. Perkins (*Mississippi Sta. Rpt. 1904, pp. 36–39*).—This is a report on the plat experiments conducted during the year.

Of 12 varieties of cotton the 2 leading were Edgworth and Prize, yielding 1,920 and 1,895 lbs. of seed cotton per acre, respectively, while Garrard Prolific and King Improved, standing at the foot of the list, produced, respectively, 1,382 and 1,505 lbs. per acre. As in previous years, the use of different fertilizers had but little effect. No rust appeared in the cotton this season, which is thought to be due to the good preparation of the soil and abundant moisture throughout the entire season.

Twelve varieties of corn were under test and the 2 leading varieties, Southern Snowflake and Mosby, yielded 75.1 and 73 bu. per acre, respectively; while of the 2 least productive varieties, Blount Prolific yielded 26.7 and Champion Early White Dent 42.6 bu. per acre. The use of fertilizers showed no appreciable increase in yield except where 2 applications of nitrate of soda were made.

A plat of wheat treated with 129 lbs. of nitrate of soda per acre yielded 1,948 lbs. of hay per acre, as compared with 948 lbs. on the check plat. Four plats of oats, receiving 100 lbs. of nitrate per acre, gave an average yield of 2,325 lbs. of hay, while 2 check plats yielded 1,437 lbs. per acre. Nine varieties of wheat ranged in yield from 3 to 10 bu. per acre, and duplicate plats produced from 2,800 to 4,000 lbs. of hay per acre.

Fourteen varieties of cowpeas varied in yield of seed from zero to 15 bu. per acre, Whip-poor-will being the leading variety. The same varieties following wheat on

good soil grew up with Johnson grass and yielded 2.6 tons of hay per acre. In a test with Johnson grass alone it was found that the use of cotton-seed meal and nitrate of soda as a fertilizer for this crop yielded a profit of $3.03 per acre, and that thorough preparation of the soil more than doubled the crop.

Six Japanese varieties of soy beans and Mammoth Yellow, a variety procured from seedsmen, were tested. Mammoth Yellow produced 4.5 tons of hay per acre with 40 per cent of moisture present. A yield of 24 bu. per acre was secured on a part of the field. A variety of Egyptian clover gave promise of value, and sorghum produced a better yield and a better quality of soiling than Kafir corn and milo maize. Experiments in growing Bermuda grass from seed were only partially successful. Alfalfa is reported as growing with success at the station. Thorough and deep plowing and frequent use of the harrow have given good results as a method of soil preparation.

Report of work at McNeill Branch Experiment Station, E. B. FERRIS (*Mississippi Sta. Rpt. 1904, pp. 40–42*).—The work of the station comprises the determination of crops and varieties best suited to the pine belt, the best use of fertilizers in connection with their culture, and the planting of certain crops in sufficient quantities to determine the commercial side of growing them. The crops under test include vegetables, fruits, corn, cotton, sugar cane, cassava, sweet potatoes, and forage crops. The results with these crops, which are in nearly all cases promising, are briefly noted.

[Report on field crops], J. H. SHEPPERD (*North Dakota Stat. Rpt. 1904, pt. 1, pp. 66–138, pls. 2*).—The customary description of the work of the agricultural department of the college and station in 1904 is given and the results of different experiments are reported.

During the season 51,000 individual plants, including wheat, oats, barley, flax, buckwheat, millet, alfalfa, emmer, spelt, rye, einkorn, and corn, were grown in the plant-breeding nursery. The record of the seed distribution from 1898 to 1904, inclusive, shows that 1,734.5 bu. of seed of different field and forage crops were distributed to 770 persons. Some of the reports from different parts of the State with reference to these seed trials are reproduced.

The results of red clover trials in cooperation with the Bureau of Plant Industry of this Department show that seed from Missouri, eastern Ohio, Russia, and Wisconsin made a much better showing than the seed from other sources. On September 10 the plats sown with seed from Missouri and Wisconsin looked especially favorable, while those sown with seed from Illinois and Russia were also promising.

Fifty-seven varieties of wheat were tested in 1904. No difference in hardiness or rust resistance was detected between the fife and blue stem wheats, while the durum varieties were very much superior to either in these respects. The leading varieties in the different classes were North Dakota crossbred fife, with a yield of 16.4 bu. per acre, North Dakota crossbred blue stem with 17.3 bu., and Black Don U. S. No. 1446 durum with 25.9 bu. per acre. The average yields of the best 6 varieties of wheat in each class for 1904 were as follows: Durum 23.5, fife 16, blue stem 16.9, and blue stem and fife 16.4 bu. per acre. Eleven out of the 12 varieties giving the largest yields this season came from the plant-breeding nurseries of the North Dakota and Minnesota experiment stations.

A comparison of the average yields of the best 3 varieties of durum wheat with fife and blue stem for 6 years gave an advantage of 4.85 bu. per acre in favor of the durum wheat. The average yields for the last 2 years, as well as the results with the best 5 strains of fife and blue stem were in nearly every case in favor of varieties coming from the plant-breeding nurseries. Four varieties of winter wheat sown in the fall of 1903 were completely winterkilled.

In a culture test corn land disked in the spring for wheat gave nearly 3 bu. more per acre than fall-plowed corn land, and fall-plowed land produced a little over 1 bu.

more per acre than spring-plowed land. The best quality of wheat was produced on the spring-disked ground. A test of sowing rape and wheat for fall pasture resulted in a little larger yield from the mixture. The rape made but a slight growth after the wheat was harvested until frost.

Of 35 varieties of oats, U. S. No. 5168 led in yield per acre with 75.4 bu., being followed by Sensation with 70 bu. The side oats required the longest period for maturing and were less affected by rust than the branching varieties. This season the earliest maturing variety gave the largest yield, but in general the late-maturing sorts produced uniformly larger yields than the early varieties. The largest average yield on record at the station, 74.3 bu. per acre, was produced by U. S. No. 5168, which has been grown for 3 successive years.

Twenty-four varieties of barley were tested, and of these 5 were new additions coming from this Department. The barley plats were very little affected by rust, while the adjacent oat and wheat plats on similar soil were badly affected by it. The best yields this season were obtained from Highland Chief and Chevalier, while for the last 2 seasons Highland Chief and Success stood first in average production.

Thirty-two samples of flax were grown, including 20 varieties furnished by this Department. The best yield for the season, 24.2 bu. per acre, was obtained from U. S. No. 10014. Of the varieties grown for a series of years, Select Russian stands first with an average yield of 20 bu. for 3 years. The fiber varieties gave small yields in comparison with the seed strains, and were not profitable for seed production alone.

In 1904 North Dakota emmer yielded 46 bu., and a variety from this Department 52.9 bu. per acre, the bushel being calculated at 40 lbs. The average grain production of different crops for 6 and 7 years was as follows: Emmer, 2,096 lbs.; barley, 2,025; oats, 2,035; wheat, 1,733; and durum wheat 1,883 lbs. per acre.

Notes are also given on experiments with buckwheat, millet, corn, potatoes, and peas. Buckwheat has not generally given good crops at the station. In seed production the millet varieties were a complete failure in 1904. Of the different varieties of corn grown the following, in the order given, stood first in the proportion of ripe ears produced or in the degree of ripeness attained: Wills Dakota, Gehu, North Dakota No. 1 (a variety bred up from Minnesota King), Northwestern dent, Golden dent, Bloody Butcher, and Longfellow. Corn planted in drills 30 in. apart produced the tallest plants, measuring 5 ft. 9 in. Corn sown in ordinary wheat drills 6 in. apart and thick in the row reached a height of only 3 ft.

The yield of air-dry fodder, in 7 years' experiments, was greatest from planting in 6-in. drills. Corn planted in hills in rows 22 in. apart gave much better results than corn in rows 42 in. apart. The test of planting corn at different distances in the drill, the width between the drill being uniformly 3½ ft., showed that nearly 34 bu. of ear corn was obtained with the plants at 6-in. intervals in the row, and that the yield gradually decreased as the intervals between the plants increased. The results of a test of planting corn in hills show that where 6 stalks were grown in a hill a higher yield of both ears and fodder was obtained during 5 years than from thinner plantings.

The percentage of ripe corn in the last 2 seasons was regularly reduced when more than 2 stalks were grown per hill. It was also noticed that the ears were shortened as the thickness in the hill increased, the variation in length being from 4¾ to 6¼ in. The results from 4 years' work in planting corn in drill rows on different dates show that plantings made May 23 and 30 in 6-in. drills reached the silking stage, while in the later plantings no ears were formed. Planting in 42-in. drills gave much the same comparative results as those obtained in 6-in. drills, but there was a greater difference in the degree of maturity of the early and late-sown plats.

The results of different methods of cultivation tried this year were in favor of giving shallow cultivation early and deep cultivation late in the season. The average for 5 years shows the greatest yield of fodder from shallow cultivation.

The Edgeley Subexperiment Station, O. A. THOMPSON and J. H. SHEPPERD (*North Dakota Sta. Rpt. 1904, pt. 1, pp. 153–168*).—A general report on the work at the station in 1904. The plant-breeding nursery this season contained 19,500 individual plants, including barley, wheat, flax, buckwheat, millet, and oats.

The best yield of wheat, 35.2 bu. per acre, was obtained from Velvet Don, a durum variety. The best yield among the fife and blue-stem wheats was 13.9 bu., produced by Selected Powers and Selected 66 fife, and American blue stem. North Dakota emmer produced 67.9 bu. per acre, as compared with 65.3 bu. for Washington emmer and 60.1 bu. for Success, the best yielding variety of barley. Nine varieties of oats varied in yield from 27.5 to 85.7 bu. The best yielding varieties, in the order mentioned, were Silver Mine, Swedish Select, and Abundance, the last 2 producing each 79.2 bu.

In seed production Siberian and Selected Russian flax outranked Russian and Selected Riga, which produced the largest yields of straw. The best yields of corn fodder were secured from the following varieties: Minnesota Dent No. 13 3,630, Triumph 3,542, and Pride of the North 3,281 lbs. per acre. Of 15 varieties of potatoes Hammond Wonderful and Banner led in yield. Ten varieties of millet were tested, including Pencilaria and Japanese, both of which failed. The best yield was obtained from Red Orenburg, which produced 4,660 lbs. of hay per acre. An outline is given of a crop-rotation experiment carried on by the station, and work with brome grass and alfalfa is briefly noted.

Field experiments in Staffordshire and Shropshire and at the Harper-Adams Agricultural College (*Harper-Adams Agr. Col. Joint Rpt., 1904, pp. 1–10, 15–40*).—At the college fertilizer tests on 10 plats of meadow land showed that superphosphate was very active, and when given with sulphate of potash proved the most economical of the different applications in increasing and improving the herbage. Barnyard manure produced a coarse and rank growth of grass, and nitrate of soda gave no increase in yield. Among 12 varieties of oats Thousand Dollar ranked first in quality and Waverly in yield; and of 6 varieties of wheat Standard Red and Red Stand Up proved best in yield of grain and in quality of grain and straw.

Different fertilizer applications increased the yield of mangels, but produced a marked reduction in the sugar content. The largest yield was obtained with the use of barnyard manure, together with a complete dressing of commercial fertilizers. Yellow Globe, Yellow Intermediate, Golden Globe, Mammoth Long Red, Golden Tankard, and Sugar Mangel, given in the decreasing order of yield, stood first among 15 varieties, while in quality the order was approximately reversed. The dry matter in the different varieties varied from 10.35 to 13.33 per cent, and the sugar in the juice from 7.04 to 9.60 per cent. Sutton Sugar Beet grown in the test contained 20.17 per cent of dry matter and 13.86 per cent of sugar in the juice.

In studying the effect of premature seed production, or running to seed the first year of growth, it was found that normal roots contained 8.7 per cent of sugar, and roots which had run to seed 5.64 per cent. The age of the seed or injury to young plants did not seem to influence premature seed production. It was also noticed that the number of plants going to seed during the first year differed within the same variety. The character of the season was the only factor recognized with certainty, as it was observed that in dry and warm seasons the plants ripened quickly and showed a greater tendency to produce seed than in cold and wet seasons. In trials with swedes, Sutton Magnum Bonum and Garton Model ranked first in yield with over 23 tons per acre. A home-mixed complete fertilizer for this crop was much more economical than a ready-mixed fertilizer.

Cooperative experiments were carried out in Shropshire with potatoes and mangels. For potatoes a complete application of commercial fertilizers, either alone or with barnyard manure, proved most econominal. In a potato variety test Scottish Triumph, Royal Kidney, and Factor produced the highest yields. Scotch seed

potatoes produced much better yields than seed of the same varieties grown in the district the previous year. Whole tubers for seed gave a larger total yield than either sets with single eyes or plants from cuttings. The fertilizer tests with mangels showed a large increase in yield from the use of barnyard manure and commercial fertilizers. Of 6 varieties, Yellow Globe produced the heaviest weight of crop, but Golden Globe, Golden Tankard, and Sugar Mangel were superior to it in quality.

In Staffordshire cooperative fertilizer tests were made on grass land, and experiments were conducted with potatoes, mangels, and swedes. In the fertilizer tests on grass at Blurton 1 cwt. of nitrate of soda and 5 cwt. of basic slag per acre, applied singly, gave an increase of 5 cwt. of hay per acre, but when given together the yield was no greater than on the check plat. Barnyard manure produced a good increase, but was not profitable. At Knightley 10 tons of barnyard manure gave a large increase in yield, but the quality of the grass was reduced. The next largest increase was obtained with 3 cwt. of kainit and 1 cwt. of nitrate of soda per acre, and the same increase resulted where 5 cwt. of basic slag was given in addition. The use of 5 cwt. of basic slag alone per acre gave the increase at the lowest cost per cwt. of hay. The best results at Macr were secured from an application of barnyard manure, together with a complete dressing of commercial fertilizers.

Of 12 varieties of potatoes, Royal Kidney, Factor, and Up to Date gave the best yields and also ranked well in quality. In a fertilizer test the commercial fertilizers had little effect, and the heaviest yields were obtained from the use of 20 tons of barnyard manure per acre.

Memoranda of plans for arid farm investigations (*Utah Sta. Circ. 3, pp. 29, dgms. 6*).—This circular contains outlines of the arid farm investigations for 1905 on the 6 experiment farms established under the direction of the State legislature, and gives complete instruction with reference to conducting the experiments and to the management of the farms in general.

Effects of manures throughout rotations of crops, D. A. GILCHRIST (*County Northumb. Ed. Com., Bul. 3, pp. 15-22*).—Fertilizer experiments were conducted on a light sandy loam soil throughout 2 courses of a rotation.

In the first rotation turnips, oats, hay, and oats, and in the second, swedes, barley, hay, and oats were grown, in the order named. The standard application of commerical fertilizers per acre consisted of 1 cwt. of sulphate of ammonia, 5 cwt. of superphosphate, and 1 cwt. of muriate of potash, containing 25 lbs. of nitrogen, 75 lbs. of phosphoric acid, and 50 lbs. of potash, and the application of barnyard manure of 10 tons per acre.

Barnyard manure was of greater value than commercial fertilizers, but both were satisfactory. Where the 2 were used on the same plat it was found best to apply the manure to the swedes and to use the commercial fertilizers for the hay. Twenty tons of barnyard manure did not prove profitable, and doubling the quantity of commercial fertilizers was of benefit only when divided between the swedes and the hay. The omission of potash nearly obliterated the gains obtained from the application of commercial fertilizers. The use of 10 tons of barnyard manure made up the deficiency of potash in this soil.

Forage crops, E. R. LLOYD (*Mississippi Sta. Rpt. 1904, pp. 13, 14*).—Winter wheat was grown for hay and followed by cowpeas sown at the rate of 2 bu. per acre. The cowpeas came up with Johnson grass and gave 2 cuttings. The yield of hay from peas and wheat was 3.85 tons per acre, obtained at a cost of $3 per ton put into the barn. Oats were cut for hay in the dough stage and followed by Early Amber sorghum, sown at the rate of 2 bu. per acre.

Sorghum gave 2 cuttings, and the total yield for oats and sorghum was 6.25 tons per acre, costing $2.77 per ton in the rick. Two acres of alfalfa, which suffered to some extent from the lack of drainage, furnished pasturage for 14 pigs for 1 month

and yielded 6,541 lbs. of hay. Soy beans planted in April in rows 3 ft. apart and cultivated twice yielded 1½ tons of cured hay per acre.

Wyoming forage plants and their chemical composition—studies No. 1, H. G. KNIGHT, F. E. HEPNER, and A. NELSON (*Wyoming Sta. Bul. 65, pp. 52, pl. 1, figs. 18*).—The forage conditions of Wyoming are briefly discussed, and the botanical and general description and the analyses of green and air-dry substance of the following plants are given: Western wheat grass (*Agropyron occidentale*), northern wheat grass (*A. dasystachyum*), bearded wheat grass (*A. caninum*), slender wheat grass (*A. tenerum*), western couch grass (*A. pseudorepens*), Indian millet (*Eriocoma cuspidata*), yellow spear grass (*Poa lucida*), Buckley spear grass (*P. buckleyana*), rough fescue (*Festuca scabrella*), squirrel-tail grass (*Hordeum jubatum*), native hay, alfalfa (*Medicago sativa*), fringed brome grass (*Bromus ciliatus*), alkali meadow grass (*Puccinellia airoides*), Nelson needle grass (*Stipa nelsonii*), tufted hair grass (*Deschampsia cæspitosa*), Bodin vetch (*Astragulus bodini*), pretty milk vetch (*A. elegans*), woodland hedysarum (*Hedysarum philoscia*), winter fat (*Erotia lanata*), wire grass or Baltic rush (*Juncus balticus*), Nuttall saltbush (*Atriplex nuttallii*), tumbling saltbush (*A. volutans*), Australian saltbushes (*A. semibaccata*, *A. halimoides*, and *A. holocarpa*), and sweet or Bokhara clover (*Melilotus alba*).

[Experimental work upon weeds and forage plants], L. R. WALDRON (*North Dakota Sta. Rpt. 1904, pt. 1, pp. 56–64*).—This study on the vitality of weed seeds is in continuation of previously described work (E. S. R., 16, p. 882).

In 1899 a quantity of weed seeds was buried at different depths to ascertain the effect of this treatment on germination. In June, 1904, samples of these seeds were dug up and tested. Over 200 seeds of French weed showed no germination at first, but when dried and tested again 3 months later nearly 90 per cent grew. Green foxtail seeds buried 5 in. gave a germination of 8⅓ per cent, and seeds buried 10 in. deep, 6⅔ per cent. Of 15 seeds of Kinghead buried 10 in. deep 4 germinated, while of the shallow seedings no growth was obtained. Wild mustard gave the following results from the different depths: Three inches 26⅔ per cent, 5 in. 16, 7 in. 27, and 10 in. 11 per cent. Wild buckwheat and wild oat seeds all decayed.

In some special observations on the French weed the following 3 classes of seed were studied: Seed gathered with grain and sown with it the following spring, seed from winter annual plants which falls to the ground in June, and seed from spring plants which falls to the ground in July. Not any of the seed germinated until September, which allows the plant to develop sufficiently to live over winter. It is concluded that this weed is pernicious only as a winter annual, and that proper harrowing before seeding and plowing the land in the spring will reduce its prevalence. Observations on peppergrass (*Lepidium apetalum*) and tumbling mustard (*Sisymbrium altissimum*) led to the same conclusion.

The relative aggressiveness of different weeds was determined by sowing on May 10, 1904, 800 seeds each of 6 different species—Russian pigweed (*Axyris amaranthoides*), tumbling mustards, wild mustard (*Brassica arvensis*), French weed, false flax (*Camelina sativa*), and ball mustard (*Nesla paniculata*). On July 19, when the plants had attained their maximum size, there were found 520 plants of false flax, 356 of wild mustard, 281 of Russian pigweed, 195 of ball mustard, 24 of French weed, and 3 of tumbling mustard.

The results of spraying weeds with different solutions indicated that Thistleine, a preparation for the destruction of weeds, has no special value over sodium arsenite or copper sulphate. The cost of this substance is also much more than either of the other chemicals. It is stated that if Canada thistles are killed by spraying, this is caused by the destruction of the foliage and not by a distribution of the poison through the plant. It was observed that a relatively long period of time elapses after spraying before the thistles again begin to grow, and this is considered as possibly

due to the surface of the ground retaining some of the poison. Quack grass was not very much affected by the use of any of the solutions.

Observations made on the growth of wild oats showed that the seed was ripe enough to grow 85 days from seeding and 8 days after blossoming. The ripe seed fell to the ground 15 days after blossoming, or 92 days from seeding. The author calls attention to the fact that since wheat at the station requires 100 days to reach maturity, the wild oats are certain to reseed themselves before the wheat harvest.

An inspection of grass and clover seed, L. R. JONES and W. J. MORSE (*Vermont Sta. Rpt. 1904, pp. 402-417, 533-546, figs. 2*).—Samples representing 735 lots of seed were secured by the station from dealers in all parts of Vermont, and the examination of the samples as to purity and germination were made by the Seed Laboratory of this Department and the results obtained are given for each sample. A summary of the examination is shown in the following table:

Purity and germination tests of grass and clover seeds collected in Vermont.

Seed.	Number of samples.	Agricultural Department standards.		Average purity of samples.	Average germination of samples.	Samples below standard of purity.	Samples below standard of germination.
		Purity.	Germination.				
		Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Timothy	222	98	85.90	98	88.0	32	23
Redtop	83	....	....	80	87.0	....	....
Kentucky blue grass	8	90	45.50	63	55.0	....	....
Orchard grass	11	90	....	55	56.0	100	....
Meadow fescue	1	95	85.90	92	46.0	....	....
Millets	103	99	85.90	96	90.0	....	....
Red clover	134	98	85.90	91	87.0	91	24
Mammoth red clover	30	98	85.90	90	85.0	98	12
Alsike clover	105	95	75.80	85	77.0	90	27
White clover	14	95	75.80	86	59.0	100	57
Crimson clover	4	98	85.90	96	12.0	....	....
Alfalfa	10	98	85.90	91	79.0	90	70
Rape	1	99	90.95	94	98.5	....	....

Nine lawn grass mixtures contained 86 per cent of pure grass and clover seed. The value of the samples of seed as a whole was reduced by a considerable amount of inert foreign matter, dirt, chaff, etc., by the occurrence of weed seeds and of foreign seeds of various kinds having more or less agricultural value, and by the low germination shown in various cases. Methods of testing seeds are briefly described, and some of the more important State laws regulating the sale of agricultural seeds are summarized, the Maine law being given in full.

Grain score cards, J. H. SHEPPERD (*North Dakota Sta. Rpt. 1904, pt. 1, pp. 147-152*).—Outlines of the score cards used at the college in judging corn, wheat, oats, and barley are given.

Variety tests of wheat, oats, and potatoes, G. C. WATSON and A. K. RISSER (*Pennsylvania Sta. Rpt. 1904, pp. 183-196*).—The results of variety tests with wheat have been noted from another source (E. S. R., 16, p. 364). The varieties of oats and potatoes were grown on plats similar to those described for wheat.

Twenty varieties of oats were sown at the rate of 8 pk. per acre on April 20 and harvested August 5. The yields of grain ranged from 47.52 to 64.60 bu. per acre. The leading varieties, Czar of Russia, Japan, and Silver Mine, yielded 64.60, 63.66, and 63.09 bu. per acre, respectively. Long White Tartar led in weight per bushel, with 33.41 lbs. The heaviest yield of straw per acre, 3,447 lbs., was produced by Japan. This variety, under test for 13 years, has given an average yield of 49.66 bu. per acre. Among 4 varieties grown for 6 years Mortgage Lifter ripened about one week earlier than the others. From 1899 to 1903 White Maine, Fourth of July, and Heavy Weight Champion gave better yields of grain than Japan. Gold Giant Side and Czar of Russia stood first in yield among the varieties tested for 3 years.

In the potato tests for 1903 Carman No. 3 headed the list witn 270.2 bu., while White Mountain stood last with a yield of only 21.8 bu. per acre. The late varieties were much injured by blight, and this caused the low yield of White Mountain. Early Rose ranked second in total yield with 250.2 bu., and first in the production of marketable tubers with 221.2 bu. per acre. The largest proportion of marketable tubers was produced by Heath Medium Late Surprise and Heath Late Beauty, and the smallest proportion by New Bovee Seedling. The results for a series of years showed that Carman No. 1, Freeman, Enormous, Washington, White Giant, Hiawatha, Pride of Michigan, Extra Early Crusader, Heath Late Beauty, Heath Late Surprise, Heath Favorite, and White Mammoth have given good returns. A description of the varieties tested is given in tabular form.

Alfalfa in Vermont, J. L. HILLS and L. R. JONES (*Vermont Sta. Bul. 114, pp. 109–132, fig. 1, maps 2*).—This bulletin gives a description of the alfalfa plant, and presents notes on its culture, value, and uses. The results obtained by growing alfalfa in northern Maine, New Hampshire, northern New York, and Vermont, and the views of New England and Canadian experiment stations on alfalfa culture are briefly reported. Of 56 trials at as many different points in Vermont 12 were permanently successful. The best results in the State have so far been obtained in the Champlain Valley.

Improvement in the quality of barley in Austria, J. STOKLASA (*Ztschr. Landw. Versuchsw. Oesterr., 8 (1905), No. 1, pp. 1–69, pls. 7*).—The fertilizer requirements of barley are pointed out, the mechanical and chemical composition of some of the typical Austrian barley soils is described, and the results of experiments to determine the influence of the principal plant-food elements upon the quality of barley are reported. The experiments were conducted in the greenhouse and on the experiment field of the station, as well as by a number of farmers. A bibliography of books and articles relating to the subject is given.

The plants were grown on ordinary field soil and on fine sand, and the 3 essential plant-food elements were applied in combination in one series of tests and separately in others. The complete application increased the yield of grain 99.9 per cent and the yield of straw 58.7 per cent over the check tests. The use of phosphoric acid alone on the field soil gave an increase of 44.7 per cent of grain and 26.3 per cent of straw, and the use of potash salts also largely increased the yield. The grain from the pots receiving the complete application stood highest in starch content, with 76.52 per cent, and lowest in protein, with 10.18 per cent. Corresponding results were obtained on the fine sand. Chlorid of potash proved more effective than sulphate of potash.

In the series of pots receiving nitrate of soda alone the starch content ranged from 70.03 to 71.51 per cent, being about the same as in the check tests, while the protein content varied from 17.56 to 18.5 per cent. As compared with the no-fertilizer tests, nitrate of soda increased the yield of barley 38.4 and 29.7 per cent, and the yield of straw 45.1 and 55.5 per cent on the field soil and the fine sand, respectively. The increase in straw production due to the separate use of phosphate of lime, sulphate and chlorid of potash, and carbonate of lime and magnesia, ranged from 9.4 to 26.3 per cent on the field soil and amounted to 1.5 and 23.4 per cent for chlorid of potash and phosphate of lime, respectively, on the sand.

It is pointed out from these results that barley after sugar beets gives heavy yields of straw because the soil is well stocked with nitrogen, while the supply of phosphoric acid and potash is relatively low, and that by the application of these elements the yield of grain may be increased and that of the straw diminished.

A second experiment was conducted to determine the effect of potash salts on the development of plants. Soil samples from Aufinoves and Modian were used in pot experiments.

The pots were divided into 4 series of 10 pots each, one being the check series and the others receiving superphosphate and nitrate of soda, or superphosphate and chlorid of potash, or the 3 substances together. The check test with Auřinoves soil gave an average yield of 90.4 gm. of grain and 90.572 gm. of straw. The heaviest yield of grain, 142.549 gm., was obtained with the complete fertilizer, the yield of straw being 135.167 gm. Where phosphoric acid and potash were given the yield was increased to 128 gm., with a considerable increase in the starch content. This experiment indicates that although the soil was comparatively rich in available potash, the use of potash salts was beneficial.

In the case of the other soil, which contained less available potash, the check test yielded on an average 80 gm., the series of pots receiving superphosphate and chlorid of potash 178 gm., and the series with the complete application 188 gm., or a difference of 10 gm. apparently due to the nitrate of soda. It is concluded that leaching the soil with solutions of citric and oxalic acid points out whether or not potash may be profitably applied to the soil in barley culture.

In the check tests on both soils the proportion of hulls ranged from 11.37 to 12.86 per cent, and in the superphosphate and nitrate of soda series from 10.94 to 11.89 per cent; but when chlorid of potash was given in addition to the superphosphate it ranged from 8.64 to 10.04 per cent, and with the complete application, from 9.2 to 10.53 per cent. The starch content varied from 66.82 to 70.22 per cent in the check test, and where superphosphate was used, from 68.84 to 70.14 per cent; but when chlorid of potash was added it varied from 72.34 to 73.88 per cent. With the complete application a starch content of 72.85 to 74.10 per cent was recorded. The protein content of the barley was considerably increased by the use of nitrate of soda. In the superphosphate and nitrate of soda series of pots it varied from 12.35 to 12.73 per cent, but the application of chlorid of potash reduced it.

In the cooperative field experiments different combinations of superphosphates, nitrate of soda, and kainit at the rate of 250, 200, and 300 kg. per hectare, respectively, were applied. The results showed that 1 gm. of assimilable potash produced from 23 to 25 gm. of starch, and that the quality of brewing barley can be improved by supplying potash and phosphoric acid in the fertilizer, especially when the soil is rich in nitrogen compounds or when nitrate of soda is applied.

Analysis of individual stalks of corn, E. F. LADD (*North Dakota Sta. Rpt. 1904, pt. 1, p. 31*).—Analysis of 2 successive generations of 2 corn plants are given. The 2 lots of corn from the same parent seed showed a protein content of 14 and 14.5 per cent in 1903 and of 16.06 and 15.38 per cent in 1904.

The work on flax, H. L. BOLLEY (*North Dakota Sta. Rpt. 1904, pt. 1, pp. 64, 65, pls. 3*).—This is a progress report on the work with flax, consisting of a comparative study of varieties and a test of their resistance to the wilt disease. The development and maintenance of immunity to the disease is described.

Fertilizer experiments with hemp, KUHNERT (*Mitt. Deut. Landw. Gesell., 20 (1905), No. 14, pp. 99, 100*).—In 2 tests barnyard manure was applied alone and together with different combinations of Thomas slag, kainit, and nitrate of soda in quantities of 30, 25, and 15 kg. per hectare, respectively.

Given in addition to the manure, each substance by itself produced an increase in yield, but the best and most profitable returns were secured with the complete application. On the barnyard manure plats the average yield amounted to 1,890 kg. and on the plats receiving the complete application of commercial fertilizers in addition to 2,240 kg. of hemp per hectare. No difference in the quality of the fiber from the various plats was apparent.

The potato and its culture, W. T. MACOUN (*Canada Cent. Expt. Farm Bul. 49, pp. 48, pls. 2, figs. 6*).—This bulletin briefly notes the importance of potato culture in Canada, reviews the history of the plant and its improvement, summarizes the

experimental work with the crop at the Central Experimental Farm, and gives general directions for its culture.

The 12 most productive varieties grown at this farm for 5 years are as follows: Dr. Maerker, Late Puritan, Burnaby Mammoth, Money Maker, Carman No. 1, Dreer Standard, Sabean Elephant, Canadian Beauty, Rural Blush, I. X. L., Pearce, and Clay Rose. The 6 most productive early varieties for 5 years were Irish Cobbler, Early Elkinah, Vick Extra Early, Rochester Rose, and Rawdon Rose.

Some of the earliest varieties are Early Snowball, Eureka Extra Early, Burpee Extra Early, Rochester Rose, Bliss Triumph, and Early Ohio; and the 12 varieties freest from blight are Dr. Maerker, Late Puritan, Burnaby Mammoth, Carman No. 1, Dreer Standard, Sabean Elephant, Rural Blush, Clay Rose, Rose No. 9, Holborn Abundance, State of Maine, and Swiss Snowflake. From 1887 to 1905 about 844 varieties have been tested at the Central Experimental Farm.

In a 3-year test of growing potatoes after clover an average increase of 37 bu. per acre was obtained, as compared with growing potatoes without the use of clover. For fertilizing the land for potatoes the author recommends the use of a moderate quantity of barnyard manure applied on the clover in the fall, or of well rotted manure used in the spring, or if commercial fertilizers are used, an application of 500 to 800 lbs. or more per acre in the proportion of 250 lbs. of nitrate of soda, 350 lbs. of superphosphate, and 200 lbs. of sulphate or muriate of potash. An increase of 40 bu. per acre was obtained in a crop cultivated 6 times as compared with one cultivated only 3 times. In a 3-year test spraying with Bordeaux mixture apparently increased the yield 94 bu. The cost of growing an acre of potatoes yielding 300 bu. is estimated at $52.14.

Variety tests with potatoes in 1901–1904, G. MARTINET (*Ann. Agr. Suisse, 6 (1905), No. 5, pp. 179–198, figs. 2*).—The yields and descriptions of a large number of varieties of potatoes are given in tables. In 1902, 2 plants were selected for their productiveness and the quality of their tubers, but one was superior in yield and quality to the other. The seed of these 2 plants grown for comparison showed a difference in yield of 32.7 per cent in 1903 and of 41 per cent in 1904 in favor of the seed from the best plant.

Solanum commersoni and its variations at Verrières, LABERGERIE (*Ann. Sci. Agron., 2 ser., 10 (1905), I, No. 1, pp. 57–139, figs. 12; abs. in Jour. Agr. Prat., n. ser., 8 (1904), Nos. 51, pp. 803–807, figs. 4; 52, pp. 831–834, figs. 2*).—This is a report of work with *Solanum commersoni* and includes notes on observations made in cultural tests with this plant by other investigators.

Experiments have been in progress since 1901, and the results have shown that the characters of the primitive types are readily influenced by cultivation and selection. In very fertile friable soil, varying with the time the plants had been established, the yields ranged from 20,000 to 27,000 kg. per hectare and in sandy soils the yields, owing largely to the dryness of the soil, ranged from only 4,500 to 16,000 kg. per hectare. The plant grew well on dry soil, but produced very long stolons with the tubers from 20 to 30 cm. beneath the surface. The resistance to disease was good and the tubers showed perfect keeping qualities. Tubers grown in 1904 on fertile soil contained 19.91 per cent of starch and 72.59 per cent of water, and those grown on poor sandy soil 23.21 per cent of starch and 67.48 per cent of water.

Descriptions are given of variations observed in 1904, comprising varieties with yellow, white, and violet tubers. The violet variety appeared to be of value on fertile and humid soils, absolutely disease-resistant, very productive, and of good quality. A dozen plants this season produced tubers varying in color from almost white to a deep red. Six of these plants produced these variations, together with the violet tubers, on the same stolons.

Correlative changes in rye breeding on the basis of color in the grain, K. VON RÜMKER (*Fühling's Landw. Ztg., 54 (1905), No. 7, pp. 238–245*).—Experiments

in breeding Petkus rye by selecting differently colored grains for seed are briefly reviewed, and the results secured up to date are summarized.

Green-colored grains showed an indefinite transmission of the color, the progeny varying from green to a dull gray. As the dullness of the color in the kernel became more distinct the power of transmitting the color was apparently decreased. Yellow kernels did not readily transmit their color, but in some stools it was found to be very definite and showed regular progress. Bluish and brown veins were very strong in transmission of color.

Plants from short grains showed a marked reduction in the length of the straw. The longest straw was produced by the green-colored grains, followed by the blue, yellow, and brown kernels, mentioned in decreasing order. The green-colored grains produced a softer and looser straw than the other forms, while the straw from blue kernels was tough and hard. The best formed culms and heads were found in the plants from blue seed. In weight of grain the brown group stood last.

Data on the comparative winter resistance of the different strains, obtained only for the season of 1903, showed that the blue seed ranked first with 84.66 per cent, and the short seed last with 66 per cent of the stand secured in the fall.

Method of tobacco-seed selection, W. W. Cobey (*Maryland Sta. Bul. 103, pp. 225–235, figs. 4*).—This bulletin contains popular directions for the selection of seed plants in the field, and the method of bagging the flower heads and securing the seed. The work in tobacco-seed selection at this station is carried on in cooperation with the Bureau of Plant Industry of this Department.

Tobacco experiments, W. Frear (*Pennsylvania Sta. Rpt. 1904, pp. 30–39, pls. 12*).—The work here reported represents shelter-tent experiments with Sumatra leaf.

The site and the soil under which the experiments were conducted are described and the method of constructing the tent over one-half acre of ground, with the outlay involved, is given in detail. The planting, cultivation, harvesting, curing, and sweating of the crop are briefly discussed and the results are reported. The weight of the cured leaf produced was 856 lbs., which was reduced to 814 lbs. by sweating. The sorting of the leaf as to color and size gave the following results: First quality—light, 7.5 per cent; medium, 22 per cent; dark, 12.9 per cent. Second quality—light seconds, 18.6 per cent; dark, 13.5; trash, 25.5 per cent.

After the finishing sweat the tobacco was compared with Connecticut tent-grown Sumatra of the same season. There was no apparent difference in the quality of the 2 lots, neither of which was considered equal to the imported article. In the opinion of the author the results at present do not warrant the encouragement of this method of culture, but indicate the desirability of continuing the experiments in a more favorable season and possibly on lighter soil.

Experiments with fertilizers on tobacco, C. E. Thorne (*Ohio Sta. Bul. 161, pp. 213–228, figs. 2, dgms. 2*).—Notes on the establishment of a test farm in the Miami Valley to be devoted chiefly to work with tobacco are given, the plan of the fertilizer experiments inaugurated is outlined, and the results thus far obtained are reported.

In one series of experiments the tobacco is grown in a 3-year rotation with wheat and clover, and in a second series it is grown continuously on the same land. As the experiments have just been begun, only the most general conclusions are drawn. Barnyard manure proved very effective and profitable. Commercial fertilizers also produced a good effect, but the net gain was not so large as from barnyard manure.

The results show that the greatest total yield and net profit were produced by a fertilizer containing nitrogen, phosphoric acid, and potassium, in approximately the ratio to each other in which they are found in barnyard manure. The large quantity of nitrogen required in this application greatly increased the cost. As a carrier of nitrogen, nitrate of soda appeared much more effective than tankage.

Experiments in fertilizing tobacco, C. Dusserre (*Ann. Agr. Suisse, 6 (1905), No. 5, pp. 199–203*).—A cooperative study was made of the effect of sulphate and

carbonate of potash used alone or with superphosphate. The quantities used per hectare were as follows: Three hundred kg. of sulphate of potash; 246 kg. of carbonate of potash, in quantities furnishing 150 kg. of potash; and 500 kg. of superphosphate containing 75 kg. of phosphoric acid. A general dressing of barnyard manure was given at the first plowing in the spring.

In one of the tests superphosphate increased the yield of leaves, and sulphate and carbonate of potash also produced a small increase. A second test gave inconclusive results in this connection. The proportion of phosphoric acid in the leaves was not at all increased in one test and but slightly in the other by the use of phosphatic fertilizers. The lime content was slightly increased in the product from land fertilized with superphosphate.

The use of potash salts increased the potash content of the leaves. The superphosphate produced large leaves of good maturity and of good strength, while the influence of potash salts was less marked. In general, the fertilizers applied did not appreciably affect the burning quality.

Winter wheat, T. L. LYONS and A. KEYSER (*Nebraska Sta. Bul. 89, pp. 52, fig. 1*).—The results of variety tests of winter wheat in 1902, 1903, and 1904, conducted in cooperation with this Department, are described. Among the varieties tested 4 were from Hungary and a large number from Russia. Previous accounts of these varieties are recorded in a former bulletin (E. S. R., 14, p. 36).

The results in general indicate that the variety best adapted to Nebraska is Turkish Red, although Kharkof, one of the new Russian sorts, has proved hardier in the extreme northern part of the State. Several of the Hungarian varieties, although somewhat better in quality than Turkish Red, are later in maturing and consequently less productive. It is reported that these late-maturing Hungarian and Russian wheats are becoming earlier and may, therefore, be of value.

The observation of the station with reference to "yellow berry" in hard winter wheat has led to the conclusion that the chief causes of this condition are allowing the wheat to become overripe and the failure to stack the sheaves. As compared with the hard, red normal kernels, these kernels or "yellow berries" have a lower gluten content and are lighter in weight.

Tests of seed wheat from various sources resulted in the best yields in every case from locally grown seed of the same variety. In this test locally grown Turkish Red seed yielded better than imported Crimean for each of the 3 years tested. Turkish Red seed from western Kansas yielded nearly as well as Nebraska-grown seed and was of better quality during the dry years, but suffered more from scab or blight in 1903 and 1904.

The importance of good tillage was shown by growing very poor seed wheat on well-tilled land, which resulted in a yield of several bushels more per acre than the average of the county or State for each of 3 successive years. This favorable result is ascribed to the rotation of crops, the use of barnyard manure, and good tillage. In studying the effect of season and climate on the composition it was found that wheat stores up more nitrogen in the form of protein in dry seasons and more starch in wet seasons.

The yautias, or taniers, of Porto Rico, O. W. BARRETT (*Porto Rico Sta. Bul. 6, pp. 27, pls. 4*).—This bulletin gives a description of these plants in general and of the various types in particular.

The cultivated varieties of Porto Rico are classified under the following 6 types: Blanca, Manola, Amarilla, Martinica, Vino, and Violacea. The semicultivated varieties and the so-called false yautias are also noted. Cultural directions are given and the uses of the plant are described. The plant proportions of the principal varieties are reported as follows:

Proportions of different parts of the yautia plant.

Variety.	Leaves.	Root-stock.	Offsets.	Tubers.	
	Pounds.	*Pounds.*	*Pounds.*	*Pounds.*	*Per cent.*
Amarilla	7.25	2.5	4.25	1.5	10
Guayamera	4.5	2.0	1.75	2.5	21
Martinica	6.0	1.25	1.75	2.5	22
Rolliza	3.5	2.25	1.50	3.75	34

The composition of 2 samples of yautias determined at the Maine Experiment Station is compared with the composition of Irish potatoes and sweet potatoes in the following table·

Composition of yautias and potatoes.

Yautia and potato.	Water.	Protein.	Fat.	Total carbohydrates.		Ash.	Fuel value per pound.
				Sugar, starch, etc.	Crude fiber.		
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Calories.*
White yautia	70.0	1.7	0.2	26.3	0.6	1.2	529
Yellow yautia	70.0	2.5	.2	26.1	.6	.6	538
Irish potato	78.3	2.2	.1	18.0	.4	1.0	385
Sweet potato	69.0	1.8	.7	26.1	1.3	1.1	570

A sample of dried tubers of the Rolliza variety, analyzed by the Bureau of Chemistry of this Department, contained 29.17 per cent of starch and 62.25 per cent of moisture. This is considered an exceptionally high percentage of starch, but it has been found in experiments with this variety that 20 to 25 per cent of starch is readily obtained from fresh roots. The yield of starch per acre is estimated at from 8 to 15 tons, as compared with 5 to 10 tons for cassava. Yautias dried and ground yield about 30 per cent of flour at a cost of about 2 cts. per pound for the raw material. Less than 5 per cent of the gross weight of the yautia tuber is lost in peeling.

HORTICULTURE.

Report of the horticulturists, F. A. Waugh and G. O. Greene (*Massachusetts Sta. Rpt. 1904, pp. 157–167, dgm. 1*).—Reports are here given on plums and the pruning of peach trees.

The report on plums deals principally with the behavior of a large number of varieties grown at the station. Bradshaw has proved one of the best of the Domesticas grown, while Burbank, of the Japanese sorts, has proved the most profitable and productive market plum at the station.

Experiments were made in marketing plums in 3-lb. baskets such as are used for grapes. This proved a satisfactory package, as it furnished about the quantity of fruit desired by most purchasers.

Plums for canning were packed in Jersey peach baskets holding 16 qts. This proved a satisfactory, cheap, and convenient package. Most markets were found not to be fastidious with respect to the form of the package used for plums, and any small neat basket or box will answer if the fruit is of good quality and well packed.

In pruning experiments with peaches one row has been left for 9 years without pruning. These trees are quite open-headed and have generally assumed a vase form. The lower part of the main branches is bare and the fruiting wood is sparse, weak, and high up in the trees. The trees are much less thrifty and vigorous than

pruned trees of the same variety. As a result of this lack of vigor a number of trees succumbed to the cold during the preceding winter.

A row of trees next to this has been headed back moderately 2 or 3 times, as a result of which they are thick topped, with a good deal of weak, sappy growth on the inside. The annual growth, however, has been much more vigorous and the health of the trees better than those not pruned. More and stronger fruit buds have also formed. The main fruit branches are shorter and stronger and more capable of sustaining a large crop of fruit. The experiment is believed to show conclusively that the best form of peach tree can not be secured and maintained without pruning.

During the past 3 years a special experiment has been made in heading back peach trees in the spring. The conclusion reached relative to this work is that "the heading back of peach trees in early spring is good practice and in all cases advisable. In this pruning from one-third to two-thirds of the wood of the previous year should be removed," depending upon the number of living fruit buds on the 1-year-old wood. When from any cause there are no fruit buds advantage should be taken to cut back with comparative severity. Only in extraordinary instances, however, should the cutting extend back into 2 or 3 year old branches.

Some experiments were made in summer pruning peach trees. With early spring pruning it had been noticed that many weak and useless shoots grew in the center of the tree. It was thought that if a considerable quantity of the new leafy shoots on the outside of the tree were removed, thus admitting a reasonable amount of light to the inside of the tree top, some benefit might result.

"In no case were the results of this treatment convincing. The formation of strong shoots with fruit buds on the interior branches was never visibly promoted. The outside branches which were allowed to remain seemed to profit somewhat by the removal of their crowding neighbors, and this was apparently the chief benefit derived from the work. On the whole, it does not seem to us that this practice is to be greatly recommended."

Cutting back the young growth of the outside branches to correct overgrowth did not give satisfactory results. The stopping of the growing shoots was usually followed by the pushing out of side buds and shoots lower down which were nearly always too weak to set good fruit buds.

Considerable winter injury was sustained by peach trees in both 1903 and 1904. The damage was not serious in 1903, but in 1904 the trees were seriously weakened by freezing, and some were killed outright. In treating the injured trees one block was left entirely without pruning, another was pruned in midsummer after the trees had started; a third was cut back from two-thirds to three-fourths of the previous year's growth, and a fourth was headed back near to the trunk, only the stubs of the main branches being left. The following table shows the results:

Effect of different methods of pruning frozen peach trees.

Method of pruning.	Total number pruned.	Living autumn of 1904.	Dead autumn of 1904.	Living.
				Per cent.
Trees unpruned	121	113.0	8.0	93
Moderately cut back	48	47.5	.5	99
Severely cut back	68	55.0	13.0	81
Cut back to stubs	46	24.0	22.0	52

While a large number of the unpruned trees lived, the growth made by the headed-in trees which lived was much better than that made by the unpruned trees. It was the judgment of many who saw the trees that the trees moderately cut back showed the best growth and were in the best condition. The experiment is

also believed to point out that trees seriously weakened by freezing should not be cut back close to the main trunks.

Horticultural department, C. B. WALDRON (*North Dakota Sta. Rpt. 1904, pt. 1, pp. 171-178*).—An outline is given of the work of the year with vegetables, orchard and small fruits, trees, etc.

Special attention is called to the value of mulching orchard fruits as a means of preventing winterkilling. If a mulch is applied too early it induces a late fall growth. If not applied until the ground is frozen to some depth but little good is accomplished. For satisfactory results it should be applied before the ground begins freezing. It should be applied to a depth of about 6 in. and to a distance of 4 or 5 ft. from the tree. Where mulching is practiced some precaution must be taken to prevent injuries from mice. Wrapping the trees with burlap or with tar paper has given good results. Not only has mulching been efficient in preventing winter injury but the mulched trees also made 25 to 30 per cent more growth than unprotected trees.

Observations on the Hessian fly indicate that it is two-brooded. Macaroni wheat appears to be free from attacks of this insect.

Report of the horticulturist, W. STUART (*Vermont Sta. Rpt. 1904, pp. 418-445, figs. 6, dgms. 2*).—A general review of the work of the year

The peculiar behavior in the spring of many apple trees in different sections of the State is noted. These trees blossomed and partially or wholly leaved out, after which growth was arrested and the leaves withered and dried up. Later on most of the trees pushed out many new shoots at the base of the scaffold limbs or on the trunk just below their juncture with it. Careful examination of these trees by the author led to the belief that the injury was due to root killing caused by the abnormally cold winter of 1903-4. The trees most seriously injured were 8-year-old Rhode Island Greenings.

In the winter forcing of tomatoes tests were made of the relative earliness and productiveness of Sutton Best of All, New Stone, and Lorillard. Sutton Best of All gave a slightly heavier yield of ripe fruit for the first few pickings than New Stone, but over a period of 5 or 6 weeks the results were uniformly in favor of New Stone. "In one season's trial Lorillard proved superior in every respect to Sutton Best of All. Lorillard is apparently the earliest and most prolific for forcing purposes of the 3 varieties tested."

Investigations were also made as to the relative value of chemical fertilizers and rotted manure for tomatoes in winter forcing. "The average weight of large fruits for the 2 seasons was 90.4 gm. from chemical fertilizers and 92 gm. from rotted manure. On the same basis the average number of large fruits per plant from the chemical-fertilizer sections was 17.3 as against 18.3 from plants grown in rotted-manure sections. This shows an average gain in weight of fruit per plant of nearly 8 per cent in favor of the rotted-manure sections." The greatest number of large fruits early in the season was also secured from the section which had been fertilized with rotted manure.

The studies in indoor lettuce culture involved a comparison of different forms of chemical fertilizers and of chemicals and rotted manure for lettuce. The average yield of fruit per plant was as follows: Plat (1) fertilized with acid phosphate, nitrate of soda, and muriate of potash, 133 gm.; (2) acid phosphate, dried blood, and muriate of potash, 131 gm. (the comparison in these 2 instances being made between nitrate of soda and dried blood); (3) dissolved boneblack, nitrate of soda, and muriate of potash, 137 gm.; and (4) raw bone meal, nitrate of soda, and muriate of potash, 153 gm. Plats 3 and 4 are to be compared with plat 1, mentioned above, and with each other.

The results show that there is very little choice between dried blood and nitrate of soda as a fertilizer for this crop, while raw bone meal produced a decided increase in

the weight of the product. A soil liberally dressed with rotted manure gave slightly better results than commercial fertilizers. During 2 seasons comparisons were made between the yield of lettuce on surface-watered and subwatered sections. The results for the 4 crops grown during the 2 seasons are without exception in favor of subwatering, the average increase being about 15 per cent.

During the preceding winter a number of trees in the orchard were girdled by mice. The following spring many of these were bridge grafted by students in the junior class. Trees thus treated grew successfully, while untreated trees died. Illustrations are given of treated and untreated trees.

A test was made during the winter of the value of ether in forcing rhubarb. The rhubarb roots were dug in the fall and placed in a cold frame where they were subjected to the action of frost in the usual way. A part of 4 separate lots was etherized, the first lot, December 18–20; the second, January 9–11; the third, January 30 to February 1; and the fourth, February 24–26. Sulphuric ether was used at the rate of 10 cc. per cubic foot in all cases except with the third lot, where 17 cc. was used.

The first and second lots which were etherized gave results decidedly in favor of the process. The third lot, which received 17 cc. per cubic foot, was injured by the treatment, while the fourth lot was etherized so late in the season as not to show marked benefits from the treatment. The increased yields in lots 1, 2, and 4 were 34.4, 89.7, and 5.7 per cent, respectively, in favor of etherization, while in lot 3 the untreated plants gave an increased yield of 26.8 per cent over the etherized plants.

Considering only the 3 lots which are strictly comparable, the gain in favor of the etherized plants for the different pickings was as follows: First picking, 622 per cent; second, 86 per cent; third, 23 per cent; and fourth, 47 cent. These results show a decided increase in earliness and in weight of product due to etherization. It is believed that still better results might have been obtained had the work been undertaken a month or 6 weeks earlier. Forcing took place under the benches in the greenhouse in darkness.

The real Luther Burbank, E. J. WICKSON (*Sunset Mag., 15 (1905), No. 1, pp. 3–16, pl. 1, figs. 11*).—Besides an account of Burbank himself, his methods of work, and the results accomplished, the origin of some of his productions is noted.

The Burbank plum was a direct importation from Japan. The crimson winter rhubarb was imported from Australia. The sugar prune is a seedling of the prune d'Agen. The crimson California poppy was obtained by selection from the yellow California poppy. The improved "everlasting" flower was obtained from the star flower from Australia (*Cephalipterum drummondii*). This flower "has undergone selection for size and color of its paper-like bracts, until they have become large, rosy within and white without, and have similated the structure and texture of artificial flowers to such an extent that manufacturing milliners talk of its use by the million as serving the same end with much more grace and less cost than their cloth-and-wire creations."

The Wickson plum was produced by crossing Burbank and Kelsey. The stoneless prune was obtained by crossing an European species, "which has never been of horticultural value," with the French prune, followed by selection. The Shasta daisy was obtained by combining the moon daisy of Europe, the ox-eye daisy of America, and a species from Japan, and selection. The spineless cacti has been evolved by hybridization and selection between 5 species of opuntia.

Bud variation. Facts that prove its occurrence, O. W. BLACKNALL (*Country Gent., 70 (1905), No. 2717, p. 179*).—The author cites examples of bud variation with the Winesap apple, the Scuppernong grape, and the Wilson Albany strawberry. Having proved satisfactorily to himself that bud variation does occur, he suggests as a practical result in propagating fruit trees and all other plants by means of buds that the scions should be taken only from plants of highest productivity.

Asparagus growing in Arkansas, E. WALKER (*Arkansas Sta. Bul. 86, pp. 37–46*).—Asparagus is very little grown in Arkansas, only 1 acre being credited to that State by the United States Census of 1900, and the author believes it should be brought more extensively into use. Detailed directions are given for cultivating asparagus for the home and market, with suggestions for the control of insect pests and fungus diseases.

Asparagus and salt, E. WALKER (*Arkansas Sta. Bul. 86, pp. 31–36*).—In order to determine the value of salt in asparagus culture, one-half of a bed of 4 varieties of asparagus covering a total of one-seventh of an acre was fertilized with salt at the rate of 1,000 lbs. per acre.

The asparagus field was in its second year at the time the experiment was started. No cutting was done during that season, but as far as could be seen there was no appreciable effect of the salt upon the growth of the plants nor in preventing the growth of weeds. The following spring the portion of the plat which had received salt the preceding summer was again salted and this time at the rate of 2 lbs. per square yard applied in 2 equal applications at intervals of 20 days.

With each variety larger stalks and an increased yield were secured where the salt was applied, the average increase being 13.5 per cent in favor of the salted area. Not only was the growth increased in the spring, but there was also an increased vigor manifested in the plants throughout the summer, and a notably increased glaucous appearance in the salted plants. The salt was entirely effective in preventing the growth of weeds. On the salted area without any hoeing but few weeds appeared, and those late in the season. On the unsalted area weeds appeared in abundance as the season advanced.

The author believes that while the beneficial action of the salt may be attributed in part to its effect in preventing weeds, in the sandy soil, upon which the experiment was conducted, there was an effect and beneficial action beyond this. While in modern methods of field culture salt may not be especially useful, it is believed that for the small garden patch where intensive culture is practiced it may answer a very useful purpose, especially in keeping down weeds.

The author has used asparagus along division and back fences, where it serves the double purpose of ornament and use. In such locations he has also found salt beneficial.

Onions and bunch crops at Beeville, J. K. ROBERTSON and E. C. GREEN (*Texas Sta. Bul. 77, pp. 28, figs. 14*).—Experiments are reported on the culture of onions with and without irrigation, and of beets, radishes, lettuce, carrots, and turnips for bunching for the early market. With each crop tests of varieties were also made. The growing of early garden crops for northern markets is rapidly developing in south Texas.

Onions (pp. 4–14).—With this crop the seed was sown in beds and the onions transplanted to the field when they had attained suitable size. Thrips, which seriously affected the onions in the seed bed, were kept under control by spraying with whale-oil soap used at the rate of 2 lbs. dissolved in 6 gal. of water. At setting out time the tops of the onions were trimmed to about 5 in. and the roots cut back to about 0.75 in. Eight cultivations were given. In addition the unirrigated plat received one hoeing.

Level cultivation was practiced and at no time was it deeper than 1.5 in. The irrigated plat received 4 irrigations in addition to the preparatory one which was given to both irrigated and unirrigated plats alike. A mixed fertilizer containing 5 per cent nitrogen, 6 per cent phosphoric acid, and 9 per cent potash was applied at the rate of 500 lbs. per acre and worked in each side of the row in March.

On one-twentieth of an acre the irrigated plat yielded 1,928 lbs., of which only 2 lbs. were unmarketable. The unirrigated plat of the same area yielded 987.4 lbs., of which 12 lbs. was unmarketable. These yields are at the rate of 676.5 bu. and 350

bu. on the irrigated and unirrigated areas, respectively. The onions sold at Beeville for 2 cts. a pound. The net profits from one-twentieth of an acre with irrigation was $33.45 and from the unirrigated plat $15.69. All of the expenses, such as cost of preparing land, irrigating, transplanting, cultivating fertilizing, harvesting, sacking, seed, etc., are shown in tabular form. The variety used was the Red Bermuda.

It is believed that the results secured in these tests with irrigation would have been greater had the irrigating facilities been more efficient. At times the onions suffered from lack of moisture. In the variety tests 19 varieties were compared. The Bermuda again proved superior in point of earliness and yield. Brief descriptions are given of the different varieties tested.

Beets (pp. 15–20).—The beet is the favorite bunch crop of south Texas truckers. The crop requires from 80 to 90 days to reach marketable size from the time the seed is sown. With good culture two crops can be grown between October and May.

In the station experiment bat guano was used broadcast at the rate of 500 lbs. per acre when the land was prepared. Six irrigations and 9 cultivations were given. Frost and ice occurred 12 times during the months of January and February, but the freezes were not sufficiently severe to seriously injure the crop, though they did retard growth. The bunches were shipped in ventilated barrels without ice. From 19 to 25 doz. bunches were packed in each barrel, the tops toward the center. Details are given as to the cost of each of the different operations in the growing of the crop and the length of time employed.

The crop was marketed in Kansas City and St. Joseph, Mo. In March and April they brought 40 cts. per dozen bunches and in May 25 cts. The net returns from the sale of beets grown on one-tenth of an acre was $67.51 and the cost of production $13.28, leaving a profit of $54.23. The authors state that a net profit of $500 per acre for a single crop of beets is within the range of possibility in that section.

Variety tests indicated that the Electric variety can be most safely recommended. Crimson Globe and New Meteor of the newer varieties are considered especially promising. Details as regards date of planting, period of growth, productivity, etc., are given for 12 varieties grown in the test and these varieties are briefly described.

Radishes (pp. 20–25).—Three profitable crops of radishes can be grown during the fall and winter seasons in the vicinity of the station. From one-tenth of an acre 169 doz. bunches were sold, each bunch containing from 12 to 16 radishes. The cost of growing one-tenth of an acre of radishes was $5.60. The radishes sold for $39.27, leaving a net profit of $33.67. Exclusive of the radishes sold, about 1.5 bbls. were destroyed by a severe frost on the night of January 25.

In shipping radishes they are packed in unventilated barrels in concentric circles with the tops toward the center of the barrel. When the barrel is about one-third full of radishes a layer of crushed ice is put in. A second layer of ice is added when the barrel is two-thirds full of radishes, and the final layer when the barrel is nearly full. The ice is broken up so that none of the lumps is larger than a hen's egg. About 50 lbs. of ice is used per barrel. Enough radishes are heaped on the top layer of ice so that when the barrel arrives at its destination it is about level full with the radishes.

Twenty-eight varieties were grown in the variety test. The turnip-rooted varieties are considered the most desirable for the western markets. Of these Scarlet White Tipped is the most popular on account of its attractive appearance. The test indicated that Round Scarlet Chinese and Icicle are worthy of trial for the kitchen garden, as they were of the best table quality. All of the long-rooted varieties except Market Gardener Long Scarlet, Chartier, and Early Short Top Long Scarlet became pithy or hard and woody before reaching a suitable market size, the last two mentioned being recommended when a long-rooted sort is wanted.

Lettuce, carrots, and turnips (pp. 26–28).—The cultural tests with these crops failed, but the results secured in tests of 21 varieties of lettuce are recorded with brief

descriptions of the varieties tested. All the varieties of lettuce suffered from lack of water and insufficient fertility and none of the plain-leaved varieties headed up satisfactorily. "The crinkled and loose sorts made the best heads and were slower to run to seed." Rice birds destroyed the carrot crop. Of the 16 varieties of turnips tested the Purple Top White Globe and the White Dutch Strap Leaf are recommended to truckers as of market value. The Purple Top Flat Strap Leaf and Extra Early White Milan are also considered satisfactory.

Rhubarb in Arkansas, E. Walker (*Arkansas Sta. Bul. 86, pp. 47–52*).—Rhubarb has been grown at the station for the past 4 years with excellent results. It does not thrive in the warmer parts of the State, but has been grown successfully at elevations of 1,500 ft. It is believed that it can be successfully grown over a large part of northern Arkansas where suitable soils can be found. Popular directions are given for growing the crop out of doors and for forcing.

Pruning; wounds and their treatment; pruning tools, H. H. Hume (*Bul. N. C. Bd. Agr., 26 (1905), No. 1, pp. 31, figs. 30*).—Right and wrong methods of cutting off limbs in pruning are described and illustrated, and a discussion given of when to prune and how to treat the wounds made in pruning. Illustrations and descriptions are also given of pruning tools, with estimates as to cost and directions for their use.

Nitrate of soda as a fertilizer for fruit trees, B. Trenkner (*Gartenwelt, 9 (1905), No. 27, pp. 313–316, figs. 4*) —An account is given of the increased yield of cherries and apples secured when nitrate of soda was used as a fertilizer.

Illustrations are given which show graphically the difference in yield when this fertilizer was employed and when it was omitted. The author has applied as much as 500 lbs. per acre without injurious results Injury to fruit trees through overfertilizing with nitrate of soda first shows itself in the youngest shoots, which turn brown, wrinkle up, and look as though they were burned.

As a result of 10 years' experience in the use of this fertilizer in connection with potash and phosphoric acid fertilizers the author holds that not only is the nitrate beneficial and profitable, but for those who would secure the greatest returns it is indispensable.

A straw mulch in the orchard, U. T. Cox and W. J. Green (*W. Va. Farm Rev, 13 (1905), No. 4, p. 18; reprinted from Stockman and Farmer*).—An account is given of mulching 250 apples trees with straw.

Eight tons of straw costing at the rate of $9.50 per ton were used. About 25 trees were left unmulched for comparison. The fall season was very dry, there being but very little rain from the middle of August until December. The mulched fruit was increased considerably in size and the percentage of first-grade fruit increased about 14 per cent by the use of the straw. As a result of the better appearance and higher grade of the mulched fruit, it is estimated that it would bring 25 cts. more per barrel than the unmulched fruit.

"The color was much better where mulched, as the dry weather caused the leaves to fall from the unmulched trees before the fruit fully matured in some cases. The gain in number of barrels and increased size of fruit was about $135, and if that extra 25 cts. per barrel be added would make it $235 gain, and probably half the value of the mulch remains for future crops. . . .

"Some of the fruit from the unmulched trees looked dead, felt spongy, and was tough, while that from the mulched trees was bright, crisp, and solid. The mulched trees seem to be in condition to bear next year and the others are not likely to bear for 2 years. The drops are clean and not bruised where there is a good mulch, will keep, and are worth more than those from rocky bare ground. The variety was nearly all Rome Beauty in the tests, and all that were counted were of that variety."

Plums in South Dakota, N. E. Hansen (*South Dakota Sta. Bul. 93, pp. 88, pls. 16, fig. 1*).—An account of plums and plum growing in South Dakota.

Plums of large size and good quality can be raised in abundance in all the farming regions of South Dakota and in the grazing regions wherever irrigation can be had. The only varieties which succeed, however, are native kinds. Of the hundreds of varieties which have been brought from Europe, Japan, China, Persia, other parts of Asia, and from the Gulf and Atlantic regions of the United States all have proved unsuitable owing to the vicissitudes of the climate. The varieties which succeed best are those which have been developed from the native sorts which grow in the region from Iowa and Nebraska northward through Minnesota, Wisconsin, the Dakotas, Manitoba, and Assiniboia.

Historical notes and brief descriptions are given of 83 named varieties of plums and of a number of seedlings. The fruit of many of these varieties is illustrated. A discussion is given of different sorts of stocks for plums and plum propagation, cultivation, marketing, and breeding, with notes on the culinary uses of plums.

Keeping apples, J. C. M. JOHNSTON (*Country Gent., 70 (1905), No. 2732, p. 538*).—To keep apples successfully over winter the author states that the storage room should be cold to prevent rot, damp to prevent wilting, and dark to prevent ripening. Cellars which have water on the floor from September to June are considered best for apples. In the fall the cellar windows should be left open on cool nights and not closed permanently until there is danger from freezing. A cellar temperature of about 30° F. is advocated.

Small fruits in 1903, J. P. PILLSBURY (*Pennsylvania Sta. Rpt. 1904, pp. 253–262*).—This work with small fruits is in continuation of that previously reported (E. S. R., 16, p. 773) and deals with the yields of strawberries, gooseberries, and currants at the station.

The wide-matted row and hill systems of strawberry culture which have previously been observed at the station have been changed to the narrow-matted row with better results. The berries in the narrow-matted row are of a more uniform size and the percentage of small ones is decreased. The principal factor influencing the crop of strawberries is the amount of rainfall in May and June, especially in the former month. A lack of rain, however, can be partially overcome by the use of a mulch and thorough cultivation.

By these methods at the station berries were secured in spite of dry weather long after local dealers were able to obtain fruit from other sources in the neighborhood. A table is given showing the sex, fruiting season, freedom from disease, vigor, yield, etc., of a large number of varieties.

The ferment of the tea leaf, III, H. A. MANN (*Indian Tea Assoc. [Pamphlet 2], 1904, pp. 12*).—In the present report experiments conducted on a practical scale are cited which confirm the results given in the two former reports (E. S. R., 15, p. 451) relative to the dependence of the fermentation upon an enzym, and the relation of the quantity of this enzym to the quality of the tea.

Data are given showing more exactly the time required for the best results in withering when the temperature is high, low, and medium, and when the atmosphere is dry or wet. Relative to the latter the table below is given, which shows the maximum time required for the greatest development of enzym in the withering leaves at different temperatures under normal conditions and in a saturated atmosphere:

Maximum time required for the greatest development of enzym in tea during withering.

Temperature range.	Time required under normal withering conditions.	Time required with saturated atmosphere.
78–84° F.	Not exceeding 22 hours	Not exceeding 25 hours.
78–88° F.	Not exceeding 18 hours	
80–90° F.	Not exceeding 16–18 hours	Not exceeding 18–21 hours.
84–92° F.	Not exceeding 14.5–16.5 hours	Not exceeding 18.5 hours.

The figures in the table were obtained with Assam leaf. "Given normal withering conditions, the leaf should be so spread as to be physically ready for rolling in approximately the times indicated in the first column above. If, on the other hand, the atmosphere is so saturated that withering does not take its usual course, the chemical condition of the leaf will begin to deteriorate after approximately the times given in the second column of the above table. Whether the manufacturer will find it of advantage to leave his leaf longer than this before manufacture, in the hope of getting leaf in better condition for rolling, is a matter for him to settle, but if he does so leave it it is at the cost of losing some of the quality of the tea produced."

Some attention has been paid to the changes other than that of the enzym in tea during withering, and it has been shown that the total soluble constituents of the tea leaf are considerably increased by withering. Attention is called to the desirability of sterilizing with boiling water the vessels used in handling the leaf, as well as the racks and rollers in the factory, if the best quality of tea is to be produced.

Earlier experiments seemed to indicate that the enzym of tea was not destroyed during fermentation by the presence of salicylic acid, but further work indicates that "its use always brings about a thinner liquoring tea than otherwise, and this has now been explained by the discovery that the ferment was slowly destroyed by its action. Twenty hours, as a matter of fact, after the addition of salicylic acid to a strong solution of the tea ferment, all the latter had disappeared."

Growing chrysanthemums for a retail trade, F. CANNING (*Massachusetts Sta. Rpt. 1904, pp. 168–172*).—Directions are given, based on the work in the college greenhouse, for growing chrysanthemums for a retail trade.

The culture of chrysanthemums is discussed and the varieties most suited for this purpose are mentioned and described. Methods of using the score card in connection with the judging of chrysanthemums are included. As to the merits of solid beds or benches the author's experience is in favor of solid beds. The soil used for benches and pot plants is a good turfy loam composted the previous fall or in the early spring of the same year. To 3 parts of this soil is added 1 part of well-rotted manure and about a quart of bone meal to each barrowful of compost.

FORESTRY.

Trees, a handbook of forest botany, H. MARSHALL WARD (*Cambridge: Univ. Press; New York: The Macmillan Co., 1904, vol. 1, pp. XIV + 271, figs. 137; vol. 2, pp. X + 348, figs. 125; 1905, vol. 3, pp. XII + 402, figs. 143*).—This series of volumes is designed to furnish students of forest botany with a guide to the study of trees and shrubs, and will be found useful to the amateur who wishes to know something of the trees and shrubs about him, and to the technical student as well. The language is not unnecessarily technical, and the books will serve as an introduction to the more modern methods of systematic botany and morphology. The author seeks to encourage first-hand acquaintance with trees in their natural surroundings, which requires a knowledge not only of the characters usually employed by systematists but also of buds, twigs, leaves, seeds, seedlings, etc., which are commonly disregarded in all but special treatises on the subjects.

The volumes already issued bear the titles Buds, Leaves, and Flowers and Inflorescences, and the succeeding volumes will treat of Fruits and Seeds, Seedlings, and Habit and Conformation of Trees. At the end of each volume keys will be given for use in the field, each series being based upon the characters treated in the volume.

Forest preservation and national prosperity (*U. S. Dept. Agr., Forest Serv. Circ. 35, pp. 31*).—This circular contains portions of addresses delivered at the American Forest Congress, held in Washington, January 2–6, 1905, by President Roosevelt, Ambassador Jusserand, Secretary of Agriculture Wilson, and others.

European study for foresters, T. S. WOOLSEY, Jr. (*Forestry and Irrig.*, *11* (*1905*), *No. 6*, *pp. 160–163*).—The desirability and advantages of a few months' study and observation in the forestry schools and state forests of Germany, France, and India are discussed.

The forest flora of New South Wales, J. H. MAIDEN (*Sydney: Govt.*, *1905*, *pt. 16*, *pp. 125–140*, *pls. 4*, *fig. 1*).—Botanical descriptions, with the local names, and an account of the propagation and timber uses of the weeping myall (*Acacia pendula*), *Eucalyptus amygdalina*, forest oak (*Casuarina torulosa*), and the ivory wood (*Siphonodon australe*).

Timber resources of Liberia, E. LYON (*Mo. Consular Rpts.* [*U. S.*], *1905*, *No. 296*, *pp. 135–138*).—Attention is called to the opportunities in Liberia for hard-wood lumbering. The principal woods are mahogany, oak, cedar, rosewood, mangrove, burrwood, white and black gum, mulberry, brimstone wood, red peach, pepper wood, persimmon, iron wood, greasy peach, poplar, cherry, hickory, saffron, ebony, etc.

It appears that there are no efficient sawmills now operating in Liberia, and that most of the imported lumber is not adapted to the climatic conditions or to resist the attacks of destructive insects, which devour an ordinary house built out of foreign pine in less than a year. Locations suitable for sawmills are pointed out, and estimates given as to probable cost of installing.

Planting red pine (*Forestry and Irrig.*, *11* (*1905*), *No. 5*, *pp. 235–238*).—The red or Norway pine (*Pinus resinosa*) is said to be a light-demanding species. It bears less shade than white pine but more than the jack pine.

In a natural seeding on sandy soil the red pine grew 0.97 ft. per year for the first 15 years, while jack pine grew 1.32 ft. For the first 50 years it is stated that the jack pine grows fastest, red pine second, and the white pine last. The white and red pine live from 280 to 310 years, while the jack pine rarely exceeds 90 years.

The red pine is generally propagated from seed which fall from the cones the same year they mature. The seed appears to be borne at intervals of 2 to 4 years. A pound of red pine seed contains about 40,000 seeds, of which about 80 per cent should germinate under favorable conditions. The seed when planted in drills is sown at the rate of $\frac{1}{8}$ to $\frac{1}{28}$ oz. per running foot, or from $\frac{1}{4}$ to $\frac{1}{7}$ oz. per square foot. When seeded broadcast the average number of seedlings per running foot the first year varies from 16 to 22, and the second year from 8 to 10.

Seed is sown early in the spring in about the same manner as white pine, but less shade is required. The best stock to plant is 2-year-old seedlings. On poor soil plants may be spaced 5 ft. apart each way, while on richer soil it is best to make the spaces wider. A number of examples are given showing the growth of red pine in comparison with white pine in different plantations.

An instance is cited in which red pine seeds were accidentally planted with jack pine seed in Nebraska. The following winter all the jack pine seedlings were winter-killed, while some 40 or 50 plants of the red pine came through the winter without injury, making a good growth the following summer.

Pitch pine in Pike County, Pennsylvania, J. BENTLEY, Jr. (*Forestry Quart.*, *3* (*1905*), *No. 1*, *pp. 1–17*, *pl. 1*).—This is an account of a study of the life history and growth of the pitch pine near Milford, Pa., by H. S. Graves, assisted by members of the junior class of the Yale Forestry School during the summer of 1904.

This region is 1,000 to 1,400 ft. above the sea. The various factors studied were local distribution, form and development, sylvicultural characteristics, reproduction, and growth in volume, diameter, etc. The 2 prominent characteristics which largely determine its distribution are (1) its extreme intolerance of shade and (2) its ability to withstand adverse conditions, such as poor soil, exposure to wind, fire, etc. Observations on the height growth for trees 1 to 10 years old showed an average increase

in height of about 6 in. per year. Mature trees grown in the open rarely exceed 50 ft. in height and are irregularly shaped.

Pure stands are comparatively rare. In one instance a pure stand of 18-year-old trees, covering about an acre, ranged in height from 10 to 16 ft. A sample square rod 12 yards distant from the parent tree showed 27 young trees, of which 11 were dominant. In mixtures the pitch pine must be a dominant tree, and remain so if it is to exist. Under such conditions the trees grow from 60 to 70 ft. in height and in some cases 80 ft. The dominant pitch pine found in hard woods is of most economic value.

The pitch pine appears to be most intolerant to shade during the early years of growth. Observations indicate that trees 12 to 25 years of age growing singly require an area whose radius is from 8 to 10 ft. The tree grows on nearly all kinds of soil, but prefers a sandy, loamy, or even a stony soil to the heavy clay soils. It appears to be especially resistant to the attacks of fire due to its unusually heavy bark, which in mature trees is often as much as 1.5 in. thick. It is used sylviculturally as a nurse for white pine. Trees 8 years old bearing cones were observed. These cones, however, were sterile.

The cones on trees 20 to 30 years of age produce some fertile seeds. The seed years appear at intervals of from 3 to 5 years. The cones are very persistent and the seeds frequently ripen and fall from the cone while it is still on the tree. Wind appears to be the most important agent in the distribution of the seed. This pine sends up sprouts from the old stump. Tables of volume and growth are given showing the stem analyses, as regards volume and rate of growth, of 67 pitch pines cut during the summer.

Cultivation of the cinchona tree in Java, R. M. BARTLEMAN (*Mo. Consular Rpts. [U. S.], 1905, No. 296, pp. 159, 160*).—The methods of cinchona tree culture in Java are described.

Zapote tree and chicle gum, A. J. LESPINASSE (*Mo. Consular Rpts. [U. S.], 1905, No. 296, pp. 241-243*).—The wood of the zapote tree is described and an account given of the chicle industry in Mexico.

Continuous tapping of the zapote does not appear to seriously injure the tree providing the incisions are not too deep. Trees have been tapped 25 years, at the end of which time they produced only from 0.5 to 2 lbs. of sap. When allowed to rest 5 or 6 years they produced from 3 to 5 lbs. New trees produce from 15 to 25 lbs. of sap according to size. In order to produce the latter amount a tree would have to square about 2 ft. and be from 25 to 30 ft. high.

Guayule and its economic importance, R. ENDLICH (*Tropenpflanzer, 9 (1905), No. 5, pp. 233-247*).—A description is given of the guayule rubber plant (*Parthenium argentatum*), which grows wild in Mexico and which is being harvested and used commercially for the production of rubber.

The methods of extracting rubber from this plant are briefly described and the possibilities of the industry discussed. At present the dried plants bring from $30 to $40 per ton. Recently methods for manufacturing the rubber from the plant have been so improved that besides the water content of the rubber there is but from 10 to 15 per cent of foreign substance. The dried plants furnish from 8 to 12 per cent of rubber, depending upon the amount of moisture which they contain.

The author figures that a commercial factory which would turn out 1,000 kg. of guayule rubber per day would require from 10,000 to 14,000 kg. of dry raw material. This would require the material from 16 to 24 hectares daily, or from 6,000 to 8,500 hectares during the year. The plant grows very slowly and after it has once been cut off requires about 10 years to again reach suitable size for cutting. These calculations give an idea of the extent of land required to make the growth of this plant profitable commercially.

Some of the advantages are that the plant will grow on very poor and dry land. It grows best in a subtropical climate, which is of advantage from the standpoint of labor, and is not injured by night frosts. The crop can be worked up at any time during the year. In districts suited to its culture it is believed that the crop can be grown profitably, especially if culture and manufacture are combined.

An English translation of this article has recently appeared in *The India Rubber World, 33 (1905), Nos. 4, pp. 335, 336, fig. 1; 5, pp. 367-369.*

Caoutchouc plants; an agricultural-geographical study, P. Reintgen (*Tropenpflanzer, Beihefte, 6 (1905), No. 2-3, pp. IV+73-218, dgms. 4, map 1*).—Part 1 of this treatise deals with the discovery and uses of caoutchouc and part 2 with the individual caoutchouc plants, describing them and giving their habitat, cultural requirements, and economic value in each of the different countries in which they are grown. Statistics are included as to the production and exports of different countries. A bibliography of 65 papers on the same subject is included.

Eucalyptus screens as fire protection belts (*Indian Forester, 31 (1905), No. 5, p. 297*).—A note is given in which it is stated that in Cape Town, South Africa, 6 rows of eucalyptus planted 6 by 6 ft. are placed around plantations, etc., and within 5 or 6 years they form a barrier which no fire can cross, since they kill out all the grass completely and at the same time prevent burning leaves, etc., from being blown across.

A successful root-pruning device now in use at the Government nursery in Nebraska, L. C. Miller (*Forestry and Irrig., 11 (1905), No. 6, pp. 168-170, figs. 3*).—From observations in the Bureau of Forestry Nursery at Halsey, Nebr., where two and a half to three million seedlings are grown annually, it has been found that the seedlings should be 2 years old before planting to their permanent sites.

To transplant these seedlings at the end of the first year greatly increases the cost of production. As a substitute for transplanting, the seedlings are root pruned. The author devised a tool for this purpose by which 2 men working 8 hours can prune from 100,000 to 150,000 seedlings. "The important feature of this tool is the cutting blade. This is 1 in. wide and one-eighth of an inch thick, and made from a first-class piece of steel. It is U shaped, and the perpendicular sides are 7 in. long and the horizontal base is 6 in. long.

"This blade is riveted to substantial collars, which are made to fit on a Planet, Jr., garden hoe frame. This is a single-wheel frame, and in order to have the wheel run between the rows of trees it was necessary to change it to the outer side. . . . The cutting blade is filed to a keen edge and kept so during the pruning operation. By having such a thin blade and keeping it sharp, there is practically no resistance offered in passing through the soil, and all roots are cut without the usual injury done with a heavier tool." Two men are required to operate the tool satisfactorily, one to pull it through the soil and the other to guide it.

The movement of wood prices and its influence on forest treatment, B. E. Fernow (*Forestry Quart., 3 (1905), No. 1, pp. 18-31, dgms. 2*).—A paper read before the American Association for the Advancement of Science at its December meeting, 1904.

Statistics largely from German, Austrian, and Swiss sources are drawn upon to show that there has been a steady advance in wood prices during recent years. The distinction is made between wood prices and lumber prices, for while various factors, such as improvement in machinery for sawing timber and handling lumber, may tend to keep down the price of lumber, the stumpage prices of wood are steadily increasing. In Prussia wood prices have doubled within the past 50 years.

In America stumpage prices appear to be rising relatively faster than lumber prices. Stumpage of pine is now held at \$2 to \$3 per 1,000 which 10 years ago could be bought for 50 cts. to \$1. The average stumpage price in Europe for work wood is placed at 6 cts. per cubic foot, or about \$10 per 1,000.

DISEASES OF PLANTS.

Report of the botanist, G. E. Stone and N. F. Monahan (*Massachusetts Sta. Rpt. 1904, pp. 7–34, dgms. 2*).—A report is given of the investigations carried on by the botanist and his assistant, most of the work being conducted in the greenhouses in connection with the cultivation and diseases of roses, carnations, violets, tomatoes, and melons.

Brief reports are given on field investigations, and it is stated that asparagus rust was more prevalent than during the previous year. Considerable damage is reported to cultivated dandelions by stem rot, and the cucumber and melon blight, which have been previously quite troublesome, during the season reported upon were hardly observed at all. The worst injuries reported were due to winterkilling and the effect, as shown upon various shrubs and trees, is described.

In continuation of previous work, the authors have carried on experiments in soil sterilization, and in the present report a résumé is given of the results obtained from this practice. Sterilization has proven a satisfactory means for lessening the amount of infection in lettuce houses where the plants were affected with drop and Rhizoctonia, and also as a means of ridding them of nematodes. It was found that sterilization of the soil modifies the texture of lettuce, having a decidedly stimulating effect.

In connection with the stimulated growth, plants are somewhat more subject to disease and on this account greater attention must be given the ventilation and temperature of the houses. It is believed by proper ventilation and watering that the Botrytis rot of lettuce can be eliminated to a great degree. With cucumbers, sterilization of the soil was found to force the plants to a considerable extent, especially when under favorable conditions regarding light.

Where the conditions of growth are abnormal the sterilization was without any value in stimulating growth. A decidedly beneficial effect on the growing of carnations was shown where sterilized soil was used, the amount of disease being greatly reduced. No detrimental influence on the soil itself has been observed in the extensive series of experiments which have been carried on at this station.

In continuation of previous investigations (E. S. R. 16, p. 335), a report is given on the influence of electrical potential on the growth of plants. Comparisons were made of the growth of roots and tops of radishes when electrified and when not subjected to such treatment, which show that the leaves of the electrically treated plants were quite different from those of the normal ones. The electrical stimulation seems to give rise to conditions similar to those caused by lack of light which results in a partial etiolation.

Comparisons are reported of the atmospheric electrical potential in trees and in the free air, which show that some trees have a greater tendency toward conducting the electricity from the air to the earth and others have a tendency for conducting the electricity from the earth to the air. In all probability the exchange of electricity from the earth to the air or vice versa does not take place at the same time from the same tree. It is probable that some trees always conduct electricity from the air to the earth, while others conduct electricity from the earth to the air; and it is also probable that in the vicinity of large trees there may be a detrimental influence to crops and vegetation in general which can not be accounted for by lack of sunshine or soil moisture.

References are given to the more important literature relating to diseases of crops which are believed not to be caused by fungi or insects. This is supplemental to the previous publications of the Connecticut State Station (E. S. R., 5, p. 1078; 13, p. 154). The list is intended to supplement those previously mentioned and to give the more important publications of the experiment stations and the United States Department

of Agriculture relating to a number of functional and unknown disorders of cultivated plants.

Report of the botanist, H. L. BOLLEY (*North Dakota Sta. Rpt. 1904, pt. 1, pp. 33–56, pls. 7*).—In studying the cause of the wheat blight, which results in the so-called "white heads," or unfilled heads of a white color, the author has been unable to isolate a definite organism causing the disease, but he believes that the trouble is due to a fungus which is transmitted by way of the soil, in a somewhat similar manner to that causing the wilt of flax. The disease seems to be more general in poorly drained areas and in fields in which wheat has been continuously cropped, and for the present the author recommends draining of the heavy areas and rotation of crops as means for preventing this disease.

Considerable attention has been given to the cause of "starchy," spotted grains in hard wheats, the trouble being locally known as "white belly." Grains of this character are generally graded as soft wheats, and are believed to be inferior to the hard wheats of the Northwest. A number of experiments were carried on in which germination trials, microscopical tests, and cross-fertilization trials were made, and also the effect studied of exposure of harvested bundles to the ordinary weather conditions.

From the results the author believes that the white spots are not due to crossing, nor are they matters of heredity, but that this peculiar mottling is due to the action of moisture, air, and sun upon the grain while it is yet in the chaff. If the weathering action is long continued, the grains become evenly bleached over their entire surface. The color and hardness of the grain can be maintained by proper care in harvesting and curing.

Experiments to determine whether an efficient dry process of treating wheat for the prevention of smut could be discovered indicated that while this might be possible the methods tested were not as efficient as the use of formaldehyde, etc., and required quite as much care in their application. The claims for Ozonet powder as a smut preventive were not found to be justified.

In tests of the effect of evaporation upon solutions of formaldehyde, covering periods of from 1 to 15 days, it was found that the solutions, instead of becoming weaker on standing, became more concentrated. Hence, solutions which have stood open for a number of days may be depended upon as being fully as strong as when first made. Experiments on the effect of different types of water on formaldehyde treatment showed little or no influence.

Regarding the popular belief that smutted wheat may be safely used for seed after it has been stored for a period of years, tests of the influence of age upon the germination of smut spores showed that they do not lose their vitality under ordinary methods of keeping for a period of at least 7 years. An account is given of investigations on the breeding of wheat for resistance to smut and rust, with a general discussion of the effect of rust on the wheat crop. The author suggests that seed may be used from rusted crops providing it is thoroughly screened, and where this practice is carried out the effect of breeding will be secured to some extent.

Notes are given on the germination of light-weight wheat from a rusted crop, and also germination tests of frosted grains. From a microscopical examination of frosted grains the author states that apparently the injury is confined to the outer bran layer, and that there is no apparent change in the inner layer or contents of the grain. Whether the quality of the grain for producing flour is injured would be determined only by a chemical and manufacturing test.

For more than 12 years the author has been carrying on experiments on potato scab, and during these studies he has often noticed what appeared to be a tendency to immunity on the part of certain individuals or strains. From 1893 to 1900 some selective work was carried on with the Early Ohio potato, and the results obtained show that it is possible to increase resistance to disease to a considerable extent.

Through all these experiments it was found that while the methods of culture remained the same, the yield per hill became greater each year and the tendency to disease was less apparent. The work with potatoes is being continued, and the author has undertaken to secure immunity through the breeding of resistant strains where the conditions supposed to favor disease are artificially produced and persistently maintained.

A brief account is given of experiments on internal tree feeding and medication, which the author states will be fully described in a future publication. It is stated that sufficient facts have been obtained to warrant the belief that valuable individual trees may be saved from the action of certain diseases by this method, but more extensive experiments will be necessary before the work will be adapted to ordinary horticultural practice.

Report of the botanists, L. R. JONES and W. J. MORSE (*Vermont Sta. Rpt. 1904, pp. 383–402*).—After reviewing the occurrence of plant diseases during 1904, commenting briefly on potato blight, arsenical poisoning of potatoes, various diseases of orchard and small fruits, etc., the authors give the results of spraying experiments in 1904, discuss the relation of the date of digging to the development of rot and the value of liming for the prevention of potato rot, and describe experiments with formaldehyde gas for the disinfection of scabby potatoes

The results of the spraying experiments in 1904 are described at considerable length. This season's work constitutes the fourteenth year in which records have been kept on the use of Bordeaux mixture for spraying potatoes. In 1904 the results obtained, as indicated by the total yield, were not as pronounced as usual, which is attributed to the very late appearance of blight. The early potatoes were practically all out of the way, and in most cases the later varieties had nearly matured before the disease made its appearance. It is believed that owing to the unusual conditions much of the spraying done in Vermont during 1904 was performed at actual loss, but the average results obtained for the 14 years would indicate that the use of Bordeaux mixture, when properly applied, is economically advantageous for the prevention of potato blight.

In continuation of previous work (E. S. R., 15, p. 1088) the authors have investigated the relation of the date of digging to the development of rot, and as a result of 3 successive seasons' work they recommend the following as a safe rule for Vermont farm practice:

"When potato tops have been killed by the late blight fungus and there is consequent danger of rot of the tubers, do not dig them until a week or more after the tops were killed. A longer delay will do no harm. With late varieties, where the progress of the disease is slow, do not begin digging until the third week of September at the earliest, and if practicable wait until after the tops are killed by frost."

As a result of two years' trials the authors doubt the practical value of lime as a preventive of rot.

A description is given of the disinfection of scabby potatoes by formaldehyde gas. The authors have devised a method for the treatment of seed potatoes in large quantity in storage bins, the value of which is shown. A portion of formaldehyde was added to water, and the solution distilled into an air-tight compartment containing the potatoes, after which the potatoes were allowed to remain in the fumigation chamber for 24 hours or longer. This method of treatment has given highly satisfactory results.

New work upon wheat rust, H. L. BOLLEY (*Science, n. ser., 22 (1905), No. 550, pp. 50, 51*).—The author reports a definite establishment of the fact that the uredospores of *Puccinia graminis* are able to pass the winter in a viable form.

Experiments carefully controlled seem to indicate that these spores may remain unimpaired by the dry winds of autumn and the intense cold of a North Dakota winter. In some instances as high as 90 per cent of all spores examined were capable of

germinating. The spores were found on dead leaves, straw, and on the partially dead or green leaves of living grain or grasses. This also applies to a number of other important rusts which attack wheat and allied grasses.

In the case of *Puccinia rubigo-vera*, it has been found wintering freely on living leaves of wheat or winter rye, and upon the matured leaves and straw of the same, from Mississippi to North Dakota.

Report on the root-rot investigations, Z. KAMERLING (*Verslag van het wortelrot onderzoek. Soerabaya: H. van Ingen, 1903, pp. 209, pls. 5*).—The author reports on the various studies he has made to determine the cause of root rot of sugar cane.

The physical structure of the soil has been found to be one important cause, and physically poor soils are defined as those on which the cane develops poorly or dies prematurely. Such soils have a very close structure, the grains of less than $\frac{1}{10}$ mm. being all distinct and separate from each other. Better soils are those in which few or many of these small grains adhere in masses, forming a more open structure. In the latter case the soil particles may be stuck together either by humates, by iron hydroxids, or by iron silicates. The structure of the soil may be improved by the addition of river silt, by cultivation, and by irrigation.

Soils which are in poor physical condition become closely packed, so that they are poorly aerated and hard, making it difficult for the cane roots to penetrate. This condition causes malformation of roots as well as stunted growth. Measurements of cane roots made from plants growing in especially prepared soils showed that the volume of soil penetrated by roots growing in soil of good physical structure was eighteen times as great as the volume of soil penetrated by cane roots growing in soil of poor physical structure.

A number of tests were also made on the relative permeability of soils to water, and it was found that the soils in which the root rot occurred were much less permeable than other soils. The details of the results of these experiments are illustrated by several diagrams.

Poor physical structure of the soil is partly due to loss of humus, which loss, the writer finds, amounts in 3 years to 0.09 per cent for the upper foot of soil. This loss can be made up by adding organic fertilizers in the shape of stable manure with which rice straw, cane leaves, and other organic substances have been composted, or by turning under green plants.

In regard to the presence of root parasites the author expresses the opinion that on otherwise healthy plants the presence of parasites is no very serious matter. It is only when, by reason of poor soil conditions, the plants are weak that parasites are able to do much damage.

A nematode, *Heterodera radicicola*, and several kinds of fungi which occur more or less frequently are described.—H. M. PIETERS.

Smut preventives and their effect on the germination of grain, R. W. PEACOCK (*Agr. Gaz. N. S. Wales, 16 (1905), No. 3, pp. 251, 252*).—The author tested the effect of solutions of copper sulphate and formalin in various strengths, and the hot-water method of seed treatment, for the prevention of smut to determine the possible effect on germination.

In dry districts the use of copper sulphate in solutions of ordinary strength was attended with a loss of 50 per cent of the grain. Formalin was found to be preferable under unfavorable conditions, and the hot-water treatment was decidedly efficacious but can only be recommended to careful operators on account of the narrow limits within which the temperature must be kept.

Disease-resistant potatoes, W. STUART (*Vermont Sta. Bul. 115, pp. 135-140*).—The author has been engaged for 2 years in studying the varying resistance of varieties of potatoes to disease, particularly the late blight (*Phytophthora infestans*).

Of the varieties tested in 1903 one, which is designated as Rust Proof, proved quite resistant to the disease. In 1904 a more extended list of varieties of potatoes together

with a number of distinct species of Solanum were tested for disease resistance. The relative resistance of the different varieties is given in tabular form, marked differences being shown. Of the established varieties tested Rust Proof, Sutton Discovery, June, Mexican, Mammoth Gem, and Manum No. 3 were the most resistant, their power of resistance being in proportion to the order of enumeration.

Resistance to the rot of the tubers and to scab was also investigated, and attempts are being continued in the development of plants, by hybridization and selection of seedlings, that will be more resistant than those now in use.

Potato rot in New Zealand, C. T. MUSSON (*Agr. Gaz. N. S. Wales, 16 (1905), No. 5, pp. 423–428, fig. 1*).—The author suggests special precautions against the introduction of diseased tubers, and the breeding of new varieties of potatoes which have a greater resistant power.

Spraying the plants with Bordeaux mixture is advised to prevent the disease from spreading, and the red-skinned varieties are said to be less liable to attack. For white-skinned ones deep planting is recommended to minimize the chance of tubers being affected, and it is said that nitrogenous manures render the plants more susceptible to disease, while potash manures assist them in resisting attack.

Diseases of melons and cucumbers during 1903 and 1904, J. L. SHELDON (*West Virginia Sta. Bul. 94, pp. 121–138, pls. 5, fig. 1*).—Brief notes are given on the leaf spot (*Cercospora citrullina*), downy mildew (*Plasmopara cubensis*), leaf mold or blight (*Alternaria brassicæ nigrescens*), and damping off, due to *Fusarium* sp.

The results of the author's investigations on the anthracnose (*Colletotrichum lagenarium*) are given at some length. The author describes cultures of the fungus, the germination of the spores, development of the mycelium, etc., and gives the results of inoculation experiments that were made to determine whether the fungus causing the disease known as anthracnose of the watermelon could produce anthracnose in other plants. Inoculations were made from pure cultures and from watermelon fruits into a number of other plants, and the anthracnose was successfully produced on muskmelons, cucumbers, gourds, and watermelons. Failures are reported in all the attempts to inoculate beans, and doubtful results were obtained with inoculations of squashes and a few other plants.

Experiments were carried on for the prevention and control of anthracnose, in which plats were sprayed with soda Bordeaux, Bordeaux mixture, and ammoniacal copper carbonate. The results of the applications showed considerable difference between the sprayed and unsprayed plats, and, considering the improved quality of the melons and the reduced amount of anthracnose, it appears that spraying with Bordeaux mixture was quite successful in combating the disease. The use of the ammoniacal copper carbonate solution was less beneficial.

Bacteria in relation to plant diseases, E. F. SMITH (*Washington, D. C.: Carnegie Institution of Washington, 1905, vol. 1, pp. XII+285, pls. 31, figs. 146*).—This is the first volume of a proposed monograph of the diseases of plants due to bacteria.

In the completed work the author hopes to present the evidence of the bacterial origin of a large number of plant diseases, many of which have been personally studied by him. This publication is intended as a supplement to the numerous textbooks of bacteriology, and while designed primarily for plant pathologists, it will be found valuable to all students of bacteriology. The literature relating to the bacterial diseases of plants is so scattered that all students will welcome its bringing together into an orderly arrangement by a competent investigator.

In the first volume the methods of work are described in detail. The morphology and physiology of the organisms are discussed at length, after which the economic aspects of bacterial diseases of plants are considered. The author then takes up laboratory methods, describing the more approved apparatus, and gives formulas for stains, media, etc. An extensive bibliography to literature is given, the arrangement being chronological by topics.

Apples injured by sulphur fumigation, H. J. EUSTACE (*Science, n. ser., 21 (1905), No. 548, pp. 994, 995*).—A request was recently made upon the New York State Station to diagnose the injury to some apples which had been carefully selected, wrapped in paper, and packed in boxes.

Scattered irregularly over the surface of each apple were conspicuous spots of various sizes where the epidermis was dead, discolored, and slightly sunken. Each spot was nearly circular, and for a few millimeters beneath the spot the flesh was dead, shrunken, and dry as though affected with the dry rot. The center of each of the smaller spots showed small bodies which proved to be the lenticels of the apple. A careful examination failed to show the presence of either fungi or bacteria, and this led to the belief that some treatment of the fruit such as fumigation might be the cause of the injury.

Sulphur being commonly used for fumigation, experiments were conducted with it, and although repeated many times with wet and dry fruit, always produced the same characteristic spots. The presence of a lenticel in the center of each spot would indicate that the sulphur dioxid passes into the center of each spot and causes at least the bleaching of the tissue. Similar effects were produced where artificial breaks were made in the epidermis. While the author's experiments were confined to sulphur, it is believed that other chemicals would produce a similar injury.

Spraying grapes for black rot in Erie County, Pennsylvania, G. C. BUTZ (*Pennsylvania Sta. Rpt. 1904, pp. 241–252, pls. 2, dgm. 1*).—During the season of 1902 considerable loss was caused by black rot of grapes in Erie County, Pa., and for the summer of 1903 the author planned a series of spraying experiments for its control.

The spraying experiments were carried on under the author's direction upon a number of vineyards. The fungicide used was the 4–4–50 Bordeaux solution, applications being made in one instance on May 26 and June 29. In this vineyard the net gain attributed to the spraying is $51.12 on 39 rows of grapes of 55 vines each. In the second experiment 5 sprayings were given the vines, the first 3 consisting of Bordeaux mixture and the last 2 of ammoniacal copper carbonate solution, and the owner of the vineyard estimated a net gain of $24 per acre. In the other experiments similar results were obtained.

The powdery mildews of Washington, W. H. LAWRENCE (*Washington Sta. Bul. 70, pp. 16, figs. 22*).—The results of an investigation on the occurrence and distribution of the powdery mildews are given. Notes are given on the life history of the mildews, methods for combating them, and on a number of the more common diseases caused by them. Keys are presented for the recognition of the different genera and species and technical descriptions given of each species.

The powdery mildew, O. BUTLER (*Bul. Cal. Vit. Club, 1905, No. 1, pp 1–6*).—A description is given of the powdery mildew of grapes and suggestions for its control, based upon compiled information.

The author suggests sulphuring the vines as soon as the mildew appears, and repeating the treatment every time an attack of the mildew appears. Thoroughness of application is essential for proper treatment. The varied susceptibility of a number of varieties is pointed out, and most of the American vines are said to be practically immune, while some of the European species are very sensitive to the fungus attack.

Concerning the identity of the fungi causing an anthracnose of the sweet pea and the bitter rot of the apple, J. L. SHELDON (*Science, n. ser., 22 (1905), No. 550, pp. 51, 52*).—The author reports having examined some sweet pea plants that were affected with some species of Glœosporium. The manner of growth of the mycelium and the way the conidia were produced suggested relationship with the characteristic bitter-rot fungus of the apple and the fungus causing the mummy disease of the guava.

Inoculation experiments were carried on between the sweet peas and apple, producing the characteristic appearance of the bitter rot. An examination showed that

the sweet peas in question had been grown near infected apple trees, and further inoculation experiments showed that seedling peas inoculated with bitter-rot spores and the ripe rot of the grape were killed in a similar way to that described on the original pea stems. It seems probable from the results obtained that the bitter rot of the apple, the ripe rot of the grape, and the anthracnose of the sweet pea are caused by the same fungus.

ECONOMIC ZOOLOGY—ENTOMOLOGY.

Kansas mammals in their relation to agriculture, D. E. LANTZ (*Kansas Sta. Bul. 129, pp. 331–404, pl. 1, fig. 1*).—An annotated list is presented of the mammals known to occur in Kansas. All species of economic importance are discussed in a detailed manner with special reference to their distribution, prevalence, food habits, and means of eradicating the harmful species.

In this general discussion, which occupies the major part of the bulletin, attention is given to the opossum, elk, deer, antelope, squirrels, spermophiles, prairie dogs, woodchuck, rats, mice, pocket gophers, rabbits, wild species of the cat and dog tribes, weasels, skunks, moles, bats, etc. Suitable destructive remedies are suggested in connection with each injurious species and a special section is devoted to the methods of applying poisons and other devices in killing harmful mammals.

Proceedings of the seventeenth annual meeting of the Association of Economic Entomologists (*U. S. Dept. Agr., Bur. Ent. Bul. 52, pp. 123, figs. 7*).—An account of this meeting held in Philadelphia, Pa., December 29 and 30, 1904, has been previously given (E. S. R., 16, p. 623). In addition to the papers there noted the following are included in the proceedings:

Preliminary report upon work against a destructive leaf hopper (*Empoasca mali*), F. L. Washburn (pp. 43–47).—Previously noted from another source (E. S. R., 16, p. 889).

Notes for the year, E. P. Felt (pp. 51, 52).—A brief account is given of violet sawfly, San José scale, buffalo tree hopper, Chinese lady beetle, and grapevine root worm. Spraying with arsenate of lead reduced the last-named pest about 50 per cent.

Distribution and migrations of the Mormon cricket (*Anabrus simplex*) *in Colorado*, S. A. Johnson (pp. 62–66).—A fuller account is given in Colorado Station Bulletin 101, to be abstracted later.

The present status of the predatory insects introduced into New Jersey, J. B. Smith (pp. 74–78).—Native species of predaceous insects (*Chilocorus bivulnerus* and *Scymnus marginicollis*) were quite effective. The author's first attempt to introduce the Chinese ladybird failed and specimens of the same insect received from this Department also died. A colony introduced from Georgia is now under test. *Paratenodera sinensis*, a Chinese mantid, was introduced but the results are not promising.

Report on the New Orleans ant (*Iridomyrmex humilis*), E. S. G. Titus (pp. 79–84).—This ant has been known in New Orleans since 1895 and is rapidly increasing in numbers. It nests on the ground or, in wet weather, in trees. The pest assists in distributing various plant lice, scale insects, and mealy bugs. The ant is very destructive to food products of all kinds and flowers. The best means of repelling them is found in the use of corrosive sublimate tape or cloths saturated with kerosene.

Report of the entomologists, C. H. and H. T. FERNALD (*Massachusetts Sta. Rpt. 1904, pp. 111–114*).—The college orchard has been nearly freed from San José scale. Several proprietary insecticides were tested, but found to be of little value. Codling moth is controlled by spraying during the egg-laying season of the pest. Brief notes are also given on various other insects, including white fly, red spider, brown-tail moth, gypsy moth, etc.

Report of entomologist, G. W. HERRICK (*Mississippi Sta. Rpt. 1904, pp. 27–34*).—Several remedies for peach-tree borer were tried. Gas tar did not injure the trees

when applied to the trunk. The life history of the bean-leaf beetle was studied, and arsenate of lead tested without very promising results. Notes are also presented on Southern corn root worm, *Ligyrus rugiceps*, bollworm, an undescribed snout beetle, false chinch bug, San José scale, mosquitoes, *Pegomyia fusiceps*, and *Dynastes tityrus*.

Second annual report of the State entomologist, R. A. COOLEY (*Montana Sta. Bul. 55, pp. 125-180, pls. 3, figs. 25*).—*Phenacoccus dearnessi* was found on apple trees and closely resembling woolly aphis. It occurs also on the elm and may be controlled with soap or kerosene washes.

Otiorhynchus ovatus greatly injured strawberry plants near Missoula. The nature of the attack is discussed and the insect is described in all its stages. Dipping the plants in arsenate of lead was found to render the plants immune for about 2 weeks. The best remedy is probably to be sought in a proper rotation of crops. Remedies for the bud moth were studied by B. J. Jones, who found that the larvæ feed entirely on the leaves after the first spring attack on the opening buds. Trees should be sprayed with arsenate of lead before the buds open and later as required.

Brief statements are also made regarding other insect pests, such as peach-tree borer, apple-tree borers, bronze apple-tree beetle, apple-twig borer, fruit-tree bark-beetle, peach-twig borer, San José scale, woolly aphis, various scale insects, codling moth, plum curculio, etc.

Report of the government entomologist for the half year ended June 30, 1904, C. P. LOUNSBURY (*Cape Good Hope Dept. Agr., Rpt. Govt. Ent. 1904, pp. 35, pl. 1*).—This report contains an account of the routine work of the entomologist, publications, plant import regulations, nursery legislation, ticks, African coast fever, heartwater, and locusts.

It was found that when the brown tick feeds on affected cattle only during the nymphal stage it does not carry infection. The nymphal bont tick carries heartwater, as demonstrated in experiments with goats. Cattle were shown to be susceptible to the disease. Horses are immune. *Rhipicephalus decoloratus* is not pathogenic. Persian sheep are highly susceptible to heartwater, but have very light attacks and are thereafter perfectly immune.

C. W. Mally also presents a report on insects affecting corn and fruit, especially on *Sesamia fusca* and *Ceratitis capitata*.

Annual report for 1904 of the zoologist, C. WARBURTON (*Jour. Roy. Agr. Soc. England, 65 (1904), pp. 273-287, figs. 4*).—During the year under report peas were greatly injured by *Diplosis pisi* and *Grapholitha pisana*. When peas are infested with these pests it is desirable that sound pods be removed at once and that infested plants be destroyed.

The adoption of a suitable system of rotation will largely control the insects. Notes are also given on phylloxera and other plant lice, with an account of their biological relations, and special notes on corn aphis, pea aphis, hop aphis, etc. A number of mites proved injurious during the year under report, and ferns were considerably damaged by a new species of mite described under the name *Tarsonemus chironiæ*.

The Hessian fly (*Bd. Agr. and Fisheries [London], Leaflet 125, pp. 3, figs. 7*).—This pest is described, with notes on its food plants, life history, and means of prevention. It is recommended that infested stubble be burned and a suitable rotation of crops adopted.

Julus impressus in the corn field, F. M. WEBSTER (*Canad. Ent., 37 (1905), No. 5, p. 172*).—The author observed what appeared to be this species infesting unripe ears of corn in Illinois and Minnesota. It may prove, however, that some other species was concerned in the production of the injury.

The wormy apple, A. L. MELANDER (*Washington Sta. Bul. 68, pp. 16, figs. 6*).—A popular account of the habits and life history of the codling moth is given, together with notes on the losses due to this insect. Suggestions are also made regarding

remedies. The cost and economy of spraying are discussed. From 90 to 95 per cent of the apples may be saved by proper spraying.

The struggle with the codling moth, W. LOCHHEAD (*Canad. Ent., 37 (1905), No. 6, pp. 197–200*).—The author briefly summarizes the various methods which have been found successful in combating the codling moth.

The codling moth, W. J. GREEN and J. S. HOUSER (*Ohio Sta. Bul. 160, pp. 197–214, pls. 5*).—The codling moth is described in its various stages, with notes on its life history.

It was found that 72 per cent of the worms left the apples before they fell. The destruction of windfall apples, therefore, seems to be of little avail. About 16 per cent of the worms were caught under bands. Adult larvæ were found throughout the growing season until October 13. The evidence obtained by the authors indicated 2 annual generations. In spraying experiments 91 per cent of the apples from sprayed trees and 57 per cent of those from unsprayed trees were free from worms. Arsenate of lead proved superior to arsenite of soda, and was not affected by mixing with Bordeaux mixture. This combination is recommended for controlling apple scab and codling moth.

Preliminary report on the codling moth in the Yakima Valley, E. JENNE (*Washington Sta. Bul. 69, pp. 16, figs. 3*).—As the result of a study of this pest in the Yakima Valley it was found that the insect is double brooded, with a partial third brood.

All commercial orchards in the valley are sprayed from 3 to 10 times. The loss from the codling moth in sprayed orchards is from 5 to 15 per cent. Of the larvæ which leave infested apples about 40 per cent crawl down the trunk of the tree and may be induced to pupate under properly placed bands. It is suggested that trees be sprayed first before the calyx closes and a second time 2 weeks later. For the second brood trees may be sprayed July 20, and August 5 and 30.

Some destructive grape pests in Ohio, A. F. BURGESS (*Ohio Dept. Agr., Div. Nursery and Orchard Inspection Bul. 5, pp. 17, figs. 4*).—Statistics are presented regarding the extent of grape culture in Ohio. The most important insect enemies of the grape in Ohio are grape root-worm, grape berry moth, and grape-blossom bud-gnat. The habits and life history of these 3 species are discussed in some detail, and suitable remedies are recommended for each pest.

In general it is urged that grapes be sprayed with Bordeaux mixture before the blossoms open, a second time with Bordeaux mixture and arsenate of lead while the blossoms are falling, a third time after an interval of 10 to 14 days, and a fourth time after another interval of about 10 days.

The most effective insecticidal treatment for the white fly, W. STUART (*Vermont Sta. Rpt. 1904, pp. 429–431*).—The white fly is a serious pest in winter-forcing tomatoes. Nicoticide, Aphis Punk, Fir-tree Oil, Lemon Oil, and X-all were tried and found to be of little avail.

Hydrocyanic-acid gas proved very effective. The cyanid was used at the rate of 0.014 to 0.2 gm. per cubic foot of space. The tomatoes were somewhat injured when the temperature of the greenhouse was high, but not at low temperatures, and the white fly was killed. Fumigation with doses of ½ oz. per 1,000 cu. ft. of space is recommended. At this rate the temperature should be 60 to 65° F. and the exposure of several hours' length.

Recent invasions of forest insects in Lorraine and means of combating them, E. HENRY (*Bul. Soc. Sci. Nancy, 3. ser., 5 (1904), No. 4, pp. 153–173, pls. 3*).—A general account is given of injuries from forest insects in Lorraine, with especial notes on *Hylobius abietis*, *Pissodes notatus*, *Tomicus bidentatus*, *Tortrix viridana*, etc. The remedies recommended against these forest pests are largely of preventive nature and consist in the destruction of the insects in their breeding places and the use of trap trees.

The elm leaf beetle, A. F. Burgess (*Ohio Dept. Agr., Div. Nursery and Orchard Inspection Bul. 4, pp. 23, figs. 10*).—This insect has recently appeared in injurious numbers in Dayton and other parts of Ohio. Notes are given on its distribution in various parts of this country and the habits, life history, food plants, natural enemies, and remedies for combating it. On account of the extremely dangerous character of this pest it is urged that effective insecticide remedies be put in operation against it.

The cocoanut beetle (*Bot. Dept. [Trinidad], Bul. Misc. Inform., 1905, No. 45, pp. 158–160*).—Brief notes are given on the habits and life history of *Rhyncophorus palmarum*. The beetle attacks many species of palms, but is most injurious to *Acrocomia lasiospatha*. In combating this pest the adults should be captured and destroyed as fast as possible and the decayed material of cut trees should be destroyed or treated so as to kill the larvæ.

Thrips and black blight, H. A. Ballou (*Bot. Dept. [Trinidad], Bul. Misc. Inform., 1904, No. 44, pp. 132–135*).—As a result of the study of this problem the author concludes that black blight causes an unsightly appearance of cacao, but is comparatively harmless. The scale insects which may precede the appearance of black blight are far more injurious, but may be controlled by the application of proper insecticide treatment. A number of instances are cited of the injury due to the cacao thrips (*Physopus rubrocinctus*).

The sheep maggot fly (*Bd. Agr. and Fisheries [London], Leaflet 126, pp. 3, figs. 3*).—*Lucilia sericata* is described in its different stages and notes are given on its life history and depredations on sheep. In combating this pest it is recommended that infested sheep be isolated, carcasses destroyed, and affected sheep be treated with kerosene and sulphur.

Preparation and use of sprays; spray calendar, W. Stuart (*Vermont Sta. Bul. 113, pp. 95–108*).—General directions are given regarding the principles of spraying for the control of insect and fungus pests, together with formulas for preparing Bordeaux mixture, copper sulphate solution, ammoniacal copper carbonate solution, formalin, Paris green, arsenate of lead, arsenite of soda, hellebore, kerosene emulsion, lime-sulphur-salt wash, pyrethrum, etc. A spray calendar is appended to the bulletin.

Electrical destruction of animal life (*West. Electrician, 36 (1905), No. 5, pp. 88, 89, figs. 2*).—An apparatus is described by which an alternating current of high voltage and low amperage can be passed through the bark of trees or through soil infested with insect or other harmful animal pests. It is claimed that these pests may be destroyed by the electric current.

The unimportance of the influence of stimulating food upon the egg laying of queen bees, Sylviac (*Apiculteur, 49 (1905), No. 4, pp. 149–155*).—As the result of a long-continued study of this subject the author comes to the conclusion that the rapidity and extent of egg laying on the part of queen bees is not greatly influenced by stimulation in the way of artificial feeding, but is determined largely by other well-known causes.

Regeneration of the thoracic feet of the silkworm, E. Verson (*Atti R. Ist. Veneto Sci., Let. ed Arti, 64 (1904–5), No. 2, pp. 429–469*).—The literature relating to this subject is briefly discussed and detailed notes are given on the special anatomical features of the thoracic legs of silkworms, with particular reference to regeneration processes as observed in these structures.

External characters which indicate sex in larvæ of the silkworm, E. Verson (*Atti R. Ist. Veneto Sci., Let. ed Arti, 64 (1904–5), No. 2, pp. 497–501, figs. 2*).—The author describes the structures which may be observed in the larvæ of the silkworm and which may be depended upon in classifying these larvæ according to their sex.

FOODS—HUMAN NUTRITION.

Macaroni wheat, J. H. SHEPARD (*South Dakota Sta. Bul. 92, pp. 39, pls. 4*).—Continuing earlier work (E. S. R., 15, p. 1098), results of studies of the milling and baking qualities of macaroni wheat are reported, as well as of its value for macaroni making.

In the investigations reported a number of samples of northern or Russian, southern or Mediterranean, and miscellaneous macaroni wheats were studied, in comparison with standard varieties of bread wheats. The milling tests showed that although some of the macaroni wheats were inferior, yet on an average this class of wheats compares favorably with standard bread wheats. As regards the varieties included in the present test, the best results were obtained with a specimen of Kubanka macaroni wheat.

"It yields a greater percentage of flour than any other. The color is not much different from the best blue stem flour, while . . . it makes a better loaf of bread than any other [of the samples tested].

"The Russian macaroni wheats as a whole give better results than the others, although there is a wide difference among the samples milled."

In a study of the distribution of protein in the different wheats, it was found that on an average the bread wheats tested contained 13.68 per cent protein in the whole wheat, 15.65 in the bran, 14.56 in the shorts, and 12.66 in the flour. The macaroni wheats tested contained on an average 15.60 per cent in the whole wheat, 15.90 in the bran, 15.29 in the shorts, and 15.00 in the flour.

From studies of the proportion of wet gluten present and the results of sponge tests, it appears that "the bread wheat glutens are slightly superior gram for gram, but the greater quantity in the macaroni seems to offset this advantage." The sponge test is regarded as a more accurate test of the tenacity of the gluten than the loaf volume, owing to the greater accuracy obtainable in the rise and measurement; and thus judged, the macaroni wheats compared favorably with the standard varieties.

A study of the bread-making qualities of the various wheats showed that the quality of macaroni flour bread was largely dependent upon the variety of wheat selected, some of the samples producing bread which in the author's opinion was equal or superior to that made from the best bread wheats, while the bread made from other varieties was of very poor quality. The data regarding the character of the macaroni made from the different samples of wheat have been summarized in the earlier bulletin previously referred to.

The color tests reported showed considerable range in the different samples, the macaroni flours comparing favorably with the standard wheats. In general, the color of the flour was found to depend directly upon the fineness of grinding. This, in the author's opinion, may explain some of the differences of opinion regarding the color of macaroni flour.

From a summary of data on the effect of soil and climate on the total protein in macaroni wheats, the conclusion is reached that these factors have not induced any general deterioration as regards protein content. In general an unfavorable season tends to lower the protein content and a favorable season to increase it. The percentage of gliadin in the total protein ranged in a number of samples of the macaroni flours examined, from 44.9 per cent with the Yellow Gharnovka, to 59.1 per cent with Kubanka. The proportion found in Blue Stem Minnesota wheat was 66.8 per cent.

A satisfactory flour for baking purposes should contain, according to the author, from 55 to 65 per cent of its total gluten in the form of gliadin. Therefore, judged by this standard, some of the macaroni flours are satisfactory while others are not.

In the author's opinion, the varieties containing the low gliadin content and poor baking qualities can not be improved by cultivation.

"The demand at present is for a durum wheat that will make good macaroni, an attractive flour, and a bread that is satisfactory in loaf, color, and flavor. This is much to ask of one variety of wheat, but our work leads us to believe that the problem is capable of a satisfactory solution. The key to success lies in choosing only the best kind or kinds for cultivation. After that the best localities for growing this best kind to perfection must be carefully determined.

"It is now well known that the macaroni wheats are preeminently dry weather wheats. This leads to the inevitable conclusion that the driest parts of our country are the natural habitats of these new wheats and it is to those localities we must look for our supply of the highest grade of macaroni wheat."

Report of the food commissioner, E. F. LADD (*North Dakota Sta. Rpt. 1904, pt. 2, pp. 1-180, 191-208, pl. 1*).—Detailed statements are made regarding the scope of the pure-food work in North Dakota, the results of the examination under the provisions of the State pure-food law of a large number of samples of sirups and sugars, preserves, jams, and jellies, canned goods, meats, catsups, candies, flavoring extracts, etc., and patent medicines, especially those containing large percentages of alcohol. Data are also given regarding the composition of a canning compound, a filler for tomato catsup and some other products.

The present condition of food adulteration in North Dakota, the use of preservatives and artificial coloring matters and other topics are discussed, and data regarding standards of purity are summarized, as well as information regarding the determination of methyl alcohol and the analysis of sugars and sirups. Information regarding the estimation and amount of sodium sulphite found in a number of samples of meat products and dried fruits is summarized from a publication previously noted (E. S. R., 16, p. 896).

The author considers that the character of the food products on sale in the State has improved, but that within the last year there has been a very large increase in the proportion of package goods showing short weight.

"Packages that are supposed to contain 16 oz. have been found to range from 10½ oz. to 16 oz. for different well-known brands. Baking powders have been found 1 and 2 oz. short. Extracts unlabeled, but supposed to contain 2 oz., would contain from 1½ to 1¾ oz. Cartons of dried fruit assumed to be 10 lbs. would net 8½ lbs. Packages of coffee sold for 25 lbs. would actually weigh less than 22 lbs. Our law is defective in that it does not require the placing of the net weight on every package of goods offered for sale in the State."

Food inspection, C. D. WOODS and L. H. MERRILL (*Maine Sta. Bul. 116, pp. 77-92*).—The provisions of the law enacted by the Maine legislature in 1905 to regulate the sale and analysis of foods are given. It is pointed out that this law contemplates "the proper and truthful branding of all articles of food, and the exclusion from the markets of deleterious food materials. The law does not seek to prevent the sale of any article of wholesome food; but in case a food material is other than it appears to be, it 'shall be plainly labeled, branded, or tagged so as to show the exact character thereof.'"

Saxony regulations regarding the sale of foods, condiments, and commercial products, E. WIMMER (*Die im Königreich Sachsen über den Verkehr mit Nahrungsmitteln, Genussmitteln und Gebrauchsgegenständen geltenden reichs- und landesrechtlichen Vorschriften. Leipsic: A. Rossberg, 1905, pp. 136; rev. in Ztschr. Untersuch. Nahr. u. Genussmtl., 9 (1905), No. 5, pp. 308, 309*).—In this volume, which is No. 168 of the series called *Juristischen Handbibliothek*, Saxony laws and regulations are summarized and some explanatory statements are given.

Examination of spices, W. FREAR, H. L. WILSON, and R. E. STALLINGS (*Pennsylvania Sta. Rpt. 1904, pp. 137-140*).—It has been suggested that the limits for ash

proposed by the committee on pure-food standards of the Association of Official Agricultural Chemists are not sufficiently wide to allow for the unavoidable contamination with clay, etc., sometimes met with in commercial products.

Analyses of a number of samples of gingers and peppers showed that the proposed limits were exceeded only in the case of one sample of Lampong black pepper. Analyses were made of the ash of the different milling products of two samples of pepper. The first or whitest product was found to contain as much ash as any portion except the last, and more ash insoluble in acid (sand or clay) than any other portion. "The sale of this light colored first product for genuine white pepper could be instantly discovered. The last portion, on the other hand, though highest in total ash, due to the excess of hull, is singularly free from sand and clay."

Analyses of the first, second, and third skins of pepper showed that the ash was most abundant in the outer skin, while the inside layers contained almost no ash insoluble in acid.

"While . . . the extract and piperin in the outer or first skin are much lower than those in the whole berry, the quantities in the second and third skins are very similar to those in the entire berry."

Determinations were also reported of the volatile and nonvolatile ether extract of a sample of Papua mace, a spice which has a very different flavor from true mace.

The value of condiments in the diet, O. LIEBREICH (*Ther. Monatsh., 18 (1904), pp. 65–68; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 9 (1905), No. 6, pp. 368, 369*).—The data reported have to do with the effect of condiments on the stimulation of the flow of digestive juices and the effect on the chemistry of digestion. In the author's opinion condiments may be said to increase digestion when they increase the flow of digestive juices.

The need of sulphur in the diet, VON OEFELE (*Deut. Med. Presse, 9 (1905), No. 5, p. 39*).—The author estimates that an adult requires 3 to 3.5 gm. of sulphur per day, and points out that the amount metabolized in youth is greater than later in life. He discusses the need of supplying an abundance of sulphur, especially in disease.

Protein synthesis in the animal body, V. HENRIQUES and C. HANSEN (*Ztschr. Physiol. Chem., 43 (1905), No. 5, pp. 417–446, fig. 1*).—The experiments reported were made with white rats. The conclusions drawn follow:

Acid cleavage products of casein, even when taken in large quantity, can not protect the animal body from a loss of nitrogen. Nitrogen equilibrium can be reached or, indeed, gains of nitrogen made, when the bodies are taken which result from a long-continued action of trypsin plus erepsin on albumins. Loss of nitrogen can also be prevented by the products of trypsin digestion which are not precipitated by phosphotungstic acid (the monamino acids). The same is true for the tryptic digestion products which are soluble in warm 96 per cent alcohol. Apparently the tryptic digestion products which are insoluble in alcohol do not have the power of preventing a loss of nitrogen.

Concerning the chemistry of the peptic and tryptic digestion of proteids, II, D. LAWROW (*Ztschr. Physiol. Chem., 43 (1905), No. 5, pp. 447–463*).—The effect of hydrochloric acid in peptic digestion was studied. Some of the conclusions which were drawn follow:

In the slow peptic digestion of proteids (gelatin and hemoglobin) hydrochloric acid had a decided effect. A 0.5 per cent solution of hydrochloric acid caused a cleavage which apparently resulted in the production of monamino acids. Hydrochloric acid was also found to exercise a marked effect on the autodigestion of pig's stomach.

The presence of hexon bases and acid amids in meat, E. ZUNZ (*Ann. Soc. Roy. Sci. Méd. et Nat. Bruxelles, 13 (1904), No. 3; abs. in Zentbl. Physiol., 18 (1904), No. 26, p. 852*).—Hexon bases and amid acids having been found in the contents of the stomach and small intestine of dogs killed 2 to 8 hours after they had been fed veal, the

author endeavored to determine whether these bodies were formed during digestion or whether they existed in the meat. When 5 kg. of lean veal, taken three-quarters of an hour after the calf was slaughtered, was boiled 0.679 gm. histidin, 0.138 gm. arginin, 0.559 gm. lysin, 0.227 gm. leucin, 0.662 gm. glutaminic acid, and 0.371 gm. aspartic acid were recovered.

Physiology of muscular work, J. M. LAHY (*Rev. Sci. [Paris], 5. ser., 3 (1905), Nos. 7, pp. 201–204; 8, pp. 230–238; 9, pp. 267–273*). A general summary and discussion of investigations which have to do with food in relation to work, fatigue, and related questions.

The ash constituents of feces, VON OEFELE (*Deut. Med. Presse, 9 (1905), No. 2, pp. 12, 13*).—Data are summarized regarding the ash constituents of feces. The author points out that the greater part of the sulphur exists in volatile compounds or is ordinarily lost in analysis.

The mucin content of feces, VON OEFELE (*Deut. Med. Presse, 9 (1905), No. 3, p. 22*).—In normal feces, according to the author, mucin constitutes only 2.02 per cent of the total dry matter. The amount seems larger on account of the large volume of water retained by the mucus. It is noted that part of the quantity present may be pseudo-mucin.

ANIMAL PRODUCTION.

Studies upon the composition of timothy hay, W. FREAR ET AL. (*Pennsylvania Sta. Rpt. 1904, pp. 40–115*).—With a view to securing a more exact knowledge of the composition of timothy hay, studies were undertaken which include a determination of a considerably larger number of constituents than is ordinarily taken into account in analysis of feeding stuffs and studies of the heat of combustion.

In every case the analytical methods are described in detail and numerous references are made to the literature of the subject. In the case of the calorimetric investigations, determinations were made of the different constituents removed from the hay by the solvents used and also of the extracts obtained by the use of solvents. In the latter case, cellulose blocks were saturated with the material tested, parallel determinations being made with the solvents used and the heat of combustion of the material extracted determined by difference. The following table summarizes the data regarding the composition of the dry matter of the timothy hay:

Composition of dry matter of timothy hay.

	Per cent.
Ash	4.730
Protein:	
Amid nitrogen as asparagin (N × 4.7)	.768
Albuminoids (albuminoid N × 6.25)	5.610
Cellulose (ash-free chlorination residue)	29.720
Lignic acids (including undetermined matter of alkali extract, less xylan disappearing during the extraction)	9.601
Hexosan (?) found in alkali extract	1.985
Hemicellulose, not xylan, decomposed by weak sulphuric acid	9.607
Hexosan (?) soluble in warm water	1.420
Xylan (including a little araban)	23.230
Reducing sugars, as dextrose	1.093
Sucrose	.909
Fat, waxes, resins, and colors (including all of ether extracts except the parts soluble in water and weak acid, and including the water-insoluble alcohol extract)	4.185

	Per cent.
Undetermined (including acids, part of the mucilage of the water extract, etc.):	
Petroleum ether extract	.056
Sulphuric ether extract	.354
Absolute alcohol extract	.671
80 per cent alcohol extract	3.860
Water extract	3.387

Owing to a slight discrepancy in the amounts of undetermined material calculated by difference and by detailed figures for the several extracts, the sum of the results as given is not exactly 100. Some of this undetermined material has already been divided into groups in the course of the investigations reported, but the author considers that the most important question to be studied is the determination of the nature of the hemicellulose—non-pentosans of the acid extract, and the hexosan (?) and lignic acid of the alkali extract.

The heat of combustion of the original hay and of the residues from the different reagents used in determining its composition is as follows, the figures being calculated on an ash-free basis:

Heat of combustion of ash-free timothy hay and its constituent parts.

	Calories.
Original hay	5,805
Residues:	
From petroleum ether extraction	4,722
From sulphuric ether extraction	4,613
From absolute alcohol extraction	4,644
From 80 per cent alcohol extraction	4,629
From cold water extraction	4,666
From dilute acid extraction	4,780
From dilute alkali extraction	4,444
From chlorination	4,118

The author's comments on some of these energy values follow:

"Confining attention to the extracts that form large fractions of the entire hay, we find that the dilute acid extract, composed chiefly of hemicellulose has a somewhat higher value than that ordinarily assigned to polysaccharids, viz, 4,100 to 4,230 calories.

"The value for the alkali extract is still higher. The value for the 'lignic acid' has been computed from the percentages of dextrose, polysaccharid or pentosan and albuminoids, allowing 3,762, 4,180 and 5,900 calories for their respective heat values; the value thus deduced for the undetermined ash-free residue, 'lignic acid,' is 5,281 calories.

"The heat value of the residue from the alkali extraction, crude fiber, is 4,368 calories without correction for ash, or 4,444 calories with such correction. . . .

"The heat value for the chlorination extract is very high. It must, however, be remembered that this value, obtained by difference, may be explained either by the low heat value of the chlorination residue or the high heat value of material removed during chlorination. The former explanation appears the more probable, since the chlorination process is distinctly oxidizing in its tendencies and the cellulose residue has the properties in part of an oxycellulose. Such an oxidation would naturally reduce the heat value of the residual organic matter."

The chemical composition and nutritive value of oats, F. TANGL, M. KORBULY, and S. WEISER (*Landw. Jahrb., 34 (1905), No. 1, pp. 65–92*).—Studies are reported on the composition and digestibility of Hungarian oats, the digestion experiments being made with both horses and sheep. The average coefficients of digestibility follow:

Coefficients of digestibility of oats.

	Organic matter.	Protein.	Ether extract.	Crude fiber.	Nitrogen-free extract.	Pentosan.	Availability of energy.
	P. ct.	*P. ct.*	*P. ct.*	*P. ct.*	*P. ct.*	*P. ct.*	*P. ct.*
Horse	59.7	68.2	54.0	7.1	69.3	15.2	58.7
Sheep	66.3	63.8	62.6	40.3	72.0	36.1	64.5

The authors calculate that with horses the physiological nutritive value of oats was 54.8 per cent and with sheep 53.85 per cent.

Sorghum seed as a feeding stuff, F. TANGL, S. WEISER, and A. ZAITSCHEK (*Landw. Jahrb., 34 (1905), No. 1, pp. 3–64*).—Data on sorghum as a feeding stuff are summarized, and an extended series of investigations are reported on the composition and feeding value of sorghum seed (*Sorghum vulgare*).

Investigations were made with horses, steers, milch cows, sheep, pigs, and different sorts of poultry. In the majority of the tests the digestibility was studied as well as the income and outgo of nitrogen, and in some cases the energy balance was calculated. In general the sorghum seed was fed with other materials and its digestibility calculated from the data obtained for the ration as a whole. The following table shows the average coefficients of digestibility with different farm animals:

Coefficients of digestibility of sorghum seed.

	Organic material.	Protein.	Ether extract.	Crude fiber.	Nitrogen-free extract.	Starch.	Pentosan.	Availability of energy.
	P. ct.	*P. ct.*	*P. ct.*	*P. ct.*	*P. ct.*	*P. ct.*	*P. ct.*	*P. ct.*
Steer	77.9	49.2	76.9	68.3	85.2	97.8	52.0	75.6
Sheep	74.2	55.9	84.0	17.1	79.2	87.6	....	72.0
Horse	63.7	41.5	60.6	28.7	74.1	82.5	24.4	66.3
Pig	75.8	60.3	71.6	19.8	83.3	98.5	44.9	72.5

The authors also calculated the physiological nutritive values. With ducks and geese the values were 46.7 and 57.1 per cent. With farm animals the figures varied from 56.5 per cent with sheep to 68.7 per cent with pigs. According to the authors, not more than 6 kg. of sorghum seed per 1,000 kg. live weight should be fed to steers. Larger quantities diminish its digestibility. It was found that substituting 1.33 liters of sorghum seed for a liter of corn gave good results with milch cows, though when cost was considered the advantage was with the corn.

The authors do not consider sorghum seed alone a satisfactory grain ration for horses, but consider it satisfactory when fed with double its amount of oats, the maximum amount recommended per day being 2.5 kg. On the basis of experimental data sorghum seed is considered a satisfactory feed for pigs. The raw seed was somewhat better digested than the cooked. Corn and sorghum mixed were not as well digested as when fed separately, since the sorghum is digested with difficulty and diminishes the digestibility of the corn. Sorghum is not considered a satisfactory feed for fattening chickens and ducks, but may be used for turkeys and geese, 1.5 kg. being equal to a kilogram of corn.

The digestibility of galactan, J. B. LINDSEY (*Massachusetts Sta. Rpt. 1904, pp. 78–84*).—In a test with 3 sheep, the digestibility of galactan was studied, the

feeding stuff selected as containing a fairly large amount of this constituent, being alsike clover seed which was fed with hay.

The dry matter of the alsike clover seed contained 34.29 per cent protein, 5.29 per cent fat, 41.42 per cent nitrogen-free extract, 13.12 per cent crude fiber, 5.88 per cent ash, and 8.07 per cent galactan. The composition of the dry matter of the hay was also given, the amount of galactan present being 1.72 per cent. On an average the coefficients of digestibility of the alsike clover seed were: Dry matter 80.49, galactan 95.78, protein 74.73, fat 84.55, nitrogen-free extract 86.26, crude fiber 86.04, and ash 51.21 per cent. The coefficient of digestibility of the galactan of hay was 75.35 per cent. Data are also recorded for the other constituents of the hay.

"All 3 sheep digested the galactan in the clover seed quite thoroughly. Such a result was to have been expected, for the reason that in the seed the galactan is supposed to be comparatively free from incrusting substances, which have been shown by various investigators to seriously interfere with the digestibility of the several fodder groups.

"Naturally, no positive conclusions should be drawn from the present single investigation. Knowing, however, the physiological and chemical character of the galactan, as well as the digestion coefficients obtained with starch and with the pentosans—bodies of similar character—it is reasonably safe to conclude that the results secured gave a fairly correct idea of the ability of the animal to utilize the galactan group."

Composition and digestibility of distillers' dried grains, A. K. RISSER (*Pennsylvania Sta. Rpt. 1904, pp. 221-238*).—Data regarding the composition of distillers' grains are summarized, and digestion experiments reported which were made with two sheep.

In the first period the ration consisted of hay, and in the second of hay and distillers' grains (Biles fourex), the digestibility of the distillers' grains alone being calculated in the usual way. The average coefficients of digestibility of the hay follow: Dry matter 50.18, protein 15.12, ether extract 14.76, nitrogen-free extract 49.75, crude fiber 60.83, and ash 48.92 per cent. The heat of combustion of the digested material was 47.43 per cent of that of the energy of the food eaten.

For the distillers' grains the values were: Dry matter 71.24, protein 65.32, ether extract 94.11, nitrogen-free extract 87.87, and crude fiber 58.98 per cent. The energy of the digested food was 71.64 per cent of that of the food eaten.

The respiration calorimeter at the Pennsylvania Experiment Station, H. P. ARMSBY (*Pennsylvania Sta. Rpt. 1904, pp. 208-220, pls. 6*).—This article is reprinted from the Experiment Station Record (15, p. 1037).

Condimental feeds and condition powders, J. P. STREET (*New Jersey Stas. Bul. 184, pp. 27*).—Microscopical, proximate, and ash analyses are reported of 50 samples of condimental foods and similar goods. Of these 17 were stock feeds, 14 poultry feeds, and 18 condition powders or tonics. The goods represent the product of 29 manufacturers and 23 were brands not previously analyzed at the experiment stations.

The goods were found to consist essentially of common drugs such as fenugreek, gentian, glauber salts, pepper, charcoal, oyster shells, etc., with common feeding stuffs such as corn meal, wheat, bran, and linseed meal. Data are given regarding the medicinal properties and dose of the drugs commonly used in condimental feeds.

"The claims of the manufacturers of condimental feeds, when not preposterous, are exaggerated and misleading. No one feed, however skillfully compounded, can serve as a remedy for all the ailments of all classes of live stock.

"Instead of being prepared according to scientific formulas, as claimed, many of the condimental feeds are heterogeneous mixtures, with little regard to the requirements of the animal, and in certain cases the drugs used have a counteracting effect on each other.

"Even where effective drugs have been used, the amount of the mixture to be given to the animal, according to the instructions of the manufacturer, is generally so small that no possible benefit can be expected from its use."

It is pointed out that the excessive cost of these feeds "would prohibit their use by the careful and economical feeder" who could obtain and mix for himself the ingredients likely to be of value "at from one-tenth to one-twentieth the cost of the prepared foods."

Concentrated feeding stuffs, J. P. STREET, W. P. ALLEN, and V. J. CARBERRY (*New Jersey Stas. Bul. 185, pp. 38*).—The feeding stuffs analyzed under the provisions of the State feeding stuffs law included 397 samples of cotton-seed meal, linseed meal, cocoanut cake, germ-oil meal, gluten meal and feed, hominy meal, corn, bran, or sugar feed, cerealine feed, germaline, maizeline feed, distillers' grains and similar goods, malt sprouts, dried brewers' grains, molasses grains and feeds, mixed and proprietary feeds, barley feed, dried-beet pulp, stock feed made from sugar beets, peanut bran, peanut middlings, rice feed, poultry feeds, animal meal and calf meal, wheat-bran middlings and feeding flour, wheat and rye middlings, rye bran and feed, corn meal, ground mixed grains, cracked rice, "corn-wheat" and buckwheat middlings, bran, and feed.

Of the 159 different brands of feed received, and which should have been guaranteed, 14 failed to meet this requirement. Consumers should at all times insist upon a guarantee, except for milling products, for which no guarantee is required.

Of the 288 samples which were guaranteed, 114 were deficient, 75 of these being low in protein.

Of the 95 samples which did not require a guarantee, 79 were of normal composition, 12 were of inferior grade, and 4 were misbranded.

Nine samples were found to be adulterated—linseed meal with cocoa shells, dried brewers' grains with coffee hulls and wheat feed with corncob.

The constantly increasing number of brands upon the markets requires, on the part of the purchaser, close attention to the amount of nutrients guaranteed and the prices asked for the same.

The purchaser of protein will rarely find any feed containing less than 15 per cent of protein a desirable or an economical purchase.

Analyses of miscellaneous feeding stuffs, M. H. PINGREE (*Pennsylvania Sta. Rpt. 1904, pp. 116–123*).—The analyses reported include cotton-seed meal and feed, sugar and oil meal, linseed meal (old and new process), flaxseed hulls, wheat bran, middlings, and mixed feed, Red Dog flour, wheat, gluten meal and feed, hominy, hominy feed and chop, corn, buckwheat middlings, distillers' grains, brewers' grains, molasses feed, beet-pulp feed, royal palm (*Oreodoxid regia*) berries, meat meal and similar goods, dried blood, and mixed and proprietary feeds.

Commercial feeding stuffs, H. J. WHEELER ET AL. (*Rhode Island Sta. Bul. 105, pp. 95–107*).—Under the provisions of the State law regarding the sale of commercial feeding stuffs analyses were made of a number of samples collected in the winter of 1904–5 including cotton-seed meal, linseed meal, gluten meal and feed, commercial mixed feeds, proprietary feeds and similar goods, wheat bran, ship stuff, middlings and shorts, hominy feed chop and similar products, corn meal, provenders, brewers' grains, distillers' grains, molasses grains, malt sprouts, stock feeds, calf meal, poultry feeds, dried molasses-beet-pulp, and peanut bran.

One of the cotton-seed meals examined was apparently very grossly adulterated with cotton-seed hulls. A mixed feed was also much adulterated and wheat bran and a number of samples of gluten feed and meal were below the guarantees in certain respects.

Security stock food, E. F. LADD (*North Dakota Sta. Rpt. 1904, pt. 1, pp. 29, 30*).—An analysis of this proprietary feeding stuff failed to bear out the claims made for it.

The principles of feeding and physiology of metabolism with special reference to farm animals, F. TANGL (*Landw. Jahrb., 34 (1905), No. 1, pp. 1, 2*).—The investigations, which are being carried on at the experiment station in Budapest for the study of animal physiology, are briefly outlined.

Live-stock score cards (*North Dakota Sta. Rpt. 1904, pt. 1, pp. 138–147*).—Specimens are given of the score cards used by the students at the North Dakota Agricultural College for judging live stock.

Calf rearing, W. T. LAWRENCE (*Jour. Bd. Agr. [London], 11 (1905), No. 12, pp. 705–716, figs. 3*).—The system of feeding calves practiced by a successful feeder in the north of England is described, the data being based on observations extending over a period of 9 years.

After 2 weeks whole milk is gradually replaced by skim milk and cream substitutes, those which have given the most satisfactory results being boiled linseed, ground linseed, and cod-liver oil. The scalded ground linseed is considered the most satisfactory. Two sorts of calf meal of domestic manufacture are spoken of, and rations suggested in which they are used.

Regarding the use of cotton-seed meal, the following statements are made:

"Loss among calves is often attributed to the use of cotton cake with the cows, but at this farm the cows when housed get in the regular way 4 lbs. of decorticated cake each per day, and for the latter half of the summer 2 lbs., and yet, with the exception of [5 calves which died from other causes], there have been no losses in 9 years out of a total of 180 calves born. It should, however, be stated that when a cow's milk falls to 5 qts. a day cake is entirely discontinued, as she does not pay for it and can be kept in good condition without it, so that practically no cow gets cotton cake for at least 2 months previous to calving, nor does she get cake in the week following; but after the first week of its life a calf is fed with the milk of any cow, or with the milk of several, that are receiving the usual allowance of cotton cake."

Calf feeding experiments, J. MAHON (*Queensland Agr. Jour., 15 (1905), No. 7, pp. 825, 826*).—In a test covering 6 weeks it was found that the average daily gain of 4 calves fed 2 oz. of cod-liver oil and 3 gal. of skim milk was 1.88 lbs., as compared with 1.66 lbs. in the case of calves fed a ration of 10 oz. of pollard, 3 oz. linseed meal, 2 oz. molasses, and 3 gal. skim milk. "The use of cod-liver oil facilitates the feeding of calves, and also lessens the danger of scouring which frequently occurs when improperly prepared or unsuitable food is fed to calves."

Raising calves on skim milk and pasture, J. S. MOORE (*Mississippi Sta. Rpt. 1904, p. 22*).—Calves were put on a skim-milk ration when 5 days old and fed grain and hay in addition as soon as they would eat it. In 391 days, the average weight was 496 lbs., and the total cost of the feed $11.47 per head.

How four hundred calves were wintered on ensilage, H. JONES (*Prairie Farmer, 77 (1905), No. 22, p. 1, fig. 1*).—Calves were fed corn and soy-bean silage ad libitum (25 to 30 lbs. per day), with clover, alfalfa, and oat hay. The grain ration consisted of 1 to 2 lbs. of cotton-seed meal, and for the last 6 weeks 5 lbs. corn-and-cob meal also. The average daily gain in the 5 months of the test was 1.78 lbs. per head, and the cost of a pound of gain 3.6 cts.

Experiment in beef production, W. J. KENNEDY ET AL. (*Iowa Sta. Bul. 81, pp. 337–372, figs. 25*).—Using 2 Jersey and 2 Holstein steers as representatives of the dairy breeds, and 2 Angus and a like number of high-grade Hereford steers as representatives of the beef type, a feeding test covering a year was made.

Both lots received the same ration of mixed grains and mixed hay with sorghum during July and August. The rations varied from month to month, the amount of corn being increased as the feeding period progressed. The average gain per steer in the case of the beef type was 606 lbs.; the average amount of dry matter required

per pound of gain 10.84 lbs., and the cost of a pound of gain 7.81 cts. In the case of the steers of the dairy type, the average gain was 597.75 lbs., the dry matter required per pound of gain 10.666 lbs., and the cost of a pound of gain 7.63 cts.

After slaughtering, the steers were used in demonstration work and the results of the slaughter tests were recorded in full in order to secure information regarding the differences in distribution of the meat in the two types. According to the author, the steers of the dairy type showed a considerably higher proportion of offal and a lower percentage of dressed weight, a higher percentage of fat on the internal organs, and consequently an increase in the total weight of the cheap parts. With the beef steers, the higher percentage of valuable cuts was noted.

"Beef type steers furnish heavier, thicker cuts; they are more evenly and neatly covered with outside fat, show superior marbling in flesh, are of a clearer white color in fat, and a brighter red in the lean meat; but there is little difference in fineness of grain.

"The low price paid for dairy steers may be due partially to prejudice and to the greater expense of carrying and selling the low-grade carcasses; but it is chiefly due to an actual inferiority in the carcasses.

"It is neither profitable nor desirable to feed steers of dairy type for beef purposes. They are unsatisfactory to the consumer, because they do not furnish thick and well marbled cuts; they are unsatisfactory to the butcher, because they furnish low-grade carcasses which are difficult to dispose of, and they are decidedly unsatifactory to the feeder, because they yield him little or no profit, and both breeder and feeder waste their time in producing such a type of steer for beef purposes."

Experiments with cattle, E. R. LLOYD (*Mississippi Sta. Rpt. 1904, pp. 14, 15*).—Data are given regarding the gains made by 2-year-old steers and by calves on pasturage. The largest gain, 300 lbs. per head, was noted with 2-year-old steers pastured from March 26 to November 1. The smallest gain, 218 lbs , was noted with calves.

In a test of the comparative feeding value of different hays it was found that 3 steers fed 4,000 lbs. of oat hay lost 40 lbs. in 103 days. A similar lot fed a like amount of Johnson-grass hay lost 50 lbs. while a lot fed practically the same amount of wheat-hay gained 13 lbs.

The comparative value of different rations containing cotton seed, and cotton-seed meal and hulls was studied with 5 lots of 5 steers each, the feeding period covering 120 days. The greatest gain, 690 lbs., was made by a lot fed a ration of cotton-seed meal and hulls. The smallest gain, 455 lbs., was made by a lot fed raw cotton seed, shelled corn, and sorghum hay. Data are also recorded regarding the dressed weight, the percentage of fat in the carcass, and the loss of weight in shipping.

From statistics which are given the average cost of feed for wintering the station cattle was $6.01 and sheep 65 cents.

Steer-feeding experiments, G. H. TRUE, T. F. MCCONNELL, and R. H. FORBES, (*Arizona Sta. Bul. 50, pp. 499–522, pls. 2*).—Of the 4 tests reported on the comparative value of alfalfa alone and supplemented by such coarse fodders as sorghum, the first has been noted from another publication (E. S. R., 12, p. 1074).

In the second trial a lot of 2 two-year-old steers on alfalfa and alfalfa hay made an average daily gain in 188 days of 1.58 lbs. per head. The gain made by a similar lot fed wheat hay and cured sorghum in addition to green alfalfa and alfalfa hay was 1.50 lbs. per head per day, and by a lot fed some rolled barley in addition to alfalfa fresh and cured, wheat hay, and cured sorghum 1.87 lbs.

The third test was made with 2 lots each containing 11 yearlings and covered 485 days. The lot fed principally alfalfa made an average daily gain of 1.21 lbs. per head, and the lot fed a ration of sorghum hay, wheat hay, etc., in addition to alfalfa 1.26 lbs. In the fourth test, which covered 522 days, 4 steers fed alfalfa as a soiling crop, hay or both, in the different periods, made an average daily gain in the whole test of 1 lb. per head as compared with 0.98 lb. in the case of a lot fed alfalfa supple-

mented principally by sorghum hay. In connection with this test 1 lot of 4 steers was kept on alfalfa pasturage to compare this method of feeding with the data obtained by the use of alfalfa as a soiling crop or hay. In 518 days there was an average daily gain on the alfalfa pasturage of 1.01 lbs. per head. From the data included in the bulletin the general conclusion was drawn that the combination rations containing alfalfa were about equal in feeding value to rations of fresh and cured alfalfa.

In all cases the shrinkage when steers were dressed was taken into account, and the conclusion was reached that although the differences were small yet this factor was slightly greater with the lots fed alfalfa combined with other materials than on alfalfa alone.

"Since alfalfa, where conditions are favorable for its production, yields the most abundant and cheapest forage grown in the Southwest, the high percentage of protein may be disregarded, although theoretically a carbohydrate feed, such as sorghum or grain hay, should be fed with it to secure the more thorough utilization of the protein of the alfalfa by the animal. In situations where alfalfa can not be produced to advantage, as with scant water supply and on excessively alkaline soils, carbohydrate rations may often be grown, especially of the sorghum class, which in combination with alfalfa give results about equal to those from the all-alfalfa ration. Sorghum rations alone are undoubtedly inferior to alfalfa alone and in combination with alfalfa yield greater gains than when fed alone.

"The quality of the meat from alfalfa-fed steers appears to be about the same as that from animals fed on the combined rations used. Animals finished with barley yielded meat of distinctly better quality, but the slight advance in price obtained did not make return for the barley fed.

"Assuming the approximately average and representative character of the forages used, the yields obtained, and the animals employed, the results of these experiments indicate that under southwestern conditions, where alfalfa may be fed or pastured all or nearly all the year, this forage is the most abundant and the cheapest feed available, giving as good gains of as good quality as can be economically produced."

Methods of steer feeding: Barn v. seed, T. I. Mairs and A. K. Risser (*Pennsylvania Sta. Rpt. 1904, pp. 197–204*).—Twelve steers fed in barns for 98 days made a total gain of 2,760 lbs., while a similar lot fed like rations in sheds gained 2,724 lbs. The test reported has been abstracted from another publication (E. S. R., 16, p. 398).

Digestion experiments with sheep, J. B. Lindsey et al. (*Massachusetts Sta. Rpt. 1904, pp. 45–77*).—Continuing earlier work (E. S. R., 16, p. 395), a number of digestion experiments with sheep were made, each covering a period of 14 days of which the first 7 were regarded as preliminary. The different materials tested were fed with meadow hay, the digestibility of the special feeds being calculated in the usual way. A summary of the work follows:

Coefficients of digestibility of feeding stuffs in experiments with sheep.

Kind of feed.	Number of tests.	Dry matter.	Protein.	Fat.	Nitrogen-free extract.	Crude fiber.	Ash.
		Per ct.	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*	*Per ct.*
Soy-bean fodder	3	63.53	82.96	65.12	77.82	38.90	21.05
Eureka silage corn fodder (green)	3	66.63	67.02	65.93	72.44	60.26	42.21
Eureka silage corn fodder (dry)	2	63.84	57.04	62.43	63.82	71.56	40.34
Apple pomace	3	70.60	....	43.41	84.30	67.31	42.81
English hay, young sheep	5	52.00	37.36	40.49	57.83	52.96	17.89
English hay, old sheep	2	58.66	42.36	46.37	64.14	60.87	22.16
Bibby's dairy cake	6	69.96	65.51	92.44	81.16	46.15	33.08
Dried molasses beet pulp	2	84.51	64.08	....	91.08	83.87	61.52
Blood meal	2	....	84.00	....	....	....	....
Medium green soy-bean meal	2	89.72	91.51	93.13	82.24	113.55	69.61
Hominy feed and chop	6	80.09	62.78	92.52	87.85	60.68	32.05

The principal conclusions which were drawn follow:

Apparently owing to the characteristic hard-wood stems, the total dry matter of soy-bean fodder seemed slightly less digestible than that of other legumes such as clover, Canada field peas, and cowpeas. Apple pomace was found to be as digestible as the better grades of corn silage. English hay was fairly digestible, and no great variations were noted due to individual peculiarities, though on an average, young sheep did not digest the material as thoroughly as old sheep.

In general the author considers that Bibby's dairy cake was only moderately well digested, and possesses a nutritive value similar to standard wheat middlings. Considerable difficulty was experienced in digesting the crude fiber, probably owing to the fact that it was derived largely from cotton-seed hulls. The sheep ate dried molasses-beet-pulp readily and digested it without trouble, and the author believes that this material has a feeding value about 10 per cent less than corn meal.

Judging from the experimental data, the author considers that the protein of blood meal is quite thoroughly utilized by farm animals. Soy-bean meal was on an average quite thoroughly digested, especially the protein and fat, its two most important constituents. As compared with the average results for corn meal, hominy feed, or chop gave somewhat lower coefficients of digestibility. "It has been assumed hitherto that hominy was as digestible as corn meal; but in view of the results obtained, this opinion is no longer tenable."

As regards the results obtained with Eureka corn fodder, the author considers them very favorable as compared with those obtained by other experimenters with other varieties of corn at a similar stage of growth. In general the dry fodder was not as well digested as the green material. "This may be accounted for partly on the ground that the sheep received the green fodder in September, after having been at pasture all summer, while the dried material was fed in March, after they had been in similar experiments for 6 months; and partly because previous experiments have demonstrated that in case of very coarse fodders sheep digest the green substance a little more thoroughly than the cured."

Effects of feeding cotton-seed meal upon the health of animals, E. FULMER (*Washington Sta. Bul. 67, pp. 28-42*).—This contains a summary of the data recorded by experiment station investigators on the effects of cotton-seed meal on the health of animals, and deductions drawn from facts obtained in connection with the author's investigations.

Of the 23 animals used in the tests with cotton seed at the Washington Station, only one died. This pig weighed 131 lbs., and had consumed 47 lbs. of cotton-seed meal, a quantity equal to 35.9 lbs. per 100 lbs. body weight. The feeding periods ranged from 14 to 98 days in duration, and in no other case were functional disorders noted. The amounts of cotton-seed meal eaten by the different pigs ranged from 7.7 to 154 lbs.

"The cool weather during the feeding period, the nature of the grain ration (chopped barley, oats, or wheat), the abundance of succulent food fed, and the opportunities for exercise, all doubtless had an influence upon the successful issue of these experiments, regarded from the standpoint of the stockman.

Cotton food products in hog feeding, R. R. DINWIDDIE (*Arkansas Sta. Bul. 85, pp. 1-26*).—Continuing the studies of cotton-seed products for pigs (E. S. R., 15, p. 68), 11 tests were made in which cotton-seed meal or chopped cotton seed were fed with different combinations of grain, cotton-hull bran, and cowpea hay; 2 in which crude cotton-seed oil was fed with bran and corn, and 1 for purposes of comparison in which the ration was composed of bran and shorts. The amounts of cotton seed eaten and the gains in weight are recorded, as well as the weight of the liver and kidneys and the melting point of the leaf lard and the body lard. The author's summary follows:

"The toxicity or otherwise of cotton-seed meal for hogs, just as for cattle, is a question of dosage. Small amounts may be fed indefinitely, larger quantities for a limited

period only, without inducing toxic symptoms. The toxic allowance is determined by the amount per day rather than by the absolute amount fed. Thirty pounds fed in 30 days may cause fatal poisoning while amounts up to 150 lbs. in proper daily allowance have been fed without harmful effects. In feeding cotton-seed meal to pigs the daily allowance in general should be arrived at from the age and weight of the animals.

"For continuous feeding the following allowances appear to be well within the danger limit: Pigs under 50 lbs., one-fourth pound per day. Pigs from 50 to 75 lbs., one-third pound per day. Pigs from 75 to 100 lbs., 0.4 lb. per day. Pigs from 100 to 150 lbs., one-half pound per day. If fed a full grain allowance, the dosage may be obtained by properly proportioning the cotton-seed meal to the other components of the ration, namely, 1 to 5, 6, 7, or 8, according to the stage of growth. When pigs obtain part of their feed by grazing a proportion of 1 to 4 or 1 to 5 can be fed by diminishing the grain allowance. A meal ration containing cotton-seed meal should also contain at least an equal amount of wheat bran to supply bulk. For the remainder, corn appears to be the only choice.

"In a ration for hogs cotton-seed meal can only be used as an adjunct and corrector for a basal corn ration, and this is obtained by the proportions mentioned. At the price prevailing and likely to prevail for cotton-seed meal it is doubtful if larger amounts could be economically fed even independent of the toxic effect of the food. In the amount prescribed above cotton-seed meal can be fed indefinitely as to the time just as any other feed. With the same breed of pigs a ration of cotton-seed meal, bran, and corn in various proportions has made quicker and more profitable gains than bran and corn alone, and this at all stages of growth.

"Cotton-seed meal has not been found to exert any specially harmful influences on breeding stock independent of its general toxic effects. Cotton seed (chopped), although eaten at first reluctantly and always with some waste, seemed so to supplement or economize the corn ration, with which it was fed, that a relatively cheap production of pork was produced by its use. (Based on one test only.) It would seem that on account of its cheapness to the southern farmer it might, if fed carefully, be utilized in pork growing. The daily allowance should be about the same as for cotton-seed meal and the feeding done in such a way that this allowance could not be exceeded. Cotton seed and corn make probably the best combination, about 1 to 6 or more if on full feed, or 1 to 3, 4, or 5 if on short allowance of grain.

"Where hogs are allowed free access to cotton seed they will likely poison themselves unless freely supplied with other food, in which case the amount eaten may not be sufficient to cause poisoning. We have had no experience with cotton seed rotted, roasted, steamed, or otherwise treated, but believe the harmful influence to be about the same in character and degree as in cotton-seed meal, being located in the kernel or 'meat.' Cotton-seed hulls are not toxic for hogs, and hence probably not for cattle either. They are only available for hog feed when ground into a 'bran,' and at the price charged this 'cotton-hull bran' is unprofitable. 'Cotton-seed feed' should also be avoided as a hog feed.

"Crude cotton oil when fed apart from the kernels has not occasioned symptoms such as we found in cotton-seed meal poisoning, although in the quantities fed it seemed to act harmfully, giving rise to unthriftiness and possibly even death. These conditions may be the effect of an overoleaginous ration or of a special toxin. Our trials have not yet decided this matter.

"The economy or profit to the southern planter of feeding cotton seed or cotton-seed meal to hogs is a subject worthy of more extensive investigation than it has yet received, such investigations being made along the lines suggested in this report. Guided by these suggestions as to rations, the prospect is favorable, but feeding in ignorance or indifference of these will only result in loss. The idea that cotton-food

products can ever take the place of corn in pork production in the South may well be abandoned. They can not replace but may prove valuable adjuncts to corn or any other starchy or carbohydrate food which may be found available in the South for hog feeding. The conditions here are not the same as in cattle feeding where the hulls are available for roughage."

The tests reported in the author's opinion do not afford much opportunity for judging of the nature of poisoning due to cotton seed. In so far as can be judged from the data obtained, he considers that cases of overfeeding with cotton seed or cotton-seed meal induce "congestion of the eliminative organs (liver or kidneys), followed by one of three conditions, according to the degree of overfeeding, namely:

"(a) Progressive engorgement with impairment of function leading to acute dropsical effusion into the various serous cavities and death within two months or less. This is the most acute form.

"(b) Primary engorgement as above followed by degenerative changes, fatty and atrophic in the liver, sclerotic and atrophic in the kidneys, with progressive loss of function.

"(c) Congestion of less degree which the organs become more or less habituated to and in which only slight and temporary symptoms develop and no marked organic changes are found.

"(d) Long-continued feeding on cotton-seed meal in the safe doses prescribed above has given rise to no gross organic changes in liver, kidneys, or other organs discoverable on slaughter. No fault has been found by the butcher purchasing our animals as to the quality of the flesh or fat. Prolonged feeding on cotton-food products has been found to greatly heighten the melting point of the lard."

Experiments with hogs, E. R. Lloyd (*Mississippi Sta. Rpt. 1904, pp. 12, 13*).—In a study of the value of alfalfa pasturage without grain, 14 pigs 2 months old gained only 33 lbs. in 37 days on 1.33 acres of alfalfa, indicating that without additional food alfalfa is "about a maintenance ration for growing pigs." When all the ripe sorghum which would be eaten up clean was fed, in addition to corn equal to 1.4 per cent of the weight of the pigs, the ration was found a little more than sufficient for maintenance.

Fourteen young pigs, running with their dams, pastured on 1.66 acres of cowpeas, made an average daily gain of 1 lb. for a period of 23 days. In a study of the gains made by pigs fed grain, as compared with those following steers and fed a small amount of grain in addition, it was found that 7 pigs fed grain in a pen made a total gain of 299 lbs. in 54 days, requiring 4.7 lbs. of grain per pound of gain, at a cost of 4.88 cts. per pound. The gain made by a similar lot following steers was 262 lbs. In addition to what they could gather, these pigs required 1.3 lbs. of grain per pound of gain at a cost of 1.15 cts. per pound.

Feeding pigs on skim milk and pasture, J. S. Moore (*Mississippi Sta. Rpt. 1904, pp. 22, 23*).—The comparative value of oats and vetch, alfalfa, and sorghum as green feed was studied with pigs in consecutive periods of 31, 132, and 31 days, the test being supplemented by a period of 45 days on skim milk and corn. Some corn was fed with the oats and vetch and with the sorghum.

The greatest gain, 0.9 lb. per head per day, was noted on oats and vetch and the smallest, 0.03 lb. per day, on sorghum. On skim milk and corn the average daily gain was 0.8 lb. per head. Considering the test as a whole, the cost of a pound of gain ranged from 1.44 cts. on alfalfa pasturage to 25 cts. on sorghum.

The horse, I. P. Roberts (*New York and London: The Macmillan Co., 1905, pp. XL+401, figs. 97*).—In this handbook a history is given of the domesticated breeds of horses in America, chapters on breeding, judging, and educating the horse; the care of horses, stables, sanitation, and paddocks; the line of draft, weight of horses, width of wagon tires, and related questions.

In the appendix are articles on The Breeding of Horses in Canada for Army Use, by J. G. Rutherford; Computing Rations for Farm Animals, by J. L. Stone; a register of the live stock registry associations with the names of the secretaries or editors; and a summary of statistical data of the number and value of horses in the United States as shown by the last census. A detailed index adds to the value of the volume, which, as a whole, embodies the results of many years of experiment and close observation, and will prove of value in connection with the work of agricultural colleges, as well as of interest to general readers.

Blomo feed for horses, J. B. LINDSEY and P. H. SMITH (*Massachusetts Sta. Rpt. 1904, pp. 88–93*).—As shown by the percentage composition, which is given, of dried Blomo feed (a mixture of ground cornstalks, or some similar material, with dried blood and refuse molasses), it contains more protein and decidedly less fat and starchy material than either oats or corn.

When this material was fed with corn and hay in place of oats to 4 horses, the weight of the animals varied slightly from week to week, but they remained in good condition and performed the amount of work required. In a second trial, 6 quarts of Blomo feed was compared with a like amount of oats, the remainder of the ration being made up of 6 quarts of cracked corn and as much hay as seemed needed. On the Blomo feed the 4 horses used made a total gain of 75 pounds in 6 weeks, and a like number on oats of 55 pounds. The work varied from day to day, and the authors find it impossible to say that one ration gave better results than the other.

"It can simply be stated that the horses ate the Blomo ration readily, kept in good condition, and did satisfactory work during the trial. Considerable of the Blomo spoiled on being kept during the warm weather, and it will be necessary for the manufacturers to reduce the moisture content in order to overcome this difficulty. . . . No injurious effect was noted from feeding a considerable quantity of Blomo as a component of the daily ration during a period of 7 months. The horses kept in good condition and did satisfactory work. Owing to a misunderstanding, whereby the Blomo and oats were fed measure for measure instead of weight for weight, it was not possible to directly compare the feeding value of these two feeds."

Digestion experiments with sheep gave the following coefficients of digestibility for Blomo feed: Dry matter, 66.7; protein, 62.7; fat, 15.3; nitrogen-free extract, 76.0; crude fiber, 61.4, and ash, 31.4 per cent. It "contained noticeably less digestible matter than corn or oats, and at the prices usually prevailing the nutritive matter it contains must be regarded as decidedly expensive."

Poultry experiments, W. P. BROOKS, F. R. CHURCH, and S. B. HASKELL (*Massachusetts Sta. Rpt. 1904, pp. 153–156*).—When wheat and corn supplemented by animal meal were compared for egg production it was found that in the winter period, February 3 to March 17, the average egg production on wheat was 43.33 eggs and on corn 38.33 eggs per 100 hens. For the summer period, May 17 to September 30, the average daily egg production per 100 hens was 19.1 eggs on wheat and 20.66 eggs per day on corn. The cost of food per egg in the winter period on the wheat ration was 0.611 ct. and in the summer period 1.657 cts.; similar values for corn were 0.505 ct. and 1.315 cts.

When wheat and corn supplemented by milk albumin and corn oil were compared, the average egg production on wheat in the winter period was 46.33 eggs per day per 100 hens, and on corn 43.25. Similar values for the summer period were on wheat 31 and on corn 30.17. The cost of food per egg for the two periods on wheat was 0.547 and 1.341 cts., and on corn 0.392 ct. and 0.918 ct.

When wheat and rice were compared, milk albumin being used as a source of animal food in both rations, the average daily egg production per 100 hens on wheat in the winter period was 38.13 and on rice 40.75. For the summer period, the corresponding values were 22.5 and 30.17 eggs, respectively. For wheat the cost of feed per egg in the two periods was 0.698 ct. and 1.59 cts. and for rice 1.186 and 2.379 cts.,

respectively. The author states that rice, which contains very little fat, was selected in order to secure data regarding the importance of this constituent in the ration of laying hens.

"The ration including rice this year as last has given one of the most satisfactory egg products obtained. The high cost of this food at the present time seems to preclude its becoming a question of much practical importance whether rice is well or ill suited as a food for egg production. . . .

"The large egg product where rice is prominent among the foods used seems to indicate that fat is less important than has been judged as the result of some of our earlier experiments. Among the various grains, cleaned rice, as put upon our markets, contains least fiber, and rice is known to be the most digestible of all the grains. It is perhaps these peculiarities of this grain which account for its apparent good effect on the egg product."

Poultry report for 1904 (*North Dakota Sta. Rpt. 1904, pt. 1, pp. 169, 170*).—Brief statements are made regarding the number of poultry kept at the station farm, the eggs laid, stock on hand, etc.

A hatching experiment, W. F. BRITTIN (*Rel. Poultry Jour., 12 (1905), No. 2, p. 237*).—The author tested the effects of rations with and without oyster shells on the fertility of eggs hatched in incubators. In his opinion the results show that eggs laid by hens fed no oyster shells hatched about 20 per cent more chicks than the fertile eggs laid by the hens fed oyster shells. Apparently too much lime hardened the egg shells and prevented good hatches.

DAIRY FARMING—DAIRYING.

Feeding trials with cows, J. L. HILLS (*Vermont Sta. Rpt. 1904, pp. 462-511, 547-584*).—Feeding experiments conducted on the same general plan as in previous years (E. S. R., 16, p. 1109) were designed to test the efficiency of a 2-lb. grain ration for cows, to determine the feeding value of dried molasses-beet-pulp, India wheat meal, and hominy feed, and to secure further data on the experimental error involved in feeding trials. The trials extended over 25 weeks and included 53 cows, the individual tests lasting 5 weeks and including from 4 to 14 cows each.

Grain rations of 2, 4, and 8 lbs. were again compared, the results showing an increase in the yield of milk of 8 per cent when the 4-lb. ration replaced the 2-lb. ration, and of 14 per cent when the 8-lb. ration was fed. It is estimated that when the 2 lbs. of grain was fed instead of 4 lbs. the saving in cost of feed was $4.02 and the loss in butter not made was $1.28, and that when 2 lbs. of grain was fed instead of 8 lbs. the saving in cost of feed was $7.57 and the loss of butter was $3.02. Taking into account the value of the skim milk and manure, the figures in the first instance become $4.02 and $3.33, respectively, and in the second instance $7.57 and $7.09. The results in opposition to those obtained last year are therefore favorable to the restricted grain ration. "The writer's judgment, notwithstanding this outcome, does not approve a grain ration so very restricted in its nature."

Dried molasses-beet-pulp was compared with wheat bran, with which, pound for pound of dry matter, it was found to be equivalent in feeding value. A similar comparison was also made with corn silage with like results.

India wheat meal, produced locally from the seed of *Fagopyrum tartaricum*, was compared with wheat bran and a mixture of cotton-seed meal and linseed meal. When fed in small quantities the India wheat meal was considered a fair substitute, pound for pound, for these 2 feeds.

Hominy feed in comparative tests was found equal in value for milk production to wheat bran, but inferior to gluten meal and a mixture of cotton-seed meal and linseed meal. At market prices the hominy feed was not so economical as the gluten and cotton-seed and linseed meals.

When 6 to 8 animals are used in feeding trials by the alternation method there is believed to be practically no experimental error.

A comparison of feeding trial methods, J. L. HILLS (*Vermont Sta. Rpt. 1904, pp. 511–523*).—This gives the results of the fourth test of the 2 methods of conducting feeding trials designated the "simple alternation system" and the "combined continuous and alternation system," the same conclusion being reached as in previous years that the alternation system is the better of the two. While it is not considered likely that material change in this position will result from future trials, it is nevertheless the intention to accumulate additional data on this subject.

Record of the station herd for 1903–4, J. L. HILLS (*Vermont Sta. Rpt. 1904, pp. 523–532*).—Records of 51 cows for the year are reported. Some of the average results are as follows:

Yield of milk 5,018 lbs., fat content 5.07 per cent, total solids 14.42 per cent, yield of butter 296.8 lbs., cost of food $48.11, and proceeds from sale of butter, $89.05. Records of the herd for 10 years have now been obtained, and the commencement of an attempt to digest this mass of data has been made which, it is hoped, may be reported upon in the near future.

Report of dairy department, J. S. MOORE (*Mississippi Sta. Rpt. 1904, pp. 16–22*).—Records of 9 Jersey cows and of 5 native or grade cows for 1 year are reported. The average yield of milk of the Jersey cows was 4,902 lbs. for the year, and of the other cows 3,904 lbs. The average cost of producing 1 lb. of butter in the former case was 7.48 cts. and in the latter 11.9 cts.

In an experiment lasting 4 weeks 4 cows were turned on native pasture and 4 were put on a 3-acre field of hairy vetch. The cows on vetch pasture received in addition cotton-seed hulls and meal, while the other cows received hay, cotton-seed hulls and meal, and wheat bran in addition to the native pasture. The cows fed hairy vetch produced in the 4 weeks 272 lbs. more milk than the other cows. Allowing market values for the feeds consumed and the milk produced, a difference of $15.44 was credited to the 3 acres of hairy vetch. The yield of vetch seed was apparently not decreased by the grazing.

Forage and soiling experiments, 1903, G. C. WATSON and T. I. MAIRS (*Pennsylvania Sta. Rpt. 1904, pp. 170–172, 174–182*).—Ten forage crops were grown during the season and fed to 5 cows, the work being in continuation of experiments previously reported (E. S. R., 15, p. 998). The authors summarize the results obtained as follows:

"(1) Of the various crops grown alfalfa produced the largest yield of air-dry substance per acre. As a green forage this crop was quite satisfactory. The cows ate it with considerable relish, and everything considered it proved a most satisfactory soiling crop. Wherever alfalfa can be grown successfully it is to be recommended for soiling purposes.

"(2) Flat peas produced next to the largest yield of dry matter and also next to the largest yield of total protein. This plant when well established gives a large yield of forage that is rich in protein, but as a soiling crop for dairy cows it is not to be specially recommended for several reasons. It requires two or three years to become well established. It is not relished by cattle and it may impart to the milk an undesirable flavor when not cautiously fed.

"(3) Corn ranks third in a production of air-dry substance, and is one of the best and cheapest of soiling crops. The most serious objection to this crop is due to the fact that its period of maturing is so late in the season that it can not be profitably fed in the fresh condition except in the latter part of the season.

"(4) Sorghum and cowpeas produced a large yield of nitrogenous and palatable food. This combination proved most satisfactory in all respects. The cows ate it readily, and from the feeder's standpoint very few objections were noted.

"(5) Rye is praised as a soiling crop on account of its rapid growth early in the season. A mistake is often made in cutting this crop too late in the season. Cutting should be commenced before the rye heads out. After heads are formed it rapidly becomes woody and unfit as a soiling crop. Under ordinary conditions it can not be fed very long after heading out without causing a decrease in the flow of milk.

"(6) Soja beans and cowpeas produced a fair yield of dry matter per acre and proved quite satisfactory as soiling crops. From the trials made at the station with these two crops, cowpeas are preferred to the beans. The vines are less woody and from the feeder's standpoint are preferred.

"There seems to be quite a marked difference between the different varieties of soja beans. Some varieties mature very much earlier than others. As both soja beans and cowpeas are hot-weather plants and thrive best in warm countries the early maturing varieties should be sown.

"(7) Where Canada field peas grow well they make a most excellent forage crop when sown with oats. It is essential to have the sowing made early in the spring in order to secure a good germination. If the seeding is made late in the spring the peas should be sown somewhat deeper than the oats. This crop produced a good yield and proved to be a most excellent soiling crop. It has the advantage of some other crops of being readily converted into good hay if more is raised than is needed for soiling purposes.

"(8) Rape is not to be commended as a soiling crop. Cattle do not eat it well and in some instances it is said to have imparted an objectionable flavor to the milk. It is not so early as some other crops and neither is it as good."

The feeding value of apple pomace, J. B. LINDSEY (*Massachusetts Sta. Rpt. 1904, pp. 85–87*).—The average composition of 2 samples of apple pomace is reported as follows: Water 80 80 per cent, protein 0.98, fat 1.09, nitrogen-free extract 13.38, crude fiber 3.09, ash 0.67. The average coefficients of digestibility as determined in 6 trials are as follows: Dry matter 71.5, fat 45.3, nitrogen-free extract 84.4, crude fiber 64.4, ash 48.7. Apple pomace is therefore believed to approach corn silage in feeding value.

From 15 to 30 lbs. of apple pomace have been fed daily to dairy animals at the station with satisfactory results. When fed in a balanced ration it is estimated that 4 lbs. of apple pomace is equivalent to 1 lb. of good hay. Feeders are cautioned against feeding too large quantities of apple pomace at first. "Judging from all the data available, it is believed that farmers living in the vicinity of cider mills will find it good economy to utilize the pomace as a food for their dairy stock."

A milking machine that promises to be a success, H. H. LYON (*Hoard's Dairyman, 36 (1905), No. 33, p. 855*).—The author describes briefly and comments favorably upon the use of the Burrell machine.

The composition of cow's milk obtained at one milking from the different quarters of the udder, R. HANNE (*Milchw. Zentbl., 1 (1905), No. 8, pp. 356–363*).—In these experiments with 15 cows the yield of milk from the different quarters of the udder varied greatly. In general the hind quarters yielded more than the fore and the right half more than the left. Marked differences were observed in the composition of the milk from the different quarters at the same milking, and these variations were not constant for any cow in successive milkings.

Investigations on the influence upon milk production of food fat and other food constituents when added to scanty rations, A. MORGEN, C. BEGER, and G. FINGERLING (*Landw. Vers. Stat., 62 (1905), No. 4–5, pp. 251–386*).—This series of experiments, conducted with 8 sheep and 1 goat, is in continuation of similar work previously noted (E. S. R., 16, p. 696). The basal ration fed in the present experiments was normal as regards nutritive ratio but restricted in quantity. In some of the experiments the quantity of fat in the basal ration was also deficient. The food constituent particularly studied as an addition to this ration was fat, though more attention was paid to carbohydrates and protein than in the earlier work.

When fed under these conditions the addition of fat and of protein had always a very favorable influence on milk production, though in an essentially different manner, the food fat being considered as exerting a specific influence on the formation of milk fat, while the protein showed no such specific action. The addition of carbohydrates was without influence on either the total yield of milk or the production of milk fat. The additional quantity of food fat increased the refractometer number of the milk fat. Protein and carbohydrates showed no such influence. The variations in the live weight of the animals due to the supplementary foods was unimportant and warranted no definite conclusions.

While not able to prove that protein and carbohydrates have no specific influence in the production of milk fat, the authors believe from the results obtained in their investigations to date that food fat in quantities appropriate to the individual is especially suited to the formation of milk fat and, perhaps up to a certain limit, can not be generally replaced by the other food constituents. The reliability of the method employed in making corrections for the decreased production of the animals in successive periods is also discussed.

The chemistry of cow's milk, L. L. VAN SLYKE (*Arch. Ped., 22 (1905), No. 7, pp. 509–522*).—This discussion is based largely upon data obtained by the experiment stations in the United States.

"The knowledge thus furnished impresses one with the following facts: First, analyses of milk, either averages or individual, furnish little real information unless we know something of the history of the samples. Second, analyses made in other countries may have little or no value when applied to milk produced in the United States. Third, any statement of so-called average composition of milk is misleading, because normal cow's milk varies so much in composition, while many averages that have been published are entirely misleadiug and thoroughly absurd."

The author considers the nature and amounts of the different constituents in milk, and suggests that in modifying milk for the use of infants and invalids the only way that is really safe is to ascertain the actual content of fat and proteids in the milk to be used for this purpose, rather than to take any average statement of composition as a basis for such modification.

On the origin of lactose, C. PORCHER (*Compt. Rend. Acad. Sci. [Paris], 141 (1905), No. 1, pp. 73–75*).—In continuing his studies on the physiology of the mammary gland (E. S. R., 16, p. 192), the author made use of 4 goats and 1 cow in full lactation, removing the mammary gland in each instance. The results are in accord with those previously obtained, and indicate that the transformation of glucose into lactose is an intramammary function.

The detection and interpretation of the presence of ammonia in milk, A. TRILLAT and SAUTON (*Ann. Inst. Pasteur, 19 (1905), No. 8, pp. 494–502*).—As applied to milk the nitrogen iodid test for ammonia, previously noted (E. S. R., 17, p. 113), is made preferably as follows:

Ten cc. of milk is placed in a test tube and treated with 10 cc. of a 10 per cent solution of iodin trichlorid. The filtrate is neutralized carefully by the addition of lime water, when in the presence of ammonia a black precipitate of nitrogen iodid soluble in an excess of the reagent is formed. According to the authors, as small a quantity of ammonia as 1 in 100,000 may be detected in this way and approximate quantitative determinations made colorimetrically.

The milk of healthy cows was not found to give this reaction. The authors then investigated the conditions under which ammonia may be present in milk. Milk inoculated with sour milk and with typhoid, coli, anthrax, tubercle, and cholera germs did not show the presence of ammonia during 72 hours. On the contrary, milk inoculated with *Micrococcus ureæ, Tyrothrix tenuis, T. filiformis, Bacillus V* of Flügge, sewage, and putrefying materials responded after some hours to the test. So also did pure milk diluted with 10 per cent of water from the Seine River.

While the absence of ammonia is therefore no proof of the purity of a sample, its presence must be considered as an indication that the milk has been watered or otherwise contaminated, and this method of examination therefore becomes of importance from the standpoint of hygiene.

Are nitrates eliminated by the mammary gland? M. HENSEVAL and G. MULLIE (*Rev. Gén. Lait, 4 (1905), No. 22, pp. 512–518*).—The presence of nitrates in milk is usually accepted as an indication of watering.

In endeavoring to ascertain if nitrates are ever excreted in milk, the authors have carried on experiments since 1903 with 20 cows, most of which were diseased. The results with only 1 cow are reported in this preliminary note. This animal, which was affected with actinomycosis, was given potassium nitrate, and the milk obtained showed often, though not uniformly, the characteristic reaction of nitrates.

The fat of top milks, J. W. ENGLAND and C. H. LA WALL (*Jour. Amer. Med. Assoc., 45 (1905), No. 13, pp. 893, 894*).—Fat determinations by the Leffmann and Beam method were made of the layer of cream in certified, guaranteed, and ordinary bottled milk as sold by 8 or 9 dairies in Philadelphia. It is stated that marked differences were found in the fat content of the cream from pint bottles as compared with quart bottles, and for that reason pint bottles should never be used in obtaining top milk for modification in infant feeding.

Biological and biochemical studies of milk, C. J. KONING (*Milchw. Zentbl., 1 (1905), Nos. 7, pp. 289–305; 8, pp. 338–356*).—The studies here reported in continuation of previous work (E. S. R., 16, p. 817) deal with the acidity of milk. Among the conclusions reached are the following:

In market milk there is no definite relation between the number of bacteria and the degree of acidity. The loss of carbon dioxid, through which the acidity is reduced, is not replaced during the bactericidal stage by the production of lactic acid. Not until the degree of acidity has passed a certain limit is there a definite relation between the production of acid and the multiplication of lactic-acid bacteria. If, however, sterilized milk is inoculated with lactic-acid bacteria there is a definite relation between the acidity and the bacterial content.

Infection from the air of the stable is of great influence in the souring of milk. It is not possible to draw conclusions as to the age of a sample of milk from the increase in acidity in a certain time at a definite temperature. In some investigations in Holland the morning's milk contained more bacteria than the evening's milk. Prompt cooling lengthens the bactericidal phase and delays the decomposition of the milk. Cleanliness in milking and low temperatures in keeping milk are essential in delaying souring.

Any particular brand of commercial culture for the ripening of cream was not found to be uniform in chemical composition, and many of the bacteria were found to be dead or incapable of growth.

Does centrifuging lessen the number of bacteria in milk? S. A. SEVERIN (*Centbl. Bakt. [etc.], 2. Abt., 14 (1905), No. 18–20, pp. 605–615*).—Counts were made of the number of bacteria in samples of milk taken immediately before and after (1) ordinary centrifugal separatiou, (2) separation with the centrifuge protected with sterilized cotton to prevent entrance of bacteria from the air, and (3) before and after centrifuging or shaking in closed bottles. The interval between the taking of samples was about 15 minutes.

The number of colonies developing on agar and gelatin plates was increased to a marked extent by all three methods of treatment. Contamination from the air during separation or shaking was therefore excluded as a cause of this increase. The explanation offered by Dunbar and Kister that groups or clumps of bacteria which develop as single colonies in the first instance appear as a greater number of colonies on the second series of plates is not accepted by the author, who suggests instead that

the natural process of vegetative division is hastened by the mechanical action, so that bacteria about to become separated are torn apart sooner than would ordinarily occur.

On the effect of heat on cow's milk, O. JENSEN and E. PLATTNER (*Ann. Agr. Suisse, 6 (1905), No. 6, pp. 205–223; Rev. Gén. Lait, 4 (1905), Nos. 16, pp. 361–368; 17, pp. 388–397; 18, pp. 419–424*).—Samples of mixed milk were heated momentarily or for periods of 5, 15, 30, or 60 minutes, or 5 hours, at temperatures ranging from 50 to 140° C., and subjected to chemical examination.

The albumin was partly coagulated at 60° when the heating was prolonged for 5 hours, though the greater part was not precipitated below a temperature of 70–75°. All the albumin was coagulated by heating at 77.5° for 1 hour, 80° for ½ hour, or 90° for 5 minutes. Momentary boiling, provided the milk was brought rapidly to the boiling point and promptly cooled, left traces of albumin in solution.

The casein was coagulated by heating for 30 minutes at 130° or for 5 minutes at 140°. By heating at the latter temperature for 30 minutes a fourth of the casein was transformed into soluble nitrogenous substances nonprecipitable by acetic acid. Changes in the casein, however, occurred at lower temperatures and contributed in producing the browning usually ascribed solely to a caramelization of the lactose.

The degree of acidity was at first reduced by heating on account of the expulsion of carbon dioxid, but at higher temperatures it was increased, which was believed to be due to the decomposition of the casein and the formation of acids rather than to changes in the lactose. The cooked taste was believed to be closely associated with the changes produced in the albumin.

Storch's paraphenylenediamin test gave negative results when applied to milk heated momentarily at 80°, 5 minutes at 75°, 30 minutes at 72.5°, or 5 hours at 70°. The total destruction of the superoxydase, upon which this test depends, occurred, therefore, sooner than the complete coagulation of the albumin. In general Storch's reaction ceased precisely at the point where the cooked taste manifested itself.

Heating increased the time required for the coagulation of milk by rennet gradually up to the point of minimum acidity, at which stage the time required for coagulation increased very abruptly and then remained constant until the heating was sufficient to cause a browning of the casein, when a further marked increase in the time of coagulation was observed. The first of these two critical stages was reached by momentary boiling or by heating for 5 minutes at 80°, 1 hour at 77.5°, or 5 hours at 70°, and the second by heating for 5 minutes at 120° or 30 minutes at 110°.

To determine the cause of this delayed coagulation the authors added milk enzyms in the form of separator slime and also lactalbumin to heated milk without affecting to any marked extent the time required for coagulation. The main alterations in heated milk affecting its coagulation with rennet and occurring at the two stages mentioned are, therefore, believed to be due to changes in the casein molecule. The minor changes as regards coagulation brought about previous to the first critical stage are considered as due to the expulsion of carbon dioxid and probably also to the destruction of natural rennet in the milk and in some cases to the precipitation of lime salts.

The lactose as determined polarimetrically showed a marked reduction as a result of heating above 120°. Gravimetric determinations, however, did not show this reduction. The fat globules showed fusion only when the milk was heated above 120° for short intervals or at 70° for 5 hours.

From the above and other results obtained in these investigations, the authors conclude that in order to preserve the properties of raw milk, which is especially desirable in infant feeding, the heating should not be continued for several hours at 60° nor exceed for a single instant 70°. The temperature should not exceed that necessary for destroying pathogenic bacteria, more particularly the tubercle bacillus,

for which heating for 20 minutes at 60° has been found by T. Smith and 5 minutes at 65° by Bang and Stribolt sufficient when proper precautions are observed. The home pasteurization of milk for infant feeding is recommended.

Experimental investigations on the sterilization of milk with hydrogen peroxid, with special reference to the method of Budde, M. LUKIN (*Centbl. Bakt.* [*etc.*], *2. Abt., 15 (1905), Nos. 1, pp. 20-32; 4-6, pp. 165-174*).—The literature of hydrogen peroxid as a milk preservative is reviewed, and extended experiments are reported, from the results of which the author draws in substance the following conclusions:

Milk can be sterilized by the addition of hydrogen peroxid. In neutral or in weakly alkaline solutions the bactericidal action of hydrogen peroxid is much greater than in acid solutions. Commercial hydrogen peroxid always contains hydrochloric acid, and for that reason such preparations should be neutralized, preferably just before using.

The temperature exerts a great influence on the bactericidal action of hydrogen peroxid, the lower the temperature the weaker the action. Quantitative investigations have shown that for the sterilization of milk at room temperature a much greater quantity of hydrogen peroxid is required than at incubator temperature. The author's experiments have shown that the temperature of 52° C. recommended by Budde is still more favorable, the quantity required for sterilization being at this temperature reduced to a minimum.

The number of bacteria in the milk is of importance in sterilization by hydrogen peroxid. At room and incubator temperatures the quantity required increases with the bacterial content. At 52° this relation is no longer so noticeable.

For the sterilization of milk at the lower temperatures a relatively large quantity of hydrogen peroxid is required—in the author's experiments 0.07 to 1.5 per cent, corresponding to 24.5 to 600 cc. of the 3 per cent solution per liter. This method is not practical, as the milk so treated is too greatly diluted and can not be consumed on account of its disagreeable taste.

The Budde method—addition of hydrogen peroxid with simultaneous heating of the milk to 52°—is practical for both fresh and market milk. The author's results confirm those of Budde that 0.036 per cent or 12 cc. of the 3 per cent solution per liter is sufficient, except when the bacterial content is very high, when 0.05 per cent is required. Hay and coli bacilli and streptococci added to milk in large numbers are completely destroyed by treatment with 0.036 per cent at 52°.

Milk treated by the Budde method contains small quantities of hydrogen peroxid, which is recognizable by taste. The complete removal of the hydrogen peroxid from the milk is desirable from both hygienic and practical standpoints. The author's experiments with blood serum, fibrin, meat, and egg albumin along this line have not given satisfactory results.

The author also presents in conclusion a summary of the principal advantages and disadvantages of the Budde method.

Investigations on the preservation of milk with formalin, H. DE ROTHSCHILD and L. NETTER (*Rev. Hyg. et Méd. Infant., 4 (1905), No. 4, pp. 334-352*).—The authors review the literature of this subject and present the results of experiments with dogs having gastric fistulas. In the proportion of 1:10,000, as recommended by von Behring, formalin is not believed to destroy pathogenic bacteria or prevent the development of all saprophytic species, while it lessens the digestibility of the casein.

In the experiments here reported the digestion of milk treated with formalin in the proportion of 1:2,000 was slower and less complete than that of ordinary milk, while in the proportion of 1:5,000 no differences were appreciable. One of the animals consumed daily for 6 weeks about 500 cc. of milk preserved with formalin in the proportion of 1:2,000 and gained considerable in weight. It is believed to be

erroneous to conclude from these favorable results with animals that formalin is harmless when consumed by human beings, more particularly infants.

The ripening of Hartz cheese, C. H. ECKLES and O. RAHN (*Centbl. Bakt.* [*etc.*], *2. Abt., 14 (1905), No. 22-23, pp. 676-680*).—A chemical and bacteriological study was made of the ripening of this small sour milk cheese. Contrary to generally accepted views, the ripening process was found to be unlike that occurring in soft cheeses.

In the outer portion of the cheese the acidity decreased very rapidly from 2.57 to 0.23 per cent, while in the center it decreased quite gradually for 15 days, being then reduced only to 1.26 per cent. Of the total nitrogen in ripe Hartz cheese 86.2 per cent was in the form of albumoses and peptones, 6.7 amids, 3.5 ammonia, and 3.6 per cent was insoluble, showing a much greater percentage of water-soluble proteids than in Camembert and other kinds of cheese, analyses of which are given for purposes of comparison.

The bacteriological investigations showed that yeast as well as Oidium are concerned in the process of ripening.

Micro-organisms in the cheese industry, P. MAZÉ (*Ann. Inst. Pasteur, 19 (1905), No. 8, pp. 481-493*).—This, the third article of a series on this subject, deals with the changes brought about in the casein of cheese by the action of bacteria and fungi, a number of theoretical and practical conclusions being drawn from the discussion.

Condensed milk, C. D. HOLLEY (*North Dakota Sta. Rpt. 1904, pt. 2, pp. 181-191*).—Information is given regarding the growth of the condensed milk industry and processes of manufacture, together with the results of a number of analyses of different brands of condensed milk and cream. The conclusions based upon the author's observations follow·

"The evaporated creams are not evaporated creams, but simply unsweetened condensed milks. There is a marked lack of uniformity in the composition of unsweetened condensed milks and a tendency to fall below the United States's standards. The sweetened condensed milks are of standard quality and very nearly standard weight. The unsweetened condensed milks were short weight in all cases with a minimum weight of 11.7 oz. and an average of 12.6 oz."

Some observations on milk powder, O. JENSEN (*Rev. Gén. Lait, 4 (1905), No. 23, pp. 538-542*).—Brief notes are given on the Hatmaker and Ekenberg processes of making milk powder, and an analysis of a milk powder made in Switzerland is reported. A liter prepared from 134 gm. of this powder was within the limits of normal milk in composition except as regards soda, which was in excess, due to the addition of the alkali in the process of manufacture.

VETERINARY MEDICINE.

Fungi parasitic on man and animals, F. GUEGUEN (*Les champignons parasites de l'homme et des animaux. Paris: A. Joanin & Co., 1904, pp. XVII + 299, pls. 12*).—This volume contains a monographic account of all fungi known to be parasitic on man and animals, with especial reference to the pathogenic action of these fungi. The material is treated in a systematic manner according to the position of the fungi concerned. Fungi parasitic on man and animals are found in the groups Myxomycetes, Oomycetes, Basidiomycetes, Ascomycetes, and Mucedineæ. Detailed and classified bibliographies are presented at the end of each group of fungi discussed.

Abstracts of work done in the laboratory of veterinary physiology and pharmacology, I, P. A. FISH ET AL. (*Ithaca: N. Y. State Vet. Col., 1904, pp. 53, figs. 19*).—This is the first of a series in which it is proposed to publish abstracts of scientific articles written by the department of veterinary physiology and pharmacology of the New York State Veterinary College.

In the present number an account is given of the use of Echinacea in veterinary practice; the digestive action of bile in some domestic animals; calcium sulphid in the treatment of poll evil and fistulous withers, and the effects of certain drugs upon the blood pressure and cardiac inhibition in the horse. The last-named article has already been abstracted from another source (E. S. R., 15, pp. 118, 119).

In the treatment of poll evil and fistulous withers with calcium sulphid it was found that doses larger than 10 or 15 grains daily tended to increase the discharge and hinder the healing process. A convenient method of administering this drug is in gelatin capsules, and in general no good results can be obtained without a standard quality of the drug.

Annual report veterinary department of station, J. C. ROBERT (*Mississippi Sta. Rpt. 1904, p. 26*).—In vaccinating 305 pure-bred cattle against Texas fever 12, or about 4 per cent, were lost. Several of the animals, however, were too old for successful vaccination. Blackleg vaccine has been distributed with beneficial results.

Treatment of four anemic diseases in domesticated animals by means of artificial hemoglobin, EVERS (*Berlin. Tierärztl. Wchnschr., 1905, No. 11, pp. 201–205*).—The author has carried on a number of experiments with artificial hemoglobin, also known as Damholid, in the treatment of Texas fever, lung-worm disease of sheep, anemia in dogs, and perverted appetite in cattle.

The author has treated 74 cattle for Texas fever by means of hemoglobin with a loss of only 2 animals. In 1904, 31 cattle were treated and all recovered, although 8 of this number were in a hopeless condition before treatment. Similarly satisfactory results were obtained in the treatment of other anemic diseases. The author believes that artificial hemoglobin gives the same beneficial effects when administered by way of the mouth as when inoculated subcutaneously or intravenously. Administration by way of the mouth was therefore preferred when the expense was not too great.

The classification and nomenclature of diseases known under the name actinomycosis, J. LIGNIÈRES and G. SPITZ (*Bul. Soc. Cent. Méd. Vét., 82 (1905), No. 4, pp. 64–93*).—From a study of the organisms obtained in different forms of actinomycosis, with reference to their morphology, biology, and pathogenic properties, the author comes to the conclusion that there are 3 groups of organisms causing 3 distinct diseases which are commonly referred to under the name actinomycosis.

The first group is *Actinomyces bovis*, also known as *Streptothrix actinomyces*. This organism produces the ordinary typical form of actinomycosis in cattle. The second group includes *Streptothrix israeli*, *S. spitzi*, and the species of Streptothrix studied by Doyen. This organism does not produce infection when inoculated intravenously. Positive results, however, are always obtained after subcutaneous inoculation of cattle, sheep, hogs, dogs, rabbits, and various experimental animals.

Actinobacillosis constitutes the third group and is due to actinobacillus. The cultural peculiarities of this organism are described in considerable detail. The bacillus causes serious infection in nearly all species of animals after intravenous inoculation. Subcutaneous inoculation also causes the formation of abscesses in dogs, rabbits, horses, and other animals.

The biology of the micro-organism of actinomycosis, J. H. WRIGHT (*Jour. Med. Research, 13 (1905), No. 4, pp. 349–404, pls. 10*).—The literature relating to actinomycosis is critically discussed in connection with a bibliography of 109 titles.

The author's experiments were made with actinomyces from 13 human and 2 bovine cases. Particular attention was given to a study of the morphology of the micro-organism under various conditions and on different culture media. In inoculation experiments rabbits and guinea pigs were used for the purpose of comparing the effects of bovine and human actinomyces. The results of these inoculations were not constant. Some races of the micro-organism produced relatively extensive lesions, while in other cases the effects were much less pronounced.

An elaborate discussion is presented of the biology of actinomyces. As a result of the author's study it was found that actinomyces grows well only in agar and bouillon cultures and in the incubator. It is essentially anaerobic and does not form spores. In cultures the colonies are smaller in character than those which are obtained from actinomycosis. The author concludes that there is but one species of actinomyces, since no essential difference was found between different races of the organism obtained from human and bovine sources.

Increasing the virulence of human tubercle bacillus up to that of the bovine form, D. A. DE JONG (*Centbl. Bakt.* [*etc.*], *1. Abt., Orig., 38* (*1905*), *Nos. 2, pp. 146–153; 3, pp. 254–264, figs. 12*).—Some of the recent literature relating to this subject is critically discussed.

The author carried on a number of experiments for the purpose of determining whether it was possible to increase the virulence of human tubercle bacillus so as to equal that of the bovine form. During the experiments reported in the article it was found that the degree of virulence ordinarily possessed by the bovine tubercle bacillus was reached by the human tubercle bacillus after passage through 2 goats, 1 calf, and 2 guinea pigs.

At the end of this period, the race of bacilli, which at the beginning was of comparatively low virulence had become exceedingly virulent, and was capable of destroying laboratory animals with generalized tuberculosis as quickly as the most virulent cultures obtained directly from cattle.

Experimental transmission of tuberculosis from man to cattle, A. EBER (*Ztschr. Fleisch u. Milchhyg., 15* (*1905*), *No. 7, pp. 193–204, pl. 1*).—In the experiments reported in this paper, the author made use of tuberculous material obtained from 5 children which showed tuberculous alterations in the alimentary tract and mesenteric glands.

For the purpose of comparing the virulence of this material with bovine tubercle bacilli, virus was taken from 4 cattle which after slaughter showed evidence of infection with pearl disease. Detailed notes are given on the inoculation experiments carried out with this material. The tuberculous material obtained from children was inoculated into calves 8 to 12 weeks old either directly or after a preliminary passage through guinea pigs.

As a result of these experiments it was found that the virus thus employed was very virulent for 2 calves, moderately virulent for 2 other calves, and slightly virulent for the other 3. The virus obtained from cattle was inoculated into 5 young cattle from 12 weeks to 2 years old. This material proved very virulent for 1 animal, moderately virulent for 2, and only slightly virulent for the other 2. The author interprets the results of his experiments as indicating that a difference between human and bovine tubercle bacilli can not be successfully maintained.

The pathogenesis of tuberculosis, H. VALLÉE (*Compt. Rend. Soc. Biol.* [*Paris*], *58* (*1905*), *No. 13, pp. 568, 569*).—In the experiments reported in this paper 4 calves were allowed to suck a cow affected with tuberculous mammitis at 2 times at intervals of 48 hours. The quantity of milk taken at each time by each calf was about 150 gm. Subsequently the calves obtained all their nourishment from healthy cows or from sterilized milk.

At the end of 5 weeks they were tested and all reacted to tuberculin. Three of the calves on post-mortem examination showed pronounced affection of the mesenteric glands with tuberculosis. In no case was the spleen or liver affected. This experiment is interpreted as indicating that calves may become readily infected with tuberculosis through the alimentary tract.

The frequency of tuberculous affection of the lymphatic glands of the muscles in food animals, STROH (*Ztschr. Fleisch u. Milchhyg., 15* (*1905*), *No. 5, pp. 137–141*).—The author's observations were confined largely to the lymphatic glands of the musculature, in a restricted sense including the prescapular, axillary, knee fold,

and popliteal glands. The percentage of infection of these glands is shown in tabular form, from which it appears that in cases of tuberculosis the prescapular glands are affected in 26 per cent of cattle, 40 per cent of cows, and 52 per cent of hogs. Similar variations were observed with regard to the other glands. Observations on the various cases studied indicate that mammary tuberculosis in cows occurs in 1.74 per cent of cases.

Treatment of bovine tuberculosis by means of the serum of Cuguillère, V. FAURE (*Prog. Vét., n. ser., 18 (1905), No. 1, pp. 7–14*).—According to the author's experience, bovine tuberculosis sufficiently well advanced to be recognized clinically, may be cured by treatment with the serum of Cuguillère. Cures effected by this method were tested by means of tuberculin and by subsequent microscopic examination of the old tuberculous lesions. These tubercles were found to be nonvirulent.

Protective inoculation of cattle against tuberculosis according to von Behring, LORENZ (*Ztschr. Thiermed., 9 (1905), Nos. 1, pp. 1–22; 2, pp. 131–144*).—In order to obtain as extensive and reliable data as possible concerning results of vaccination experiments thus far carried out a circular letter of instructions was sent to 15 official veterinarians in different parts of Germany. The data thus obtained are presented in a tabular form. Attention is called to the fact that while cattle immunized against tuberculosis according to the system of von Behring may subsequently react to tuberculin, this fact was known to von Behring and has been referred to by him in his publications on this subject.

The resisting power to bovine tuberculosis of two cows previously treated with tubercle bacilli of different origin, A. EBER (*Ztschr. Thiermed., 9 (1905), No. 2, pp. 81–130*).—Details connected with the vaccination of cattle against tuberculosis according to the von Behring system are outlined.

As the result of a thorough study of 2 cows treated in this manner it was found that the subcutaneous injection of 1 gm. of tuberculous material from bovine origin produced a swelling the size of a hen's egg at the point of inoculation in the immunized animal. The animal was slaughtered 6¾ months after inoculation, and at this time merely traces of the infection were discovered. In a nonimmunized animal inoculated at the same time and in the same manner much more extensive swelling took place, followed later by the inflammation of the prescapular lymphatic glands, fever, and other evidence of tuberculosis.

Similar results were obtained when immunized and nonimmunized cattle were inoculated with 2 gm. of tubercle bacilli of bovine origin. The resisting power of the immunized animal was much greater.

The reaction curve of tubercle bacilli from different sources in bouillon containing different amounts of glycerin, T. SMITH (*Jour. Med. Research, 13 (1905), No. 4, pp. 405–408*).—The author had already shown that in glycerin bouillon bovine tubercle bacilli change the reaction from acid to alkaline, while similar cultures containing human tubercle bacilli do not become alkaline. In the experiments reported in the present paper it was found that in glycerin-free bouillon growth was quite feeble or absent, while with the addition of glycerin growth became more vigorous, reaching a maximum when the bouillon contained 1 per cent glycerin.

The study of the tolerance of cattle for tuberculin, L. STUBBE and G. MULLIE (*Ann. Méd. Vét., 54 (1905), No. 4, pp. 198–205*).—Statistical data are given regarding the reaction to tuberculin in 578 cattle. In this number 20 showed a reaction within 2 hours, 68 within 4 hours, 135 within 6 hours, while only 23 failed to react after 18 hours. The reaction began within 12 hours in 441 out of 578 cases. The author believes as a result of his observations that the reaction to tuberculin ordinarily takes place within a shorter period than has usually been named by investigators of this subject.

The diseases of the mammary gland of the domestic animals, P. LEBLANC, trans. by J. A. NUNN (*London: Baillière, Tindall & Cox, 1904, pp. XII+111, figs.*

32).—The anatomical structure of the mammary gland of various domesticated animals is discussed and an account is presented of the physiology of secretion. The diseases to which the mammary gland is subject are discussed under the general heads of injuries, acute mastitis, chronic mastitis, and malignant tumors. The injuries studied by the author include contusions, wounds, abrasions, calculi, obstructions, etc. The chronic forms of mastitis discussed by the author are those due to streptococci, botryomycosis, actinomycosis, tuberculosis, etc.

Milk fever and the new treatment of Schmidt and Evers, PEYRONNY (*Rev. Vét.* [*Toulouse*], *30* (*1905*), *No. 2, pp. 81–88*).—The author describes in considerable detail 6 cases of milk fever which were treated by means of air. As a rule, the air was pumped into the four quarters of the udder until this organ was in a tense condition. The result in all cases was very satisfactory. The author believes that the rapid amelioration in these cases, after treatment with air and other successful methods, is not due entirely to the elimination or neutralization of the toxins which presumably cause the disease.

East coast fever, JARVIS (*Natal Agr. Jour. and Min. Rec.*, *8* (*1905*), *No. 2, pp. 138–142*).—In the author's opinion the only remedy which has given satisfactory results in the control of African coast fever is dipping in an arsenical solution. Instances are cited where the ticks were nearly all destroyed as the result of dipping and without excessive expense. On one farm the disease was apparently eradicated by thorough dipping of all cattle. The arsenical solution did not appear to injure the cattle seriously.

Methods adopted in dealing with east coast fever, S. B. WOOLLATT (*Natal. Agr. Jour. and Min. Rec.*, *8* (*1905*), *No. 2, pp. 178–188*).—The symptoms and pathological anatomy of this disease are described in considerable detail. Strict quarantine measures have been adopted in controling the disease, and in some instances cattle have been moved to high grazing ground for the purpose of getting them beyond the reach of infection. This method is of doubtful value, however, since the disease has been known to prevail in altitudes of 5,000 ft.

Some points to be considered in connection with Rhodesian redwater, S. STOCKMAN (*Jour. Compar. Path. and Ther.*, *18* (*1905*), *No. 1, pp. 64–72*).—Immunity toward this disease is not well understood. The confusion of opinion which prevails regarding this matter may be partly due to the fact that the African coast fever has frequently been mistaken for ordinary Texas fever.

It is not absolutely certain that cattle of a truly indigenous race are born immune. It appears certain that the disease is spread by ticks which have fed upon the virulent blood of affected animals. If such cattle pass along a road it may readily become infected, and susceptible cattle must subsequently be kept away from such roads until the infection is destroyed.

Tests of substances for tick destruction, C. P. LOUNSBURY (*Agr. Jour. Cape Good Hope, 26* (*1905*), *No. 3, pp. 387–395*).—During the year 1904 a number of experiments were made in the continuation of an investigation of insecticides for ticks.

In previous years arsenite of soda with or without the addition of soap was found to be a cheap and efficient remedy for the destruction of ticks. In subsequent tests Stockholm tar was added to arsenical dips, but this increased the cost of the dip considerably. Stockholm tar has the advantage of being a good dressing for wounds and of itself is an insecticide of considerable value. The comparative test was made between simple arsenic dips and arsenical solutions containing tar. A tar-arsenic-soap dip was also tested as a tick destroyer.

The last-named dip proved no more efficient than simple solutions of arsenite of soda, although the latter dip contained slightly less arsenic. Arsenical sprays were found not to harm any of the cattle which were used in these tests. The frequent dipping of sheep in arsenical preparations, however, causes considerable injury to the sheep, and unless great care is exercised a heavy mortality.

Serum treatment for infectious diarrhea of calves, P. HEURGREN (*Svensk Vet. Tidskr., 10 (1905), No. 1, pp. 30–33*).—The author made use of Jensen's polyvalent serum in the treatment of 10 calves for the prevention of diarrhea. The disease had appeared in 20 calves on the same estate before this method of vaccination was adopted. All of the treated calves appeared to be rendered immune, since no case developed among them.

Sorghum poisoning, W. R. PERKINS (*Mississippi Sta. Rpt. 1904, pp. 35, 36*).—Hydrocyanic acid was found in the stomach of a cow which died suddenly, and in sorghum from the field where she had grazed. The only plat of sorghum found to contain traces of the acid had made the most luxuriant growth.

Poisoning of cattle from Ranunculus sceleratus, HÖNSCHER (*Ztschr. Veterinärk., 17 (1905), No. 3, pp. 107, 108*).—Cattle fed on wild hay containing *Ranunculus sceleratus* were seriously affected. In a herd of 25 cows, 4 showed evidence of great cerebral excitement and spasms. Two died and exhibited considerable irritation of the gastric mucous membrane.

The occurrence of filaria embryos in horses and cattle, A. E. TEN BROEKE (*Tijdschr. Veeartsenijk., 32 (1905), No. 6, pp. 255–257*).—In horses infested with filaria the appetite was very poor, but the pulse and respiration were almost normal. Edematous swellings were observed in 2 cases. Fowler's solution was administered in large doses without favorable results. Death took place after a few days. Similar results were had in attempts to treat cattle.

Surra and the differentiation of trypanosomiases, A. LAVERAN and F. MESNIL (*Compt. Rend. Acad. Sci. [Paris], 140 (1905), No. 13, pp. 831–836*).—As a result of the study of these diseases the authors recognized several forms occurring in different countries. It appears that there are 3 recognizable forms of surra distinguished by their virulence and occurring in India, Mauritius, and Mbori. The methods which have proved efficacious in the hands of the authors in the differentiation of trypanosomiases may be used in distinguishing these forms of surra.

The tsetse-fly disease and immunization of domesticated animals, E. MARTINI (*Ztschr. Hyg. u. Infectionskrank., 50 (1905), No. 1, pp. 1–96, pls. 2, figs. 17*).—The morphology and biology of the trypanosome of tsetse-fly disease is discussed in great detail in connection with a series of experiments carried out by the author.

Numerous tests were made in passing the trypanosomes through various animals by means of inoculation. As a result of these experiments it was found that 2 races of blood parasites of this disease may be recognized according to their different virulence. One race proved to be fatal for the horse, ass, dog, cat, hog, goat, rabbit, etc., after subcutaneous, intraperitoneal, or intravenous inoculation.

Evidence was obtained that horses may carry the blood parasites for years and remain in good health. Some difference of opinion prevails, however, regarding the nature of this apparent immunity and its duration. A healthy animal carrying blood parasites of low virulence may not be immune, however, to blood parasites of another race.

Report on dourine in different breeds of equines, A. LINGARD (*Calcutta: Supt. Govt. Printing, India, 1905, pp. V+84+XCIX, pls. 16*).—In this volume the author presents an elaborate account of his experiments on dourine in India, together with an account of vesicular exanthema and piroplasmosis which in certain cases occurred as complications.

The volume includes a general discussion on the nature of dourine, clinical notes on a large number of spontaneous and inoculation cases, the period of incubation, eruption of plaques, the biology of the blood parasite, symptoms, diagnosis and course of the disease, and susceptibility of different animals. It was found that whenever a cutaneous plaque appears during the course of the disease the pathogenic trypanosoma is present at that point in one or more of its developmental forms.

The blood parasite persists in the plaques as long as edema is to be observed. The developmental forms of the organism are also found in the cerebro-spinal fluid, vaginal mucus, and semen. In a number of cases a mild vesicular exanthema occurred as a complication of dourine and gave rise to a high fever and emaciation in acute cases, with occasional death.

The experimental diagnosis of glanders, G. MAZZINI and A. AGUZZI (*Gior. R. Soc. ed. Accad. Vet. Ital., 54 (1905), Nos. 1, pp. 4–9; 2, pp. 25–38*).—As a result of the authors' study of glanders and the various methods of diagnosing this disease, it is concluded that negative results obtained from the inoculation of guinea pigs, with the mucus of suspected animals, does not permit of drawing the conclusion that the horse in question is not affected with glanders. It was found during these experiments that glycerin exercises a considerable antiseptic action upon the glanders bacillus.

The differential diagnostic value of glanders agglutination in the important internal diseases of the horse, R. LANGER (*Monatsh. Prakt. Tierheilk., 16 (1905), No. 6, pp. 241–254*).—The author's observations were made on 100 horses, some of which were healthy while others were affected with various diseases such as pneumonia, contagious coryza, hemoglobinuria, anthrax, tetanus, influenza, pseudoleukemia, glanders, etc.

Careful tests were made to determine the agglutinative power of the sera of all these cases toward the glanders bacillus. Results of these tests are presented in a table from which it appears that the agglutinative power of healthy horses or horses affected with diseases other than glanders is never greater than 1:500, while the agglutinative ratio of serum from glanderous horses varies from 1:2,000 to 1:5,000.

The author concludes, therefore, that the method of agglutination is perfectly reliable in the diagnosis of glanders. The literature of this subject is discussed in connection with a short bibliography.

Post-mortem diagnosis of glanders, BRETON and CHENEAU (*Rec. Méd. Vét., 82 (1905), No. 3, pp. 81–83*).—As a result of a study of the pathological lesions observed in glanders the conclusion is reached that judgment should not be pronounced too rashly if, in the examination of the lung of a horse, nodular lesions are found which resemble those of glanders. If the anterior portion of the respiratory tract is free from ulcers or old cicatrices, it is necessary to resort to microscopic study in order to determine the specific nature of the organisms concerned.

The prophylaxis of glanders, J. MCFADYEAN (*Jour. Compar. Path. and Ther., 18 (1905), No. 1, pp. 23–30*).—In this article the author reviews the present status of glanders in London, with notes on the extent of the disease, methods of dissemination, and suitable prophylactic measures.

Existing regulations are considered somewhat defective for the reason that the value of mallein is not recognized and that horses exposed to infection are not watched in a sufficiently careful manner. Attention is called to the fact that during the last 12 years from 800 to 2,000 glanderous horses have been annually slaughtered by knackers in London. Not a single case of infection among man has occurred in these establishments. This is considered as indicating that the blood and meat of glanderous horses seldom carry infection.

Mallein as a curative agent in the treatment of glanders, T. E. CARROLL (*West. Vet., 1 (1905), No. 3, pp. 9,10*).—The author's experience with glanders was had in the Philippine Islands, where glanders prevailed extensively at the time when the observations were made. Mallein was tested in a large number of horses and it was found that the temperature reaction took place up to the fourth or fifth injection. In some cases the third temperature reaction was higher than the second. In these tests mallein proved to be a reliable diagnostic agent but no improvement was noted

in any case as the result of its use and no evidence was obtained that it has a curative effect.

The internal administration of formaldehyde by intravenous injection, H. LOMAS (*Vet. Rec., 17 (1905), No. 866, pp. 498, 499*).—Formaldehyde was used in intravenous injections in the treatment of 3 cases of morbus maculosus in horses. In 2 of these cases the dose was 1 dr. in 20 dr. of distilled water, while in the third case the same dose was given in 5 dr. of distilled water. The results were perfectly satisfactory in all 3 cases, 2 of which the author did not expect to recover.

Vaccination for swine erysipelas, SCHNITKI (*Berlin. Tierärztl. Wchnschr., 1905, No. 10, pp. 189, 190*).—During the year 1904 the author vaccinated nearly 6,000 swine for the purpose of protecting them against swine erysipelas. The method adopted was that of simultaneous injection of serum and cultures in different parts of the body. Nearly 4,000 of the hogs received a second injection of virus. No case of swine erysipelas developed as the result of vaccination and only a few cases were observed in the vaccinated herds as the result of subsequent infection.

The histological diagnosis of rabies, F. ABBA and A. BORMANS (*Ann. Inst. Pasteur, 19 (1905), No. 1, pp. 49–61, pl. 1*).—The literature relating to rabies is discussed in connection with a short bibliography. Particular attention is given to the statements of Negri regarding the discovery of the pathogenic organism of rabies. Contrary to the claims of Negri the authors found that the medulla oblongata contains as virulent a virus as is to be found in Ammon's horn. Osmic acid was found to be perfectly reliable in the diagnosis of glanders in one-half of the cases if applied within 24 hours after death.

The symptoms and prevention of experimental rabies, D. KONRADI (*Centbl. Bakt. [etc.], 1. Abt., Orig., 38 (1905), No. 2, pp. 194–199*).—In the experiments reported in this paper rabbits were inoculated in the legs and face and subsequently subjected to various forms of treatment.

In general the incubation period varied between 174 and 570 days. The great length of the incubation period was apparently due to the small quantity of virus used in inoculation. The author concludes from his experiments that infection may be prevented by local antiseptic treatment. Such local treatment must follow within 12 minutes if inoculation was made in the legs and within 3 minutes if the virus is inoculated into the face. It appears that rabies may recur like other infectious diseases.

Antirabies serum, A. MARIE (*Ann. Inst. Pasteur, 19 (1905), No. 1, pp. 1–8*).—It has been observed that when suitable quantities of serum obtained from vaccinated mammals and an emulsion of rabies virus are mixed the 2 substances neutralize each other.

The author carried out a number of experiments for the purpose of testing this process more accurately and for obtaining data concerning the application of the method in the treatment of rabies. It was found during these experiments that the serum obtained from vaccinated animals is not active toward the virus of rabies except after a long preliminary treatment. The serum of untreated mammals appears not to have any power of neutralizing fixed rabies virus. There is no such power to be observed even in the serum of birds, which are naturally immune to the disease.

The action of the neutralizing serum when obtained is specific, but in many cases is confined within very narrow limits. The specific substance combines with the virus of rabies.

Infection and immunity in fowl cholera, E. WEIL (*Arch. Hyg., 52 (1905), No. 3–4, pp. 412–432*).—Attention is called to the many failures which have been experienced by different investigators in devising a successful scheme of vaccination against fowl cholera.

The bacillus of the disease multiplies with such great rapidity that death results within a short time unless the growth of the bacteria is checked. In the author's experiments rabbits were used for producing an exudate which was later used in vaccination. It was found that when the bacilli of fowl cholera in bouillon cultures were inoculated into the pleural cavity of rabbits, death took place within 5 to 8 hours. The quantity of exudate produced in the pleural cavity varies greatly in the different cases but, as a rule, is greatest when small quantities of bacteria are used for inoculation.

In one rabbit, which received 1 drop of a bouillon culture, 27 cc. of exudate was produced in the thoracic cavity. The great rapidity of multiplication of bacteria is apparent from the fact that death may result inside of 5 hours. The exudate produced in the manner just described in rabbits was found to be exceedingly virulent for experimental animals. The exudate was sterilized and used in vaccination experiments with rabbits, chickens, and pigeons. It was found possible to immunize all these animals against the most virulent cultures of fowl cholera bacilli. Even pigeons, which are normally very susceptible to this organism, were immunized by 3 injections of sterilized exudate from rabbits.

Immunization of rabbits against fowl cholera, J. C. Delfino (*Centbl. Bakt. [etc.], 1. Abt., Orig., 38 (1905), No. 2, pp. 231, 232*).—In the author's experiments Lignière's vaccine was used.

The protective treatment included 2 inoculations with an interval of 10 days. Within 10 days after the second inoculation the animal appeared to be perfectly immune. The author concludes that Lignière's method of vaccination against septicemia of birds in rabbits produces a permanent immunity which is capable of resisting enormous quantities of virulent cultures.

RURAL ENGINEERING.

Irrigation investigations on the North Platte River in 1904, B. P. Fleming (*Wyoming Sta. Bul. 66, pp. 24, figs. 4*).—These investigations included measurements of the duty of water and on the loss from canals by seepage in the Mitchell district on the North Platte near the Wyoming-Nebraska line.

"As measured at the headgate, the amount of water used on a sandy soil containing gypsum is about 5.2 acre-feet per acre, when the acreage actually watered is considered and not the acreage assessed. For an open, sandy soil the amount used is much greater, being about 11.9 acre-feet per acre. These figures are from canals irrigating lands upon which alfalfa is the crop most generally grown.

"As measured on an individual farm, alfalfa requires about 4.5 acre-feet per acre and native hay about 3, the land upon which both were grown having considerable, though not excessive, slope and consisting largely of sand and gypsum.

"For a canal with one or more canals above it the gain in flow, due to seepage from the canals above, may exceed considerably the loss from itself. For a high-line canal, in which the alignment is good, gullies are crossed by one bank on the lower side, and the soil sandy, with gypsum, the average loss to be expected may be about 1.2 per cent of the flow per mile, or 0.10 cubic foot per second per 10,000 square feet of wetted perimeter."

Memoranda of plans for irrigation investigations (*Utah Sta. Circ. 4, pp. 21, figs. 2*).—This circular contains detailed instructions and regulations for the guidance, during the whole growing season, of all connected with the cooperative investigations to be carried on in Utah during 1905. These include plat and pot experiments relative to the effects upon various crops of different total depths of water applied in irrigation, different times of irrigation, and different systems of cultivation.

A crosscut excavating machine for drainage ditches (*Engin. News, 54 (1905), No. 10, p. 250, fig. 1*).—This is an illustrated description of a new type of self-propelling excavator, with the peculiarity that the cutting is done by buckets moving transversely to the line of the canal, on a steel guide frame or template of such shape and proportions that the buckets give at once the desired finished shape to the bank of the canal.

"With a ditch 16 ft. wide on the bottom, and 6 ft. deep, having side slopes of 1 to 1, the machine frequently cut 180 lin. ft. in less than ten hours, the machine being subject to ordinary delays. This is equivalent to between 800 and 900 cu. yds., and was accomplished with the consumption of not more than a ton of coal. This machine weighed 30 tons and had a vertical boiler and a 20 H. P. engine with cylinders 7 by 10 ins., operating two buckets of 1¾ cu. yds. capacity. The only labor required comprised the engineman and fireman on the machine, and one man with team to attend to the laying of the track. . . .

"Among the advantages claimed for this new machine are a reduction in power and labor as compared with a dipper dredge of the same capacity, while the banks are left with the proper slope and in better condition to prevent slides and to give the full capacity of flow for the channel."

Contribution to the biochemistry of sewage purifiation: The bacteriolysis of peptones and nitrates, S. DEM. GAGE (*Technol. Quart., 18 (1905), No. 1, pp. 5–39*).—This article reviews the literature of the subject of the biochemistry of sewage purification, giving a bibliography containing 113 references, and reports experimental data obtained in investigations made at the Lawrence Experiment Station on the processes of ammonification, denitrification, nitrate production, a reduction of nitrates to ammonia, distribution of ammonifying and denitrifying bacteria in sewage and sewage effluents, and on the relation of peptonization to other biochemical functions.

Studies were made of the behavior of 30 pure cultures of bacteria common in sewage and sewage effluents in two solutions (1) 0.1 per cent Witte's peptone solution containing about 14 parts of organic nitrogen per 100,000, and (2) 0.1 per cent of Witte's peptone in distilled water, diluted to three different strengths at different periods of the investigation, and containing nitrogen as potassium nitrate equivalent to 2.7, 6, and 22.5 parts per 100,000. The methods of chemical analysis used are described.

Summarizing the results, the author states that the problem of sewage purification is mainly a question of the bacteria which transform (render innocuous) the nitrogenous matter.

"From the results obtained in this study it becomes possible to state definitely that bacteria common in sewage purification are able to produce ammonia from organic matter, to reduce nitrates to nitrites, to ammonia, and probably to elementary nitrogen, to liberate nitrogen from solutions of organic matter either with or without the presence of nitrates or their reduction products, and also to fix atmospheric nitrogen under the same conditions—all of which reactions have been noted by other observers, but about which there has been more or less controversy.

"Many sewage bacteria probably also produce the lower oxids of nitrogen as reduction products of nitrates, which oxids may play an important part in the further decomposition of the organic matter in solution, either through catalytic action or by direct chemical reaction. Furthermore, certain of these bacteria may perhaps produce an oxid, or at least a compound of nitrogen intermediate between nitrates and nitrites, which has apparently not been noted hitherto.

"The amount of ammonia produced by the different cultures has ranged from none to 18 parts per 100,000, and the rate of ammonification has varied considerably, some of the cultures reacting as early as the fourth day, while other cultures, which

eventually reacted strongly, did not begin to ammonify until after periods of 10 to 14 days. Similar phenomena have been noted with regard to the reaction of the cultures on nitrates."

The behavior of the different cultures was very variable both as regards rate of action and character and proportions of the reduction products.

"Regarding the distribution of ammonifying and denitrifying bacteria in sewage and the effluents from sewage filters, based on a study of the biochemical functions of over 300 representative cultures from a variety of samples, it may be said that a majority of the bacteria from these sources, which are determinable by the ordinary plate methods, using gelatin as a culture medium, reduce nitrates and decompose peptone into ammonia, although these two functions are not always present in the same species. By the use of quantitative tests for the amount of liquefaction produced in gelatin by over 150 of these cultures, we have been able to determine approximately the relation between the peptonizing power, or power to liquefy insoluble organic matter, and the ammonifying and denitrifying powers of sewage bacteria.

"We find that while many nonliquefying bacteria are able to reduce nitrates or to ammonify peptone or to do both, and many liquefying bacteria do not possess these functions, nevertheless, in a large majority of cases, the possession of the first function means possession of one and usually both of the last two functions, and the average amount of change produced in the nitrogenous matter in solution is much greater with peptonizing bacteria than with those which are unable to liquefy gelatin. Furthermore, an increase in the liquefying power appears, as a rule, to be correlated with increased ability to reduce nitrates and to ammonify peptone."

Contribution to the biochemistry of sewage purification; the bacteriolysis of peptones and nitrates, S. DEM. GAGE (*Jour. Amer. Chem. Soc., 27 (1905), No. 4, pp. 327-363*).—Substantially the same article as that noted above.

The effect of water on rock powders, A. S. CUSHMAN (*U. S. Dept. Agr., Bur. Chem. Bul. 92, pp. 24, pls. 4*).—A discussion of this subject, based upon some studies in the Division of Tests of the Bureau of Chemistry on the cementing value of various rock samples when ground wet and dry and on the color reaction with phenolphthalein of the wet-ground material, as well as upon the work of other investigators along the same line. The conclusions reached are as follows:

"(1) The effect of wet grinding is to increase the binding power or cementing value of rock powders, and there are indications that the addition of small amounts of suitable electrolytes to the water will still further increase the action.

"(2) When water comes in contact with most rock powders immediate reactions take place, which are to a certain extent analogous to those which take place with cement and powdered glass.

"(3) These reactions are shown by the alkalinity indicated by phenolphthalein, but this alkalinity is to a great degree inhibited if the solid particles are filtered out.

"(4) The microscope reveals an accumulation of amorphous material of a gummy appearance largely associated with the surfaces of the crystalline particles as the action of water proceeds.

"(5) Evidence is given to show that the basic ions set free associate themselves to a certain degree with the solid particles, leading to a concentration of the acid ions in the clear solution.

"(6) It is shown that the behavior of rock powders after being acted on by water is similar to that of coagulated colloids artificially prepared in the laboratory, and that the formation of colloids upon the surfaces of the particles would account for the increased binding power under the action of wet grinding. The word 'pectoid' is recommended to describe the condition of the particles as being more appropriate to the connection in which it is used than the words 'colloid' or 'hydrogel.'

"(7) The absorption of the bases known to take place when certain clays are treated with dilute salt solutions is explained by means of the colloid theory, as is also their increase of binding power under the action of water and certain solutions.

"(8) The possibility of rendering the potash contained in rocks available as a fertilizer is suggested."

The construction of silos, W. J. FRASER (*Illinois Sta. Bul. 102, pp. 41, figs. 34*).—This bulletin discusses the location, form, proportions, and capacity of silos, and gives a complete account of the cost and construction of a round wood silo plastered with cement, which was 20 feet in diameter and 34.5 feet deep, holding 228 tons, and which cost $383, or $1.68 per ton capacity. A brief description with illustrations is given of concrete, brick, stone, and stave silos.

Use of alcohol as a motive power and its production from farm crops, M. J. R. DUNSTAN (*Jour. Southeast. Agr. Col. Wye, 1905, No. 14, pp. 26–37*).—This is a discussion of the production and use of denaturized alcohol on the Continent, and of the probable profits to the farmer which would result from a similar use in England.

The author finds that "2 tons of sugar beet will produce 22 gals. of alcohol, the ale prices of which will be about 25s., and 2 tons of pulp at a value of 5s. per ton, so that the farmer and the manufacturer will have about 35s. to divide. The cost of production is about 4d. per gallon. A deduction of 7s. 6d. must therefore be made to arrive at the price the farmer will receive, or 27s. 6d. for two tons of beet. Taking 12s. per ton as an average figure, and allowing thirteen tons per acre as an average crop we get £8 19s. per acre as the value of the beet crop for alcohol production. "Turning now to the case of potatoes, 1 ton of potatoes will produce 22 gallons of alcohol and about 1 ton of pulp, or a value of 30s. to be divided between farmer and manufacturer. Taking off 9s. for manufacture, 21s. is left for the ton of potatoes, or on a yield or 9 tons per acre £9 9s. for all expenses of growing the crop.'

Analysis of lignite coal, E. F. LADD (*North Dakota Sta. Rpt. 1905, pt. 1, p. 30*).—This sample of a briquette, prepared for household use, "was in excellent condition for use."

RURAL ECONOMICS.

Agricultural economics, H. C. TAYLOR (*New York: The Macmillan Co., 1905, pp. VIII+327, figs. 7*).—This book is a study in the economic problems involved in modern commercial agriculture.

The subject is viewed primarily from the standpoint of the farmer, whose aim it is to secure the largest net profit in return for the time and energy which he devotes to agriculture. Some attention is given also to the problems with which the statesman must deal when he attempts to pass laws regulating the conditions under which agricultural operations and transactions are carried on.

The principal subjects discussed are: (1) The factors of production, including the quantity and the character of the supply of land, capital-goods, and laborers in the United States. (2) The principle to be followed in the organization of the farm, and more specifically in the selection of land, the selection of crops, and the selection of farm animals and other forms of capital-goods. (3) The size of farms and the intensity of culture. (4) The prices of agricultural products. (5) The rent of farm land and the profits of the farmer. (6) The principles to be followed in estimating the value of farm land and equipments. (7) The farmer's means of acquiring land, including a discussion of free land, gift and inheritance, savings, credit, taxation of mortgages, and the need of a better system of obtaining credit on land. (8) Tenancy and land ownership in the United States, including a discussion of the decline in the percentage of land-owning farmers, land values and land ownership, land ownership and tenancy among the negroes, the ownership of rented farms, and the relations between landlords and tenants in the United States. (9) The adjustment of the relations between landlords and tenants in England.

Agricultural cooperation in England, E. DRUCE (*Agr. Students' Gaz., n. ser. vol. 12 (1905), No. 3, pp. 89–93*).—This article discusses cooperation in agriculture, from three standpoints: (1) The purchase of requirements, including machinery, (2) the sale of produce, and (3) the establishment of agricultural credit banks.

It is believed that the cooperative purchase of machines for cooperative use may be very desirable in communities of small farmers, but that there is little occasion for such cooperation among large farmers. The cooperative purchase of animals is spoken of as a field in which cooperation may be extended to advantage. Horse societies are mentioned. Cooperation in the sale of products is not thought to be profitable for the better farmers. It is thought that such cooperation tends to level prices and that the tendency is for the lower level and not the higher level to be reached by this process.

It is believed that the more intelligent and energetic farmers can always secure a higher price than can the cooperative society. This is thought to be especially true in a country like England, where a dense population makes it possible for the majority of the farmers to sell their products directly to the retail dealers. The writer does not seem favorably disposed toward the agricultural credit banks. In general, it may be said that this paper represents the attitude of the conservative English farmer on the subject of agricultural cooperation.

Wages, earnings, and conditions of employment of agricultural laborers in the United Kingdom, second report, W. FOX (*London: Bd. of Trade, Labor Dept., 1905, pp. XII + 263, figs. 3*).—This report deals with the systems of engagement, the rates of wages, and the cost of living of farm laborers in the United Kingdom.

In Scotland, Wales, the north of England, and the north of Ireland most of the farm servants are employed by the year, board and lodging being usually provided free in the farmhouses for the unmarried men, and cottages in many districts for the married men. In southern England and southern Ireland laborers are usually employed by the week, and it is very rare for them to be lodged or boarded in the farmhouses.

In 1902 the average rate of wages was 19s. 5d. in Scotland, 17s. 7d. in Wales, 17s. 5d. in England, and 10s. 9d. in Ireland. Between 1898 and 1902 the average rate of wages increased 6.9 per cent in Scotland, 6.6 per cent in Wales, 5.7 per cent in Ireland, and 4 per cent in England.

It is shown by means of a map that throughout the United Kingdom the wages of agricultural laborers were higher near the large industrial and mining centers than in the purely agricultural district. The average weekly value of food consumed by the agricultural laborers, including articles purchased and those produced at home, was 15s. 2½d in Scotland, 13s. 6½d. in England, and 10s. 5¾d. in Ireland.

The economic cost of slaveholding in the cotton belt, U. B. PHILLIPS (*Polit. Sci. Quart., 20 (1905), No. 2, pp. 257–275*).—This article is based upon a study of slave prices. It deals with the general economic conditions of slaveholding, and shows the great transformation caused by the opening of the cotton belt and the closing of the African slave trade.

"From the economic point of view the American system of slavery was a system of firmly controlling the unintelligent negro laborers and of capitalizing the prospective value of the labor of each workman for the whole period of his life." Prior to the invention of the cotton gin, slavery was confined to the lowlands, but the increase in the production of upland cotton after Whitney's invention came into use resulted in the rapid opening of the inland cotton belt. This increased demand for laborers resulted in a rapid increase in the price of slaves.

Between 1800 and 1860 the price of slaves in terms of pounds of cotton increased from 1,000 to 1,200 per cent. With the rise in slave prices slavery became burdensome, because of the enormous amount of wealth which had to be locked up in the purchase of the labor supply. This investment of large sums of money in the capital

value of slaves was all the more burdensome because of fluctuations in cotton prices, for it was the value of cotton which determined the value of slave labor.

"In the great system of southern industry and commerce, working with seeming smoothness, the negro laborers were inefficient in spite of discipline, and slavery was an obstacle to all progress. . . . The capitalization of labor and the export of earnings in exchange for more workmen, always of a low degree of efficiency, together with the extreme lack of versatility, deprived the South of the natural advantage which the cotton monopoly should have given. To be rid of the capitalization of labor as a part of the slaveholding system was a great requisite for the material progress of the South."

Woolgrowing and the tariff since 1890, C. W. WRIGHT (*Quart. Jour. Econ., 19 (1905), No. 4, pp. 610-647*).—This article is a discussion of the competitors of the woolgrowers of the United States, and the effectiveness of protective tariff in sustaining the woolgrowing industry in the United States.

The principal competitors from the outside are Australasia and Argentina. The principal facts to be kept in mind regarding the tariff history of the last 15 years are the Wilson Bill of August 1, 1894, which put wool and woolens on the free list, and the Dingley Bill of July 24, 1897, which restored the duty on wool and woolens. The price of wool produced in the United States is much higher than it would be without protection, yet this difference lacks about 2 cents on the pound of being equal in amount to the tariff. This is due to the difference between the quality of imported wool and that purchased at home.

But imported wool is by no means the only competitive element affecting the wool industry of the United States. The sheep industry must compete with the cattle industry in the grazing districts, with the dairy industry in the East, and with the production of wheat, corn, and hogs in the Central States. In the Rocky Mountain States the sheep industry continued to expand during the period of free trade in wool, but increased very much more rapidly after the duty on wool was restored by the Dingley Bill of 1897.

In the Central and Eastern States wool production declined rapidly after the removal of the duty on wool and even failed to respond to the Dingley Bill. Other products proved more profitable than wool. Where the dairy industry or grain production did not drive out the sheep industry east of the 100th meridian, mutton production took the place of wool production as the chief aim in sheep husbandry.

"General agricultural conditions have been the determining factors in the course actually taken by this industry. The tariff, though not vain, has failed of the end desired. Inadequate for the task imposed, it was defeated by superior powers.

"For the future, the tendencies point to a decline in sheep-raising as an independent industry mainly for wool. Mutton will increasingly dominate the situation, and wool become secondary. In the East, where sheep promise to be incidental to general farming, and wool incidental to mutton, the basis of the industry will be such that the tariff can be of but comparatively slight importance. In the West, which offers sheep-raising far better prospects and a more independent basis, protection can do much more for the woolgrower. Here the competition of the foreign grower is likely to become a more serious factor. . . .

"In the United States the conditions are such as to render a further advance in woolgrowing highly improbable and a gradual decline likely. The power to prevent this, as experience shows, is not to be found in the present tariff." If the woolgrower is to prosper "he must have a duty that will not only enable him to compete with foreign wool, but one that will make his industry at least as profitable as any other that might be carried on in its place—only thus can his flocks be maintained. Yet even then there remain the many forms of competition which operate upon the market for wool so as to lessen the demand. Here the power of the tariff ends. Against these, duties are of slight avail; and whether the industry would thrive in spite of this only experience could tell."

Return of prices of certain classes of Irish agricultural products and live stock (*Dept. Agr. and Tech. Instr. Ireland, Agr. Statis. 1904, pp. 51, dgms. 18*).—This report gives the prices of certain agricultural products and live stock in Ireland during the year 1904, with comparative tables for preceding years since 1885. Statistics are given for the following products: Wheat, oats, barley, potatoes, hay, rye, grass seed, flax, cattle, sheep, wool, mutton, beef, pork, eggs, and butter. The figures show great fluctuations in the prices from month to month as well as in the average prices from year to year

AGRICULTURAL EDUCATION.

Agricultural instruction for adults in the British Empire, J. HAMILTON (*U. S. Dept. Agr., Office Expt. Stas. Bul. 155, pp. 96*).—This is a report by the farmers' institute specialist of this Office on the methods that have been adopted by the various governments included in the British Empire in the dissemination of agricultural information among their rural populations.

The author states that the conclusion reached years ago by Great Britain's wisest statesmen was that the only solution of the question of improving agriculture sufficiently to enable those who pursue it as a calling to maintain themselves in comfort and at the same time to produce a surplus sufficient for the use of those engaged in other occupations lies in their proper education. Accordingly the Government established schools and colleges of agriculture at home many years ago, and has since encouraged their erection in all of her dependencies, until now agricultural instruction in some form or other is given in almost every country under British rule.

The present bulletin describes the means adopted for reaching rural adults through itinerant teachers, traveling schools, farmers' institutes, and other forms of college and university extension. There is also some discussion of the higher institutions which are associated in the work of instruction of adult farmers.

Reading-course bulletins for farmers and farmers' wives (*Albany: N. Y. Dept. Agr., 1904, pp. 788, figs. 404*).—This is a reprint of all the Cornell reading-course bulletins for farmers and farmers' wives up to March, 1905.

The following subjects are treated in the reading course for farmers: (1) The soil—what it is; (2) tilliage and underdrainage—reasons why; (3) fertility of the soil—what it is; (4) how the plant gets its food from the soil; (5) how the plant gets its food from the air; (6) balanced rations for stock; (7) the computing of balanced rations; (8) sample rations for milch cows; (9) soiling crops, silage, and roots; (10) pastures and meadows; (11) how a fruit tree grows; (12) planting the orchard; (13) tilling and fertilizing the orchard; (14) pruning and spraying fruit trees; (15) picking, storing, and marketing fruit; (16) building poultry houses; (17) feeding of laying hens—the principles; (18) rations for poultry; (19) raising chickens; (20) marketing poultry products; (21) the care of milk on the farm; (22) the composition of milk and cream and their by-products; (23) construction of sanitary dairy stables; (24) farm butter making; (25) the dairy herd.

In the reading course for farmers' wives the following subjects are treated: (1) Saving steps; (2) decoration in the farm home; (3) practical housekeeping; (4) the kitchen garden; (5) flowers and the flower garden; (6) the rural school and the farm home; (7) boys and girls on the farm; (8) reading in the farm home; (9) farm home industries; (10) insect pests of house and garden; (11) suggestions on home sanitation; (12) germ life in the farm home—a second talk on sanitation; (13) brief discussion of human nutrition; (14) food for the farmer's family; (15) saving strength.

Agricultural college extension, University of Illinois ([*Circs.*] *March, 1904–July, 1905*).—Among these circulars the following are designed for use in connection with agricultural instruction or the encouragement of interest in farm operations:

Soil fertility experiments, C. G. Hopkins (pp. 8, figs. 6).—This contains explicit instructions for the direction of young people's experimental clubs and public school

pupils in agriculture in conducting pot and plat experiments with commercial fertilizers. The circular also contains a brief discussion of nitrogen-gathering bacteria in their relation to the growth of red clover and other legumes.

Some facts about sugar beets and how to grow them, F. H. Rankin (pp. 8, fig. 1).—Cultural suggestions are given for members of boys' experiment clubs who undertake experiments with sugar beets in cooperation with the College of Agriculture of the University of Illinois.

Reading course in soil fertility, C. G. Hopkins (pp. 4, fig. 1).—A suggestive outline of readings from publications of the agricultural experiment stations and this Department for farmers and instructors in agriculture in public schools.

Studies of corn and its uses, F. H. Rankin (pp. 40, figs. 8).—After explaining the purpose of the agricultural college extension work among the young people of Illinois, the author takes up the following studies: (1) Studies of the corn plant; (2) studies of an ear of corn; (3) the corn score card, (4) studies of the different parts of a kernel of corn; (5) commercial products of corn, and (6) suggestions for corn experiments. Suggestive blanks are given for scoring corn and for keeping corn records.

Testing milk on the farm, C. C. Hayden (pp. 8, figs. 3).—Suggestions and directions for members of young people's experimental clubs and pupils in agriculture in public schools.

Proceedings of the eighteenth annual convention of the Association of American Agricultural Colleges and Experiment Stations, edited by A. C. TRUE, W. H. BEAL, and H. C. WHITE (*U. S. Dept. Agr., Office Expt. Stas. Bul. 153, pp. 138*).—This is a detailed account of the proceedings of the convention held at Des Moines, Iowa, November 1–3, 1904, a shorter account of which has been given (E. S. R., 16, pp. 426–438).

Proceedings of the ninth annual meeting of the American Association of Farmers' Institute Workers, edited by W. H. BEAL, J. HAMILTON, and G. C. CREELMAN (*U. S. Dept. Agr., Office Expt. Stas. Bul. 154, pp. 90*).—This is a detailed account of the proceedings of the meeting held at St. Louis, Mo., October 18–20, 1904.

Agriculture in the public schools, M. M. PARKS (*Ann. Rpt. Dept. Ed. Ga., 33 (1904), pp. 153–167*).—A discussion of the educational value of elementary agriculture in school courses.

Agriculture in the rural schools, J. C. McDOWELL (*N. Dak. Farmers' Inst. Ann., 1904, pp. 172–180*).—This is an address giving a general review of the extent to which elementary agriculture is taught in the schools of the United States, and presenting arguments for teaching this subject by means of laboratory exercises and text-books.

Teaching agriculture in common schools, C. B. CHAPMAN (*Ann. Rept. Dept. Ed. Ga., 1904, pp. 139–144*).—Suggestions for illustrative exercises in elementary agriculture.

Tree planting, school gardening, and schoolroom decoration in Nebraska (*Lincoln, Nebr.: Dept. Pub. Instr., 1905, pp. 49, pls. 2, figs. 57*).—This is a pamphlet published by the Nebraska Department of Public Instruction in its "crusade for better school environment."

It contains leading articles, as follows: Tree Planting on Nebraska School Grounds, by Frank T. Miller; Ornamentation of the School Grounds, by W. H. Barnes; The Country Schoolhouse and Its Grounds, by Hon. James Wilson; The Planting of School Grounds, by Susan Huntington Hooker; A Girl's Vegetable Garden, by Ida M. Angell; The Planting of Rural School Grounds, by Chas. A. Scott; Hints on Rural School Grounds, by L. H. Bailey; Tree Planting on the Government Forest Reserve, by Chas. A. Scott, and Schoolroom Decoration, by Nellie May Schlee.

A list is given of prizes aggregating over $500 in value, which were offered by publishers, school supply houses, nurseries, and the State Fair Association for the improvement of school grounds and growing of vegetables, and for specimens of manual

training, drawing, and other work, which the department of public instruction is trying to promote.

Geography, nature study, and agriculture in the elementary schools, C. L. Coon (*N. C. State Supt. Pub. Instr., Teachers' Bul. 2, pp. 32*).—The three subjects considered in this bulletin are treated with reference to the common bearing they have upon the natural environment of children.

In geography such common things as soil, plants, animals, and weather are considered in their general relation to man; in nature study the arousing of the interest of children in plants, animals, weather, and the soil; and in agriculture the culture of the fields, or weather, soil, plants, and animals, considered as agencies in affording man shelter, food, and clothing. With this interrelation of geography, nature study, and agriculture in mind suggestive outlines are given for geography in the first 7 grades of the elementary school, for nature study at different seasons of the year, and for agriculture with a text-book as a basis for the work. There is also a discussion of school-garden work and a list of books on nature, geography, and agriculture for teachers and older pupils.

MISCELLANEOUS.

Seventeenth Annual Report of Massachusetts Station, 1904 (*Massachusetts Sta. Rpt. 1904, pp. 178*).—This includes the organization list of the station, a list of available publications, a financial statement for the fiscal year ended June 30, 1904, and reports of the heads of departments for the most part noted elsewhere.

Seventeenth Annual Report of Mississippi Station, 1904 (*Mississippi Sta. Rpt. 1904, pp. 42*).—This contains the organization list of the station, a financial statement for the fiscal year ended June 30, 1904, a report of the director on the work of the station and McNeill branch station during the year, reports of the different departments of the station, some of which are noted elsewhere, and a report of the assistant director on the work at the McNeill branch station.

Fifteenth Annual Report of North Dakota Station, 1904 (*North Dakota Sta. Rpt. 1904, pts. 1, pp. 183; 2, pp. 208*).—Part 1 contains a report of the director, a financial statement for the fiscal year ended June 30, 1904, and reports of the different departments containing the results of experimental work noted elsewhere. Part 2 is the report of the food commissioner, also noted elsewhere.

Annual Report of Pennsylvania Station, 1904 (*Pennsylvania Sta. Rpt. 1904, pp. 294*).—This contains the organization list of the station; a financial statement for the fiscal year ended June 30, 1904; a report of the director on the work of the station during the year; and reports of divisions, which contain several articles abstracted elsewhere.

Seventeenth Annual Report of Vermont Station, 1904 (*Vermont Sta. Rpt. 1904, pp. 365–587*).—This contains the organization list of the station, a financial statement for the fiscal year ended June 30, 1904, a report of the director reviewing the work of the station during the year and giving abstracts of Bulletins 100–108 of the station, and reports of the heads of departments containing articles abstracted elsewhere.

Abstract of Seventeenth Annual Report, 1904 (*Vermont Sta. Bul. 111, pp. 21–68*).—This is a résumé of the annual report of the station noted above.

A guide to the grounds of the agricultural experiment station at Kingston, Rhode Island (*Rhode Island Sta. Bul. 104, App., pp. 15, dgms. 2*).

List of abbreviations employed in Experiment Station Record for titles of periodicals, E. W. Allen and Mrs. D. K. Murphy (*U. S. Dept. Agr., Office Expt. Stas. Circ. 62, pp. 74*).—This has been noted editorially (E. S. R., 16, p. 841).

NOTES.

California University.—The college of agriculture announces 6 short courses for the autumn and winter of 1905–6, among which are courses in viticulture, nutrition of man and domestic animals, irrigation, and the reclamation service.

Colorado Station.—The station has begun some cooperative work in forestry through the State, furnishing seedlings for these trials and some supervision. A horse barn is being built for use in connection with the cooperative experiments with this Department in horse breeding.

Illinois University.—*The Illinois Agriculturist* states that the enrollment in the college of agriculture exceeds that of last year by one hundred. "All conditions indicate that the total enrollment for the year will reach five hundred or over." A greater percentage of the new students have had a high school training or its equivalent than formerly, and have matriculated at once and entered upon the prescribed course.

Iowa College and Station.—J. B. Davidson has been elected assistant professor in agricultural engineering to succeed C. J. Zintheo, who, as previously noted, resigned to take up work in farm mechanics in connection with the irrigation and drainage work in charge of this Office. E. T. Robbins has been elected to the position of assistant in animal husbandry, to succeed W. W. Smith, who has been elected assistant of animal husbandry at Purdue University.

Kansas College and Station.—At a recent meeting of the board of regents, a resolution was passed materially extending the duties of the director of the station and defining the function of the station council. The director is to have immediate charge of all the work of the station, including that of the branch station, and be held responsible for its execution. He is also to have charge of the expenditures of the stations, the publications, and other business matters. Reports are to be made to the board annually, and a plan of the work and the expenditures for the year is to be submitted each spring. The new plan will materially strengthen the organization of the station.

The department of dairy and animal industry has been divided, O. E. Erf remaining in charge of the dairy husbandry department, and the animal husbandry department placed in charge of R. J. Kinzer.

A wheat and corn special, manned by experts from the college and station, was run this fall over the Rock Island system in Kansas, the work occupying two weeks, beginning November 6. Stops of 30 minutes were made along the route, the schedule including nearly 150 towns. There were two coaches for audience rooms, one used for the talks on wheat raising and the other on corn.

Maine University.—G. E. Tower has been appointed professor of chemistry in the university, A. W. Gilbert instructor in agriculture, and L. T. Ernst assistant in horticulture.

Michigan College and Station.—A number of experimental silos are being constructed of cement and of wood. The materials of the latter are of several different kinds, and are treated in a number of different ways, to test their durability and efficiency.

Missouri Station.—F. W. Liepsner has been appointed assistant chemist in connection with the soil survey work, and C. H. Hechler assistant in animal husbandry in connection with the feeding experiments now being conducted in cooperation with this Department.

Cornell University.—The registration in agriculture at Cornell University up to October 20 is reported as 216, as compared with 178 last year. This is relatively the largest increase in any department of the university.

New York State Station.—W. H. Andrews, for more than ten years assistant chemist at the station, died September 29 from Bright's disease, after a long illness. In his death the station loses a most faithful and efficient worker and his associates a sincere and genial friend.

North Carolina Station.—W. F. Massey has resigned his position as horticulturist and will devote himself to editorial work. Charles Walker has discontinued his work as assistant chemist to the station, and will hereafter devote his whole time to teaching. O. L. Bagley and R. H. Harper, graduates of the class of 1905, have been appointed assistant chemists to the station.

Pennsylvania Station.—J. H Parkins, of Fort Defiance, Virginia, has succeeded R. E. Stallings as assistant in animal nutrition.

Rhode Island Station.—Hugh L. Barnes, a graduate of the Massachusetts Agricultural College in the class of 1905, has been appointed assistant horticulturist, vice M. A. Blake, who, as previously noted, has gone to the Massachusetts Agricultural College.

Graduate School of Agriculture.—It has been decided to hold the second session of this school in the summer of 1906 at the agricultural college of the University of Illinois, under the auspices of the Association of American Agricultural Colleges and Experiment Stations and the University of Illinois. Details regarding the date of the school and the courses to be offered will be announced later.

Opening of Nova Scotia Agricultural College.—The Nova Scotia College of Agriculture, located at Truro, opened its first session for regular students on October 17, with an enrollment of twenty. Short courses in animal industry have been given at the government farm in the two previous years. Applications for admission to the short course, to begin January 30 next, have been received from over 100 intending students.

East of Scotland Agricultural College.—At a meeting of the board of directors of the East of Scotland College of Agriculture, held at Edinburgh, the chairman of the "central studies committee" reported that 58 students received benefit from the central classes last season, as against 60 in the previous year. There was a large increase in the number of students attending the evening classes, there being 170 as compared with 43 the previous year. The "county work committee" reported that during the last year there were 12,917 students in attendance. In the systematic classes there were 645 students—341 in dairying, 272 in forestry, and 32 in general farming. Application is to be made to the Committee of Council on Education in Scotland for a grant to the college, as there is great need of funds for certain classes of its work.

Forestry at the University of Cambridge.—The syndicate appointed to consider the desirability of establishing a course leading to a diploma in forestry at the university has reported, according to a note in *Nature*, (1) that a diploma in forestry should be established; (2) that forestry should form the principal subject of the final examination for the diploma; (3) that the diploma should be granted only to graduates of the university; (4) that candidates for the diploma should show evidence of having resided for the equivalent of one year in some recognized center of instruction in practical forestry. If these recommendations are approved by the senate, the syndicate proposes to draw up and submit to that body detailed regulations for the scope

and conduct of the proposed examinations, and for the courses of lectures and practical instruction to be required of candidates for the diploma.

Elementary Agricultural Education.—*The Nebraska Farmer* for October 19 is the annual agricultural school number. It contains an article on Nebraska's Western Experimental Substation, a History of the Nebraska School of Agriculture, short articles and notes concerning features of agricultural instruction in Missouri, South Dakota, Iowa, and New York, an article on Agriculture in the Public Schools, by E. C. Bishop, deputy state superintendent of public instruction, and one on The Growth, Development, and Future of Agricultural Education in America, by Chancellor E. Benjamin Andrews.

The author of the latter article in tracing the development of agricultural education in America gives credit to the experiment stations for the first real progress in this direction, in that the investigations conducted by the stations "furnished what was originally lacking--data for instruction in agriculture and the subjects relating thereto." He estimates that the greatest result to be accomplished by the colleges of agriculture is likely to be the creation of a "demand that farmer boys and girls shall not only have the training which the schools afford, but shall have in addition to that a college training in agriculture."

The Nebraska State Department of Public Instruction, in cooperation with the college and school of agriculture, is making an active campaign for the extension of agriculture to the public schools. As a feature of this work the department has announced a State meeting, December 14 and 15, of the boys engaged during the past year in a corn-growing contest, in connection with which there will be a girls' corn-cooking contest. At the time of this meeting it is proposed to organize the Nebraska Boys' Agricultural Association and the Nebraska Girls' Domestic Science Association. Each of these organizations will have branch county organizations, subordinate to which will be school district organizations. A leaflet recently issued by the department of public instruction gives suggestions for the organization of these different subordinate associations.

In the Waterford (Pa.) High School, 29 boys and 6 girls out of a total enrollment of 80 are taking the agricultural course. Elementary agriculture is now starting on its second year in the high school and is very popular. An excellent feature of the work is the laboratory work in plant life and agricultural chemistry, and outdoor work in judging cattle, horses, sheep, and swine on nearby farms.

A winter school of agriculture is announced by the Essex Education Committee, to be held at the County Technical Laboratories, Chelmsford, England, from November 20 to December 23, 1905, and from January 8 to February 3, 1906. The first course will be devoted to the soil and its cultivation and tillage crops, and the second course to fodder crops and farm stock. There will also be instruction in chemistry, physics, botany, and zoology, accompanied by practical laboratory work.

Market-day lectures are announced as another feature of educational work at the laboratories for 1905–6. These are Friday afternoon lectures, and are free for farmers and others interested in agriculture. Seventeen such lectures were given in the autumn and winter of 1904–5, and abstracts of the lectures were subsequently published for general distribution. Some idea of the character of these lectures can be gleaned from the following titles: Manuring of market-garden crops, marketing of farm produce, agricultural cooperation, hints on the management of a flock, improvement of pastures, plant breeding, poultry keeping, varieties of soils, cultivation of maize, and taints in milk.

Promotion of Agriculture in Porto Rico.—Press reports state that the establishment of a bureau of agriculture for Porto Rico is in contemplation. The University of Porto Rico, at Rio Piedras, near San Juan, has a 100-acre farm which the trustees propose to use for illustrating improved methods and for giving students practical training in agriculture. There is now a class of 28 such students. The present herd

of 12 cows is to be doubled, and a model dairy installed. The institution is now selling its milk to people in the neighborhood, and with the new equipment it is proposed to handle and put up this milk according to the most modern sanitary methods. An attempt will also be made to improve the dairy stock by the importation of a blooded bull from this country.

Thoroughbred swine are also to be introduced, and 3 stallions. One of these stallions will be kept at the university, one at the experiment station, and the other at some convenient point on the south side of the island. Slips sufficient for the planting of 100 acres of sisal will arrive within a short time, and will be distributed to persons who wish to experiment with the growing of this fiber plant. In numerous ways the propaganda for the improvement of conditions will be carried on with the cooperation of the Federal experiment station at Mayaguez, whose pioneer work has paved the way for this more popular work about the island.

Conference on Texas Fever Tick.—In connection with the annual session of the Southern States Association of Commissioners of Agriculture, held at Richmond, November 22–24, a conference was called of station directors, entomologists, veterinarians, representatives of this Department, and others interested in the question of cattle tick extermination. The purpose of the conference was to formulate definite recommendations to be presented to the commissioners of agriculture, looking to concerted action and cooperation in the extermination of the cattle tick through the South.

Reclamation Funds.—The estimated amount to be covered into the Treasury to the credit of the reclamation fund for the past fiscal year is, according to *Forestry and Irrigation*, \$4,757,978.87. The largest amount, \$870,290.01, was from the sale of public lands in North Dakota, followed by \$675,325.60 from Oregon, \$572,633.54 from Oklahoma, and \$522,203.50 from Washington. The amounts derived from other States were as follows: Arizona \$47,449.52, California \$361,557.87, Colorado \$270,060.25, Idaho \$370,272.90, Kansas \$30,478.36, Montana \$350,031.30, Nebraska \$120,786.59, Nevada \$12,157.93, New Mexico \$85,602.58, South Dakota \$174,448.96, Utah \$50,716.82, and Wyoming \$243,962.94.

Miscellaneous.—An account of the Idyllwild School of Forestry is given in the October issue of *Forestry and Irrigation*. This is a summer school, conducted for a term of two months in the San Jacinto Mountains, in Riverside County, Cal. Several permanent buildings have been erected, and lecturers and instructors are in attendance upon the course. Among those who lectured in the course the past summer were A. V. Stubenrauch, of the California College and Station, and T. P. Lukens and A. T. Searle, of the Forest Service of this Department.

With the inauguration of a 4-year course of study at the agricultural high school of Vienna, the right has been given the school to confer the doctor's degree ("*Doktor der Bodenkultur*"). The course was formerly a 3-year one, and there has long been an effort to raise the grade of work done by the school. The present action places it on a par with the universities and technical high schools.

The enrollment of agricultural students at the University of Leipsic, according to a recent note in *Fühling's Landwirtschaftliche Zeitung*, is now 152. Of these students 28 come from the Kingdom of Saxony, 44 from the Kingdom of Prussia, 21 from the remaining States of the German Empire, 15 from Austria-Hungary, 32 from Russia, 11 from other European countries, and 1 from North America. One hundred students entered the college for the 1905–6 session.

The inaugural address at the opening of the present session of the Southeastern Agricultural College at Wye, England, was delivered by Prof. H. Marshall Ward, of the University of Cambridge, and was upon the subject Botany and Agriculture.

A recent number of *Fühling's Landwirtschaftliche Zeitung* announces the establishment of an agricultural winter school at Weener, East Friesland, Prussia, with Mr. Schroer as director.

During the past year experiments with fertilizers and different field and garden crops have been conducted on the farm of the training school for feeble-minded girls and boys at Vineland, N. J., under the auspices of the Pomona Grange Experiment Committee. This committee has also been instrumental in having similar experiments conducted by farmers in different parts of the county.

In his message at the recent opening of the Mexican Congress, President Diaz announced that arrangements had been completed for the establishment of three experiment stations.

At the first regular meeting of the National Council of Horticulture, held in Cleveland October 4, the desirability of exploiting horticulture through the public press was considered. It was believed that much good could be accomplished at the present time by thus promoting horticulture in a broad way, especially along the nursery, floriculture, and seed lines. To this end leading firms in these trades will be solicited for contributions to carry on the work. Other matters considered were the standing powers of the society relative to national questions affecting horticultural interests, such as postage, customs, transportation rates, nomenclature, and the like.

O

EXPERIMENT STATION RECORD.

VOL. XVII. DECEMBER, 1905. No. 4.

The report of the Secretary of Agriculture for 1905 departs from the usual form of a progress report for the year, with a result which is unusually interesting. It is noteworthy as being the ninth annual report issued by Secretary Wilson, and owing to this unusual period of service he takes occasion to review some of the more salient features of development which have taken place in his time and to sum up the progress in a number of new lines. It is therefore a progress report for the past eight years, with such comparisons as are necessary to an understanding of the great change which has been wrought.

Such a review as this is extremely useful as well as interesting, for it will enable the general reader to get a proper perspective of the Department's work, and furnish convincing evidence to legislators and others who are watching the growing appropriations for this branch of the Government. Growth has been so steady that it is necessary to pause and view the Department in retrospect in order to realize the extent and character of the changes which have been involved. The appropriations have more than doubled in the past eight years, although it had required over forty years to reach the figure they had attained in 1897. This large increase in itself suggests the desirability of a report as to what has been accomplished in the upbuilding of a great Federal Department, and in the promotion of agriculture as a national industry. By anticipating a call for such a showing the Secretary indicates his desire to keep the public fully posted in this respect and to still further strengthen confidence in the Department.

In order that the magnitude of the interests consigned to him, as well as the far-reaching influence of this basal industry upon other industries, may be properly appreciated, Secretary Wilson prefaces his résumé with some striking statistics of agricultural production. He estimates the wealth of production on farms in 1905 at $6,415,000,000, "the highest amount ever attained by the farmer of this or any other country, a stupendous aggregate of results of brain and muscle and machine." This is an increase of thirty-six per cent over the census figures of six years ago. It is not only sufficient to supply the wants of eighty-three millions of our own people, but last

year farm products to the value of $827,000,000 were exported. The enormity of the nonagricultural industries which are directly dependent upon the farmer and his extraordinary productive ability is likewise supported by striking figures.

In a recent address Secretary Wilson said that when he came to the Department he found it necessary to build it up and strengthen it, before he could render the aid he had in mind to the agricultural colleges and experiment stations of the country. One important measure of the extent to which this upbuilding has taken place is found in the personnel of the Department. The total number of persons on the rolls of the Department in 1897 was 2,443, including 925 who were rated as scientists and scientific assistants. Last July there were 5,446 persons on the rolls of the Department, 2,326 of whom were rated as scientists and scientific assistants. These figures show an increase of over 3,000 persons in the total force, and of 1,401 in the scientific staff.

This increase in personnel and in appropriations has naturally gone hand in hand with the development and extension of the Department's work. Taking up the different branches, the Secretary points to some of the more important developments and achievements as indicating the lines along which growth has taken place, and illustrating the methods by which the Department seeks to work for the practical benefit of the farmer. There has been important reorganization, such as bringing together several straggling divisions into a Bureau of Plant Industry; and other lines have been enlarged and strengthened and developed into bureaus.

The work in forestry, for example, which has grown to a position of such recognized importance, may be said to be a product of the past eight years. At the beginning of 1898 the Division of Forestry employed eleven persons, six of whom filled clerical or other subordinate positions. Practically all of its work was office work. The actual introduction of forestry began in 1898, when, with the offer of practical assistance to forest owners in the management of their tracts, "the field of action shifted from the desk to the woods." The growth of interest in forestry, in conservative lumbering, in forest reservations, and in education in this branch is too familiar to call for comment. Public opinion has undergone a great change, and a sound national sentiment has been created. The large and varied interests dependent upon the forest have been awakened to the urgent need of making provision for the future, and States have been led to enact wise laws and enter upon a well-considered forest policy. The Secretary holds that if the Forest Service had not taken the lead in finding out just how practical rules for conservative lumbering might be laid down and carried out forestry would not have reached the point at which it now stands in the United States.

The agricultural experiment stations in Alaska, Hawaii, and Porto Rico have been established and placed upon an efficient working basis under the present administration and the influence and assistance of the Department have thus spread to these remote possessions. The investigations in problems relating to irrigation from an agricultural standpoint, as distinguished from that of engineering, have been inaugurated and organized upon a comprehensive scale. This work has proved so eminently practical and so important to irrigated agriculture that it has grown rapidly in extent and in the scope covered in its studies. Out of it have sprung the work in land drainage, which has already demonstrated great possibilities of usefulness, and the still newer investigations upon agricultural machinery, so that there has been created and put into operation a new feature of work covering the whole range of rural engineering, as a highly important division of the Department's activities.

The Weather Bureau has greatly extended the range of its observations and investigation, which has been attended by increasing efficiency and a wider application of its work. It is now said to be the most highly developed weather service in the world. The work in economic entomology has been extended to many new lines of study upon injurious and beneficial insects of the farm, garden, forest, and household, and has been more than doubled in scope, not to mention the extensive scale on which the Bureau has worked in the campaign against the cotton-boll weevil. The soil survey has been entirely developed during the present administration, and constitutes the first systematic attempt to make a comprehensive soil survey of the United States.

The Secretary points to the successful eradication of the foot-and-mouth disease in New England, and the diverse efforts which have been made to offset the evils of the cotton-boll weevil in the Southern States, both prosecuted with special appropriations for the purpose. In the latter connection, as well as independent of it, the breeding and selection of plants and varieties better adapted to special conditions or uses has been a conspicuous feature; and closely related to it is the introduction of plants from foreign countries. In 1898 Secretary Wilson secured authority to use a small portion of the Congressional seed fund for agricultural exploration, which has resulted in extensive introduction of seeds and plants which have been tested the country over. The largest collection of date palm varieties in the world has been secured in this way, and several important cereal introductions have been made, such as durum or macaroni wheat, the Spanish Select oat, and the Sixty-day oat. Durum wheat was first introduced from Russia in the spring of 1899. It is estimated that from twelve to fifteen million bushels of this wheat were grown this year in the three States of North Dakota, South Dakota, and Minnesota, and that

the crop in other sections of the country will bring the production up to twenty million bushels for the entire country. This wheat has evidently passed the experimental stage and is now an established crop in a considerable number of the semiarid States.

Referring to the propaganda for sugar-beet culture, inaugurated soon after the present Secretary came to the Department, and the widespread tests of its adaptation to different parts of the country, this industry is pointed to as one which has become well established in favored localities, whose farming side has been greatly benefited by scientific investigation. In 1897 there were but nine beet-sugar factories in the country, with a combined output of thirty thousand short tons of sugar; the estimated output for 1905 is two hundred and eighty thousand short tons. Similarly, rice culture in the Southern States, especially Louisiana and Texas, has been exploited and encouraged by the introduction of Japanese varieties, and has grown very greatly in extent.

In addition to the important investigations of the Bureau of Animal Industry on contagious diseases of animals and their means of control, the meat inspection in its charge has steadily increased. Upon this work depends in very large degree a foreign trade worth millions of dollars yearly to American stock raisers. This year the inspection covered sixty-six million live animals before slaughter, and over forty million carcasses after slaughter, representing an increase in this work of about 33⅓ per cent in the past eight years. The inspection work has also been extended to other food products intended for export, and to all foods imported into the United States, for which purpose branch laboratories of the Bureau of Chemistry have been established in the ports of New York, Boston, Philadelphia, New Orleans, San Francisco, and Chicago. A system of food standards has also been worked out as a basis for guidance in Federal, State, and municipal food inspection.

And so on throughout the report. Taking up the work of the different bureaus and divisions, the Secretary points out the more important lines of development, and enumerates the many lines in which investigations have been prosecuted with practical application to American agriculture. The showing is indeed a gratifying one. The presentation is clear and direct, and affirms how definite has been the aim in the development of the Department's work along the various lines of activity. No one can read the report without a fuller appreciation of the extent and the ramifications of the Department, and of the very many ways in which it is serving the farming public and contributing to the general welfare of the country. It is as broad in its sympathies as the relationships of the industry it stands for, and no legitimate interest within its scope will fail to awake a responsive chord when it appeals to the Department for aid.

But the very breadth and diversity of the interests concerned suggests that the Department can not be sufficient unto itself, and the Secretary is not unmindful of the other agencies which have contributed in such an important degree to this great work. He makes appreciative acknowledgment of the services of the agricultural experiment stations as cooperative agencies, and of their importance from both a local and a national standpoint.

The Secretary outlines as the twofold object of the Department that of adding to the sum of intelligence of the man, and increasing the productive capacity of the acre, and he adds that "in this important work it has the hearty cooperation of the State agricultural colleges and experiment stations, all of them working with the Department of Agriculture toward the same great end." By means of the close relations which have existed "the range and effectiveness of many agricultural investigations have been enlarged, and it has been possible to bring the Department's work into vital touch with agricultural industries and agricultural people. . . . Not only have the stations been a vital factor in making the Department's work more effective, but they have by their own investigations lifted American agriculture to a higher plane."

Furthermore, the Department and the experiment stations are "gathering the materials which will constitute the future of education in agriculture, and the permanent impression which their work will make on agricultural practice will be largely determined by their success in incorporating the results which they obtain in courses of instruction to be given the youth in agricultural colleges and schools." These are, after all, the most important considerations, for they are the most abiding and will have the greatest permanent influence in elevating and improving American agriculture in the broadest sense.

Secretary Wilson declares his purpose to render all the assistance to the stations which the Department can give them, but he recognizes that something more is required for further development along their own particular lines of endeavor. He accordingly indorses their appeal to Congress for increased appropriation in the following language: "In the increasing demand for more light on agricultural practices and the growing interest in rural life generally, the stations must have the means for meeting these demands. It is hoped that Congress will recognize this need, as it is already being recognized by some of the States themselves. There is no direction in which public moneys can be appropriated that will bring more certain and lasting returns than in helping the State experiment stations to do more research work."

For more than a hundred years, Texas fever, referred to under different names, has been one of the most serious scourges of the

cattle business in the Southern States. The tremendous losses incurred as the result of attempts at traffic in cattle between the North and South brought the matter prominently before the Federal Government in 1868, after which Dr. Curtice and others, under the direction of Dr. D. E. Salmon, carried on investigations regarding the nature of the disease and practical means of controlling it.

After a long series of experiments by the Bureau of Animal Industry, Drs. Smith and Kilborne demonstrated, in 1893, that the disease is transmitted from one animal to another by means of the cattle tick. It was also shown that susceptible cattle could be rendered immune to the disease by inoculating them with the blood of other cattle which had recovered from the disease. The elaboration of this method by the Missouri and Texas stations and others rendered it possible for northern breeders of blooded stock to immunize the animals which they wished to ship south, and thus avoid the serious losses which they would otherwise suffer.

Promising as this method has become, it has long been apparent that objections attach to it. In the first place, the immunity thus produced is not absolute. In some portions of the quarantined area native animals immunized by gradual tick infestation from early calfhood may subsequently succumb to Texas fever as a result of excessive infestation with ticks, or from infestation with unusually virulent ticks. Moreover, the method of immunization is not a permanent remedy for Texas fever, but requires a continual outlay and treatment for all susceptible animals, including native southern cattle on tick-free pastures as well as cattle north of the quarantine line intended for shipment into the South.

Obviously, the most perfect system of immunization does not remove the quarantine line, or permit the transportation of cattle from the Southern States to the northern markets without the inconveniences and restrictions which are required in dealing with such cattle. On account of this inadequacy, a number of investigators have for several years been working along another line of attack which gives hope of ultimate success. Drs. Cooper Curtice, Tait Butler, Prof. H. A. Morgan, and other investigators have demonstrated that by a simple method of pasture rotation, ticks may be eradicated from infected pastures within a single year. During the past four years Dr. Butler has practically eradicated ticks from twelve counties in North Carolina at a total cost of $15,000, and in this time not a single case of reinfestation in the area of operation has occurred.

The method of eradication is based upon known facts concerning the life history of the cattle tick, without the agency of which Texas fever can not be transmitted. The engorged cattle tick drops to the ground from infested cattle, lays its eggs, which hatch into young so-called seed ticks, and these remain upon the grass until opportunity is offered to attach themselves to cattle. After attachment they remain upon

the cattle until fully engorged and ready to drop to the ground for the deposition of eggs. It has been shown possible, therefore, to free infested animals of their ticks by placing them upon tick-free pastures in November, December, and January, during which time all ticks drop to the ground; and since the eggs will not hatch in winter, there is no risk of reinfestation during that time.

The seed ticks may live without animal hosts from September until April, but survive a much shorter time in summer. They may, therefore, be starved out by keeping stock off the infested pasture for sufficient time, or they may be destroyed by plowing the land. The cattle are then placed on tick-free pastures.

Morgan and other investigators have pointed out a way by which both animals and land may be freed of ticks in midsummer by means of the feed-lot system, the animals being excluded from the main portion of the pasture from June 1 until late autumn. Two feed lots are employed, the animals being kept in each twenty days, and the lots then plowed. Without discussing the details of this plan, which have been published by the experiment stations of Louisiana and Tennessee, it is claimed, on the basis of practical trials, that by the feed-lot method the stock on a given farm may be freed of ticks within a period of forty days, even in midsummer.

The importance of these methods to the cattle industry of the South, and to traffic of cattle between the North and South, was never more clearly set forth than at the recent meeting of the commissioners of agriculture of the Southern States at Richmond, Va. In connection with this meeting, about thirty veterinarians, entomologists, and others interested in the South, held a conference on the subject of tick extermination, notice of which had previously been sent out.[a]

It appeared during these discussions that the cattle tick is a serious pest aside from its agency in carrying Texas fever. It was said, for example, to be impossible to produce a high quality of beef in tick-infested regions. The presence of ticks stunts the growth of cattle so that they are from 200 to 300 pounds short in weight at maturity, as compared with northern-grown cattle. In some instances the presence of ticks is reputed to influence the fecundity of dairy cows to such an extent that they fail to breed until the age of 5 or 6 years. Cattle are also reduced in condition from excessive infestation to such an extent as to lead to death from starvation and irritation. In addition to these annoyances which the southern cattle raiser must suffer, the packers offer from one-fourth to one-half cent per pound less for southern than for northern animals of the same quality. Southern animals must be kept in separate pens, and are considered as tainted and dangerous, and therefore of less value.

According to statistics furnished by the Census of 1900, of the

---

[a] E. S. R., 17, p. 311.

fifteen million cattle accredited to the quarantined States, the adult cattle were valued at $7 per head less than similar animals in the North. Since this difference of $7 per head is partly attributable to the presence of cattle ticks, it is thus apparent that this pest causes a great loss apart from the other annoyances and financial losses occasioned by its existence. Its influence is even more far-reaching, for by retarding development in animal husbandry it greatly hinders the spread of diversified farming and becomes one of the greatest impediments to the improvement of the soil and other agricultural conditions.

It was generally agreed by those who had given attention to this problem that tick extermination from the South is both possible and practicable, and that it will be accomplished. In order to get effective action from this unanimous sentiment the conference adopted a resolution requesting Congress to make a liberal appropriation for the dissemination of knowledge concerning the methods of tick extermination, and for the work in pushing the quarantine line farther and farther to the South. The commissioners of agriculture of the quarantined States were also urged to use all possible efforts in securing such uniform legislation as is necessary to bring about the most effective cooperation between the State and Federal authorities in this work.

While, therefore, it is generally recognized that effective methods of tick extermination have been worked out, it remains to carry on a system of demonstration and education for the benefit of stockmen. Stock laws must also be passed in localities where such laws do not exist in order that the movements of stock may be regulated. Wherever such laws do exist it is possible to proceed at once with tick extermination, and it is believed that with the proper educational forces in the field, in the line of farmers' institutes and personal contact with interested stock raisers, the natural difficulties in inaugurating such a movement will be overcome and the movement itself will proceed with satisfactory speed.

The conference was one of great importance and developed much enthusiasm and confidence. The subject was considered as being fundamental to southern agriculture. With the knowledge already at hand regarding the habits and life history of the cattle tick, and the proper machinery set in motion to secure concerted action, there is more encouragement than ever before to look forward to the ultimate eradication of this scourge. The interests involved should lead every State and every farmer to do his part well. The work can be carried on smoothly and economically only when the most thorough cooperation is realized. It will be necessary for the individual farmer not only to appreciate the desirability of eradicating the ticks, but of cooperating in the work with the county and State officials and the Federal Government.

CONVENTION OF ASSOCIATION OF AMERICAN AGRICULTURAL COLLEGES AND EXPERIMENT STATIONS.

The nineteenth annual convention of this association was held at the Shoreham Hotel, Washington, D. C., November 14–16, 1905. The meeting was one of unusual interest and success, and the attendance was larger than on any previous occasion. The registration was undoubtedly swelled by reason of the annual conventions in Washington of several other related bodies, which occurred at about the same time. Among these were the Associations of State Universities, of Farmers' Institute Workers, of Horticultural Inspectors, and of Official Agricultural Chemists. An unusual number of persons interested in industrial education and agricultural experimentation was thus brought together in Washington, and a large proportion of these attended the sessions of the Association of Colleges and Stations, in whole or in part. Over 250 persons registered, and the delegation which paid its respects to the President on the afternoon of the first day of the convention included a considerably larger number.

GENERAL SESSIONS.

The association was addressed at the opening session by Hon. James Wilson, Secretary of Agriculture, and a former member of the association. He declared his deep interest in the work of the association and his belief in the purposes of the institutions represented. His intention upon first coming to the Department had been to make it helpful to the experiment stations, but he found that it was first necessary to strengthen the Department itself. This he had done by building up the staff of workers and securing increased appropriations from Congress; and the stage had been reached where more attention could be given to aiding the stations. Secretary Wilson declared the greatest need of the stations to be more money, and he stated that in his forthcoming report to Congress he had strongly recommended that larger appropriations be made for the use of the stations. He held that this would be an economy measure, since there is no economy so far-reaching as the strengthening of the American farmer.

The annual presidential address was delivered by Dr. E. B. Voorhees, of New Jersey, on the evening of the first day of the convention. This related in the main to some of the duties and responsibilities of the agricultural colleges and experiment stations. Doctor Voorhees

held these colleges primarily responsible for the kind and amount of work done by the stations, because the working staff is the first determining factor in station work, and it is to the colleges that we must look for the fundamental training for this work. He urged the need of more research work on the part of the stations, and declared that the lack of the present limitations were largely due to the inadequate supply of broadly trained men capable of planning highly scientific investigations. The speaker called specific attention to lines in which agriculture is in need of investigation, to prevent losses of stock and products, and to bring districts now largely wastes into more profitable cultivation. These illustrations were presented to show that "it is the manifest duty of this association, as representing both the colleges and the stations, to see to it that provision is made for the specific training of investigators; for, all things considered, our progress has been measured and its limits fixed by the available men, rather than by material equipment."

The report of the executive committee, presented by Dr. H. C. White, chairman, briefly reviewed the activities of the committee during the year, notably in securing modification of the orders of the War Department with reference to military instruction in the land-grant colleges, and its efforts in behalf of the bills before Congress for the increase of the experiment station appropriation and for the establishment of mining schools. The committee believed that the association should concentrate its efforts on a single bill, rather than attempt the support of several measures. This suggestion led to considerable discussion later in the meeting, which brought out the quite general feeling that preference should be given to the Adams bill; but to avoid embarrassing the executive committee by too rigid restrictions it was instructed to concentrate its efforts upon the bill apparently in the most favorable condition for passage, provided the mining bill be so modified as to recognize the land-grant colleges as the beneficiaries.

The executive committee suggested a reorganization of the standing committees of the association, and made recommendations in this regard, which were referred to a special committee, whose report, presented later, provided for four standing committees, viz, (1) instruction in agriculture, (2) graduate study, (3) extension work, and (4) experiment station organization and policy. These committees are to consist of six members each, to be appointed by the retiring president, and provision is made for a gradual rotation in the membership so that the terms of only two members will expire each year. Vacancies occurring during the year are to be filled by the committees themselves. The appointments upon these committees, with the terms of office, are as follows: *Instruction in agriculture*—A. C. True and T. F. Hunt, three years; H. T. French and H. C. White, two years; J. F. Duggar and W. E. Stone, one year. *Graduate study*—L. H. Bailey

and H. P. Armsby, three years; M. H. Buckham and R. H. Jesse, two years; W. O. Thompson and Brown Ayres, one year. *Extension work*—K. C. Butterfield and C. R. Van Hise, three years; B. W. Kilgore and C. F. Curtiss, two years; A. M. Soule and W. M. Hays, one year. *Experiment station organization and policy*—E. Davenport and C. D. Woods, three years; W. A. Henry and H. J. Waters, two years; M. A. Scovell and C. E. Thorne, one year.

In the course of its report the executive committee referred to the death during the year of President H. H. Goodell, who had been an active worker in the association since its organization, a member of its executive committee for fourteen years and chairman of that committee for eight years. The committee had made special provision for a memorial address upon the life and services of President Goodell, which was presented by President W. E. Stone. In this the speaker paid an eloquent tribute to President Goodell, his work and achievements, his indomitable energy and perseverance in what he undertook, and especially those sterling qualities of heart and mind which commanded the esteem and affection of all who came to know him. "He lived a full and rich life of service in a great cause, and left a record of permanent achievements, but the finest and best of his life was known only to his intimate friends and to his students, to whom he revealed a true nobility of conduct and a splendid character that was an inspiration to all who came within its influence."

Resolutions of respect and esteem were adopted by the association, and the address was ordered printed, separate from the proceedings, for more general distribution.

Dr. A. C. True presented the report of the bibliographer of the association, noting nearly a hundred bibliographies which had appeared during the year upon subjects of interest to agricultural investigators. Most of these have been listed in this journal. The report of the treasurer, J. L. Hills, showed receipts for the year of $1,563, expenses amounting to $1,200.05, and a balance on hand of $995.87.

The report of the committee on uniform fertilizer and feeding-stuff laws, by Dr. H. J. Wheeler, chairman, showed that there had been several new laws passed or modifications of old laws during the year, which had in general followed the recommendations of the committee, and that in several other States there was dissatisfaction with the present laws which might lead to changes. The opinion was expressed that in general the movement is gradually in favor of the general provisions for fertilizer legislation recommended by the association.

The committee on methods of teaching agriculture reported, through Dr. A. C. True, chairman, that 20,000 copies of last year's report of the committee on teaching agriculture in rural schools had been printed and distributed during the year. The committee desired in future to work along two main lines, viz, (1) to study courses of agriculture to

be taught in secondary agricultural schools and other high schools generally, and (2) to make a more detailed study of college courses in animal husbandry and develop some special topic of this subject from a pedagogical standpoint. Dr. True then explained the work of this Office in relation to agricultural education, pointing out the recognition it has received as a leading agency for the promotion of this branch of education, and the action of the Secretary of Agriculture in requesting from Congress an increased appropriation of $5,000 for the development of work along this line.

The committee on graduate study reported, through Prof. L. H. Bailey, chairman, that arrangements have been made for holding a second session of the school of graduate study at the University of Illinois during the coming summer. A canvass of the agricultural colleges for subscriptions of $25 a year toward the maintenance of the graduate school, as provided for by the association last year, showed 27 colleges favorable to making such subscription, 15 unfavorable, and 4 doubtful. The committee emphasized the importance of the graduate school, which it thought should be a regular and continuous work of the association. It held that the school should be an institution of the association, and that it should assume responsibility for its policy and management. The college where the school was held would then be the agent of the association. The sources of income for the graduate school would be (1) fees from the students, which it thought should be fixed at $10, (2) the contributions from the association, derived from the colleges subscribing, and (3) the contributions of the institution at which the course was given. The report of the committee, with its recommendations, was adopted.

The committee on pure-food legislation reported, through Dr. W. A. Withers, chairman, that progress had been made in extending and strengthening the State laws relating to foods, and also in the better execution of pure-food laws. It referred to the satisfactory workings of the inspection of imported foods as indicating the advantages of a national pure-food law.

The report of the committee on the collective college and station exhibit at St. Louis was presented by Dr. W. H. Jordan, chairman, and was received and the committee discharged. It was shown that of the $100,000 appropriated for this exhibit, only about $90,000 had been expended. The report gave a history of the origin and preparation of the exhibit, description of the various parts as installed, and of the so-called outside exhibit, together with other details. By vote of the association it was placed on file in the Office of Experiment Stations for future reference.

The report of the committee on indexing agricultural literature, presented by Dr. A. C. True, chairman, described the progress which has been made in the library of the Department of Agriculture in

indexing scientific periodicals relating to agricultural investigations and the preparation of cards which are printed by the Library of Congress.′ Thus far about 7,000 cards have been issued. At present there are only 10 subscribers for the complete sets and 11 for partial sets, and the question has arisen whether it is worth while to continue this work. It was pointed out that at least 35 subscribers for the complete index would be required to warrant its continuation. The undertaking was originally authorized by the association, and the members were therefore urged to investigate the character of the index to determine whether or not it should receive their future support.

The committee on rural engineering reported through Dr. W. E. Stone, chairman, that progress had been made in strengthening the courses in this subject at several institutions, but that sufficient importance had not been attached to this subject to give it a coordinate place with such subjects as horticulture, animal husbandry, agronomy, etc. It was believed that the best work could not be accomplished until this is done. The work of this Office in testing pumps, windmills, etc., was thought to be of material benefit to professors of rural engineering, as was also the work in irrigation and drainage. The committee believed there was need for a few institutions in the country to establish courses in rural engineering, and that that department should be of coordinate rank with such departments as agronomy, animal husbandry, etc.

Resolutions were passed indorsing the work of this Office along the lines of agricultural education, and also of irrigation and rural engineering.

Assistant Secretary W. M. Hays, for the committee on animal and plant breeding, reported the growth of the American Breeders' Association to an organization of about six hundred members, and the successful annual meeting held at Champaign, Ill., in February last. This committee was discharged, as it has accomplished the purpose for which it was organized.

The establishment of institutions for teaching and research work in forestry in connection with the land-grant institutions was discussed by Prof. S. B. Green, who introduced a resolution looking to national aid, and by Gifford Pinchot, of the Forest Service. As the association had decided to confine its efforts toward legislation as previously indicated, the resolution was laid upon the table.

President K. L. Butterfield offered a resolution instructing the executive committee to take steps to secure, if possible, the establishment of a department of rural agricultural education in the National Educational Association. The resolution was adopted. Hon. W. T. Harris, Commissioner of Education, made a brief address in which he expressed the view that agricultural education should be considered

each year in one of the special departments of the National Educational Association.

A vote of confidence and thanks was ordered sent to Representatives Adams and Mondell for their efforts in behalf of the bills in their charge for the further endowment of the experiment stations and the establishment of mining schools. The association also voted to lend its aid in support of national appropriation for the control of the gypsy moth. It went on record as indorsing the continuance of the collection and publication of data by the United States Department of Agriculture relative to the condition and yields of farm crops, for the use of farmers and for students in rural economics.

Invitations were received from California, Washington, and Louisiana for the association to hold its next annual meeting in these States. The telegrams from various parts of California were especially numerous, and much interest was manifested by the association in holding its next session in that State, in view of the meeting there of the National Educational Association next summer. The matter was left as usual in the hands of the executive committee.

In the election of officers M. H. Buckham, of Vermont, was chosen president; C. C. Thach of Alabama, E. H. Jenkins of Connecticut, J. H. Worst of North Dakota, B. I. Wheeler of California, and Luther Foster of New Mexico, vice-presidents; J. L. Hills, of Vermont, secretary and treasurer; and A. C. True, of this Office, bibliographer; executive committee, H. C. White of Georgia, J. L. Snyder of Michigan, W. H. Jordan of New York, C. F. Curtiss of Iowa, and L. H. Bailey of New York.

In the section on college work and administration, C. R. Van Hise, of Wisconsin, was chosen chairman, and H. C. Price, of Ohio, secretary.

B. C. Buffum, of Wyoming, was elected chairman of the section on experiment station work, and M. A. Scovell, of Kentucky, secretary.

H. P. Armsby of Pennsylvania, C. F. Curtiss of Iowa, and the secretary of the section (ex officio) compose the programme committee of the latter section.

SECTION ON COLLEGE WORK AND ADMINISTRATION.

The general theme for discussion in this section was The Field and Functions of the Land-Grant Colleges, which was considered under the three heads—curriculum, discipline, and environment.

In a paper on A Minimum General Culture Requirement, President A. B. Storms held that the students which the land-grant colleges attract are not prepared for severely technical courses, and hence provision should be made for general culture studies during the first two years of the course, with opportunity for election in the last two years. The students should not be occupied in acquiring mere manual dexterity, which can be more cheaply learned in the workshop.

President J. M. Hamilton discussed the Relative Amounts of Pure and Applied Science. He held that the land-grant colleges should give a good foundation in pure science, not for intellectual training alone, but as a preparation for the work in applied science. There should be diversity in this also, for the application of pure science frequently calls for the union of several branches. In view of these considerations he would have a large amount of pure science work in the early part of the land-grant college course, and make the later science work thoroughly industrial.

Prof. F. W. Rane, in his discussion of Courses in Agriculture, Horticulture, and Allied Subjects, confined his remarks mainly to horticulture. In his scheme for utilizing the 150 hours assigned to horticultural courses, 20 hours were given to the study of propagation, 50 to pomology, 50 to olericulture, and 30 to floriculture. Charts were also exhibited which showed a syllabus of a separate course in horticulture, and of horticulture as it is now given in several States.

Dr. H. W. Tyler discussed what constitutes a "liberal and practical education" for an engineer, making suggestions as to the allotment of time between general science and professional work; and Dr. W. E. Stone and President J. L. Snyder considered the desirability of degree courses in home economics. The former held that since the manual operations of this country are performed by the uneducated people, there is no place for manual training in the degree courses, but that skill in manual operations should be acquired in the lower schools. President Snyder maintained that manual development might to a certain extent be considered one of the legitimate aims of a college course, which ought to be in the broadest sense a preparation for life; and he outlined a tentative degree course in home economics.

In discussing these papers Prof. L. H. Bailey pointed out a tendency to react from the exclusively or severely technical undergraduate courses, and to hold somewhat closely to some of the traditions of education. He noted further a growing disposition to occupy the first two years of the college course with the fundamental or pure science subjects, a drift of opinion toward humanizing the conduct of courses in all of the land-grant institutions, and "an increasing sympathy with the work-a-day life," a desire to introduce other subjects which have to do with the every-day life of the people, and a general indication that the courses, particularly on the agricultural side, are not regarded as severely technical. Particularly was he impressed with the emphasis placed upon the ideals of education rather than practical utility.

Student Control was the topic of a paper presented by President W. O. Thompson, who discussed (1) student government as originated at the University of Illinois in 1869, and tried subsequently at a number of other institutions; (2) faculty control, and (3) administrative

control. He favored the latter method, which places the matter of discipline entirely in the hands of the president of the college and does away with the necessity for elaborate rules and regulations. The discussion following seemed in general to favor this view.

In discussing the relation of the land-grant colleges to the State universities, President W. J. Kerr stated that since 1862, in response to a demand which found its first concrete expression in the land-grant act, the courses in the State universities have been greatly modified, the changes being toward "education related more directly to the practical affairs of life." The logical division of work in the States having separate institutions he thought would be for the universities to offer courses in liberal arts and the professions, while the land-grant colleges would offer all of the technical courses in agriculture and the mechanic arts.

In a paper on The Normal Schools, President K. C. Babcock brought out the fact that comparatively little is now being done to train teachers for small towns, villages, and rural communities. He urged that the land-grant colleges should help the normal schools by offering short courses for teachers, holding institutes, and sending out their officers to give courses and lectures in normal schools. The same general conception of the duty of the land-grant colleges in the movement for the improvement of public schools was held by Dr. A. C. True, who read a paper on The Public Schools. He said that the colleges should study the programmes of the public schools, come into close touch with their school officers and teachers, provide courses of study which will be attractive to school officers and teachers, and by summer schools or otherwise seek to bring such persons into direct contact with the system of education represented in these colleges. Elementary and secondary courses in agriculture and mechanic arts in the public schools are required to direct students to the land-grant colleges and to prepare them to enter their courses.

Prof. John Hamilton discussed the relation of the land-grant colleges to the farmers, and pointed out three great fields in which these institutions should work, viz, (1) the college class room—four-year courses, short courses, and post-graduate courses; (2) college extension work, including correspondence courses, farmers' institutes, movable schools of agriculture, and practice farms, and (3) normal schools of agriculture for training capable farmers to take part in the extension work of the colleges.

SECTION ON EXPERIMENT STATION WORK.

The two subjects arranged by the programme committee for consideration in this section were (1) soil investigations and (2) how much demonstration work and what kind should the experiment station undertake?

Under the first subject Dr. C. G. Hopkins presented a paper on Soil Fertility in Relation to Permanent Agriculture, in which he called attention to the widespread decline of the fertility of farm lands in the United States, due to exhaustive systems of cropping and export of fertility from the farm. The extension of animal husbandry, involving the feeding of a large proportion of the crops grown to animals on the farm, and thus insuring the return of the fertility to the soil, would act as a partial check to this exhaustion; but it was pointed out that about 80 per cent of the farmers of the United States are giving attention almost exclusively to crop production, and that a large proportion of them will probably never take up animal production to an extent that will result in an increase of fertility of their farms in this way. It is therefore necessary for such farmers to adopt systems of cropping, supplemented by the use of fertilizers, which will enable them to maintain the balance of fertility or turn it in their favor.

The experiments of the Illinois Station with various systems of cropping and fertilizing on different soil horizons, on representative Illinois soil areas and types, were briefly reviewed, the results of chemical analysis and pot and field experiments usually agreeing in showing that in these soils phosphoric acid is usually the principal requirement and the only one which needs to be applied in commercial form. The soils are, as a rule, abundantly supplied with potash, and nitrogen is readily and cheaply obtained by growing leguminous plants. The cheapest and most efficient means of supplying the phosphoric acid has been found to be by the use of fine-ground rock phosphate in connection with green manures or other materials supplying abundance of decaying organic matter. The efficiency of such cheap phosphates as compared with the more expensive acid phosphates has also been demonstrated at the Maryland, Ohio, and Pennsylvania stations.

In the discussion following this paper, Director C. E. Thorne pointed out the fact that virgin soils and those long under cultivation behave very differently toward the same systems of cropping and manuring; Dr. H. J. Wheeler called attention to the unsuitability of untreated phosphates to exhausted soils and to market-garden crops; and Prof. W. P. Brooks stated that a large proportion of the soils of New England are in special need of potash, and that it is impossible to determine the fertilizer requirement of a soil apart from the peculiar needs of the particular crop to be grown, a fact which was strongly emphasized by other speakers.

In a paper by Dr. A. M. Peter on Some Results of an Old Method for Determining Available Plant Food in Soils, read by the secretary of the section, a compilation was given of the results of determinations, made in 1854 by R. Peter, State geologist of Kentucky, of the

relative solubility of the constituents of virgin soil, old field soil, and subsoil in carbonated water (saturated with carbon dioxid under a pressure of two atmospheres). The averages of 33 determinations in each case showed the greatest solubility in case of the virgin soil and least in case of the subsoil. The variable character of the carbonated water and its low solvent power for phosphates are considered insuperable objections to its use for this purpose. The author recommended one-fifth normal nitric acid, and reported comparative studies of the solubility in this acid of the potash, phosphoric acid, and lime of good and poor tobacco soils and of pasture soil, as well as of the first two in hydrochloric acid of 1.115 sp. gr. The results showed a small percentage of available potash, but very large amounts of available phosphoric acid and lime, in all soils and to all depths down to 2 feet. Incidentally it was found that the poor tobacco soil was much richer in nitrates than the better soil. Methods of sampling soils were briefly discussed, and the concentrating of attention on the first 6 inches of soil as that part of most importance in plant production was advised.

Director C. E. Thorne presented a paper on Soil Investigation, in which he pointed out the necessity of supplementing chemical analysis and pot experiments with carefully conducted field experiments, and also of giving more attention to the biological processes in the soil. The results of a 7-year rotation with corn, oats, and wheat, and of a 3-year experiment with clover, at the Ohio Station, using lime and various fertilizer combinations, were reviewed, showing that phosphoric acid is apparently the first requirement of cereals on the soils experimented with, and lime the first requirement of clover, potash being second in importance for this crop. The beneficial effect of the lime, particularly on the clover crop, was apparently due to the acid condition of the soil, the character of the growth of the clover being a reliable index of the acidity and the need of lime. Such acid soils were shown to be widely distributed in Ohio.

Attention was called to the fact that the action of certain forms of nitrogen, particularly ammonium sulphate, on acid soils is greatly improved by applications of lime. It was also noted that plants vary with reference to sensitiveness to soil acidity, wheat being especially resistant. While the source and nature of the soil acids are not well understood, there are indications that they may be, in part at least, the result of biological processes.

Discussing this paper, Dr. J. G. Lipman urged the importance of more careful study of the relation of acidity to bacterial activity on the one hand and to the physiological processes of the plant on the other, especially as affecting the solubility of the nitrogen compounds present in the soil or diffused from the cells of the plant roots or the root tubercles.

Dr. H. J. Wheeler made some suggestions regarding profitable lines of research in connection with soils, including study of chemical means of differentiation of the forms of phosphoric acid in soils, influence of soil treatment on the biological processes of the soil and the growth of plants, maximum limits of application of lime, influence of the growth of one plant upon the growth of its successor upon the same soil, influence of soil texture upon the growth of different plants, availability of plant food, the relative avidity with which different plants take up soil potash and soda, and the reliability and applicability of Loew's hypothesis regarding a necessary fixed ratio between lime and magnesia in productive soils.

In the discussion of the subject of demonstration work, Director Thorne explained the Ohio system of (1) test farms on which experimental work is carried on in different parts of the State; (2) cooperative experiments with farmers, taking up simpler phases of station work, and intended primarily to develop farm experimenters in each locality, and (3) special arrangement for particular pieces of work. Some features of the work done under this system are experimental and in part maintained by Federal funds; a large part is purely demonstration work and is maintained by State funds provided for that specific purpose. The importance in cooperative work of relieving the farmer from pecuniary responsibility and of maintaining strict supervision of the work through station officers was pointed out. The speaker urged the need of extension of demonstration work.

Dr. Hopkins explained the system of combined experimental and demonstration work followed in Illinois on the farms controlled by long-time lease or purchase on the various typical soil areas of that State. Prof. L. C. Corbett drew a sharp distinction between experimental work and demonstration work, holding that the latter should have as its prime object the teaching of remunerative methods of farming, as illustrated in the work of the Department demonstration farms in the cotton belt. Similar views were expressed by Director C. D. Smith, who cited various illustrations of ways in which the station had been instrumental in introducing more profitable farm practices in Michigan by means of demonstration experiments.

Dr. W. H. Jordan, of New York, thought that agricultural knowledge passed through three stages in reaching the farmer, (1) laboratory investigation, (2) test in practice, (3) general introduction. Experimental work ends with the second stage. The third is purely demonstration work, and is not the province of the stations under the Hatch Act. Director Hills, of Vermont, thought discovery to be the primary object of the stations, and that demonstration work was outside their province. Dr. Wheeler believed the discovery and test in practice of scientific truth the proper functions of the station. The dissemination of results by demonstration and like means he held to

be an educational function and to belong properly to the extension departments of the colleges. Prof. T. F. Hunt urged that more attention should be given to the study of agricultural economics, so that there will be a better basis for advice as to business methods and management on the farm.

Prof. W. J. Spillman maintained that the purpose of demonstration farms should be to teach profitable methods of farming, based upon scientific investigations and the experience of successful farmers. Demonstration work is a necessary supplement of the present system of investigation and dissemination. He briefly explained some features of the work of the Department in farm management. Dr. H. P. Armsby warned against encouraging exaggerated expectations on the part of farmers from experiment station work. The farmer should be encouraged as far as possible to work out the problem of farm management for himself, a view which was concurred in by others.

A report on the federation of agricultural organizations in different States of the Union was submitted by Dr. H. J. Wheeler. This paper showed that in 12 States federation has already been secured and that other States are contemplating federation. The report was accepted and the committee continued.

A preliminary report on the unification of terms for reporting analytical results was submitted by Dr. C. G. Hopkins, chairman of the committee on this subject. The report contained unanimous recommendations with regard to terms to be used in reporting analyses of feeding stuffs, foods, sugars, and insecticides, but the committee was unable to agree as to terms to be used in soil and fertilizer analysis, the disagreement being with regard to the use, proposed by Dr. Hopkins, of the "element" system of nomenclature.

Prof. H. Snyder presented the report of the committee on testing cereals, which noted the limited character of the literature relating to the testing of wheat and flour for industrial purposes, and discussed briefly some of the factors which have been shown to control flour yield and bread-making quality. Flour yields have been shown to be directly proportional to weight per bushel, but bread-making quality does not follow the same rule. Color and hardness are controlling factors in determining commercial value of wheat for milling purposes. There are many unsettled points in connection with the relation of the amount and character of the protein to bread-making quality. The committee proposes to take up first methods of preparing flour for test. The report was accepted and the committee continued.

The main general topic proposed for discussion by the section at the next convention was Animal Nutrition, but the opinion seemed to generally prevail that the officers of the section and the programme committee should be left free to change the topics if contingencies should arise which would make it desirable to do so.

RECENT WORK IN AGRICULTURAL SCIENCE.

AGRICULTURAL CHEMISTRY.

Methods of titration of phosphoric acid, O. J. HLAVNICKA (*Ztschr. Angew. Chem., 18 (1905), pp. 655, 656; abs. in Analyst, 30 (1905), No. 352, pp. 257, 258*).—The author describes what he considers to be a simple and practical modification of Hundeshagen's method. The phosphoric acid is precipitated as magnesium-ammonium phosphate by the citrate method, the precipitate collected on a hardened filter paper, washed first with 2½ per cent ammonia and then with alcohol until free from ammonia, the total volume of the washings not exceeding about 40 cc. "The precipitate is then washed off with cold water into a porcelain dish (total volume required about 200 cc.), and, after the addition of a few drops of methyl orange solution (strength, 0.1 per cent), decomposed with a slight excess of $\frac{3}{10}$-normal HCl, and the excess found by titration with $\frac{3}{10}$-normal NaOH (1 cc. $\frac{3}{10}$-normal acid=0.01065 gm. P_2O_5)."

A rapid volumetric method for the determination of phosphoric acid, W. B. HIRT and F. W. STEEL (*Proc. Soc. Chem. Indus. Victoria, 1905, Mar.-Apr.; Chem. News, 92 (1905), No. 2389, pp. 113, 114*).—A slight modification of Littmann's method (E. S. R., 10, p. 513) is described and recommended as preferable to Pemberton's method for commercial work.

Solubility of lime and magnesia in solutions of sodium chlorid with or without sodium hydroxid.—Application to the separation and estimation of the two substances, E. MAIGRET (*Bul. Soc. Chim. Paris, 3. ser., 33 (1905), No. 11, pp. 631-634, figs. 2; abs. in Jour. Chem. Soc. [London], 88 (1905), No. 513, II, p. 482*).—The author makes use of the fact that while lime is fairly soluble, magnesia is insoluble in solutions containing less than 160 gm. per liter of sodium chlorid in presence of 0.8 gm. per liter of sodium hydroxid in extending and making more accurate D'Anselme's method of estimating lime and magnesia.

The method proposed by the author is as follows: To 100 cc. of the solution in a 200 cc. flask add 20 cc. of a solution containing sodium carbonate, 100 gm., and sodium hydroxid, 20 gm., per liter, the equivalent of which in 2-normal hydrochloric acid is known. Heat the mixture to boiling, cool, and make up to 200 cc. with a solution of sodium chlorid, 160 gm. per liter. Shake the mixture, filter, and titrate 100 cc. of the filtrate with 2-normal hydrochloric acid, using tropeolin as indicator. The difference between twice the burette reading and the equivalent of the alkaline solution added gives the total magnesia and lime present in terms of 2-normal hydrochloric acid.

To determine magnesia alone add to 100 cc. of the solution 10 cc. of a solution of sodium hydroxid, 80 gm. per liter; dilute to 1 liter with a solution of sodium chlorid, 160 gm. per liter; shake, filter, and titrate 500 cc. of the filtrate with 2-normal hydrochloric acid, using phenolphthalein as indicator. The difference between the burette reading multiplied by 2 and the amount of sodium-hydroxid solution added gives the magnesia present. The difference between this and the first determination gives the lime present.

On the determination of nitrogen by the Kjeldahl method, S. P. L. SORENSEN, C. PEDERSEN, and A. C. ANDERSON (*Compt. Rend. Lab. Carlsberg, 6 (1905), No.*

3, pp. 126–136, 193–208; abs. in Analyst, 30 (1905), No. 354, pp. 314, 315).—The applicability of the Kjeldahl method to the determination of nitrogen in such compounds as creatin, creatinin, lysin, and uric acid is discussed and precautions to be observed to secure accuracy are explained.

A modification of the Kjeldahl method for the determination of total nitrogen in urine, A. BABES (*Bul. Pharm. et Chim. Roumanie, 1905, May–June; abs. in Ann. Chim. Analyt., 10 (1905), No. 9, p. 366*).—In the method proposed 2 to 5 cc. of urine is digested in a 100 cc. flask with 2 cc. of hydrogen peroxid, 0.1 to 0.15 gm. of sodium oxalate, and 1 to 1.5 cc. of concentrated sulphuric acid. The time of digestion never exceeds 1½ hours. Sodium hydroxid may be added and the nitrogen determined in the usual way, or it may be determined volumetrically by means of sodium hypobromite.

Volumetric determination of nitrous acid by means of ceric sulphate, G. BARBIERI (*Chem. Ztg., 29 (1905), pp. 668, 669; abs. in Analyst, 30 (1905), No. 354, p. 320*).—The nitrite is oxidized to nitrate by the addition of an excess of ceric sulphate, the excess of the latter being decomposed by the addition of potassium iodid and the liberated iodin titrated as usual.

On the determination of ammonia in water, CAVALIER and ARTUS (*Bul. Soc. Chim. Paris, 33 (1905), pp. 745–747; abs. in Analyst, 30 (1905), No. 354, p. 319*).—From the results of a series of experiments the authors conclude that the iodid method of Trillat and Turchet (E. S. R., 17, p. 112) is less sensitive than that of Nessler, no coloration being perceptible until the proportion of ammonia is as much as 3 mg. per liter. This necessitates, in case of water containing small amounts of ammonia, evaporation which is as tedious as the distillation in the Nessler process. It was also found that the black coloration of the iodid was very unstable and disappeared almost completely after 2 or 3 minutes.

Determination of the organic nitrogen in potable waters, J. C. BROWN (*Proc. Chem. Soc. London, 21 (1905), pp. 208, 209; abs. in Analyst, 30 (1905), No. 354, p. 316*).—"Details are given of a process for the determination of the whole of the organic nitrogen in water and sewage effluents. The process essentially consists in the distillation to dryness and subsequent ignition of a mixture of a portion, usually 200 cc., of the sample, without previous evaporation, with potassium hydroxid and potassium permanganate. The operation is carried out either in a Jena glass or in a copper retort, and the evolved ammonia is determined by Nessler's reagent as usual."

Report of committee on standard methods of water analysis to the laboratory section of the American Public Health Association (*Jour. Infect. Diseases, 1905, Sup. 1, May, pp. 1–141*).—This is the report made to the laboratory section at the Havana meeting of the American Public Health Association, January 9, 1905, outlining the progress in water analysis and describing the best current practice. The report is based on the results of 5 years' cooperative work on the part of several of the most active water analysts and bacteriologists of the country and covers in great detail the whole field of water analysis, physical, chemical, microscopical, and bacteriological, including under the latter a revision of the report of the bacteriological committee of the American Public Health Association published in 1897.

"The methods of analysis presented in this report as 'standard methods' are believed to represent the best current practice of American water analysts, and to be generally applicable in connection with the ordinary problems of water purification, sewage disposal, and sanitary investigations. . . . Detailed descriptions of the various methods recommended are given in concise form, covering the essential features of each determination. It is assumed that those using these directions are thoroughly grounded in the fundamental principles of chemistry and biology, and that they are also familiar with the leading literature upon the subject."

The report brings out quite sharply the limitations which have been placed on purely chemical determinations such as "free ammonia" and "albuminoid ammo-

nia" by recent investigations and the greatly increased importance of biological and physical examination, the last rendered necessary by recent progress in methods of precipitation, sedimentation, and water softening.

A bibliography is given containing "a list of references to the works most consulted in America, arranged for the purpose of assisting the reader in getting in touch with the general aspects of a method, including its history and application, together with full technical details of the procedure as now practiced.

"No attempt is made to report upon the interpretation of the results of water analyses or upon the classification of bacteria, as these subjects are receiving the attention of other committees of the association."

Progress in the chemistry of waters, including natural and artificial mineral waters, A. GOLDBERG (*Chem. Ztg.*, *29* (*1905*), *No. 70*, *pp. 915–921*).—A brief review of investigations relating to this subject, with numerous references to literature.

The volumetric determination of reducing sugars, A. R. LING and T. RENDLE (*Analyst*, *30* (*1905*), *No. 351*, *pp. 182–190*).—Ferrous thiocyanate has been found by the authors the most satisfactory indicator for titrating sugars with Fehling's solution.

The indicator is prepared by dissolving 1 gm. of ferrous ammonium sulphate and 1 gm. of ammonium thiocyanate in 10 cc. of water at a temperature of about 45 to 50° C., cooling the solution, and adding 50 cc. of concentrated hydrochloric acid. The solution is decolorized by the addition of a little zinc dust. The Fehling's solution is not diluted. The sugar solution should be of such a strength that 20 to 30 cc. will reduce 10 cc. of Fehling's solution.

A study of the hydrogen peroxid method of determining formaldehyde, J. K. HAYWOOD and B. H. SMITH (*Jour. Amer. Chem. Soc.*, *27* (*1905*), *No. 9*, *pp. 1183–1188*).—The methods of Blank and Finkenbeiner and of Fresenius and Grünhut served as a basis for the tests reported. A modified procedure for carrying out the former method is suggested.

A new method for the detection of formalin in milk, UTZ (*Chem. Ztg.*, *29* (*1905*), *No. 49*, *p. 669*).—Unless added to milk in larger quantities than are necessary for the purposes of preservation, formaldehyde was not found to interfere with the tests used to distinguish boiled from raw milk.

Winckel's test for enzyms was found very delicate for detecting formaldehyde in milk. Equal parts of milk and hydrochloric acid, sp. gr. 1.19, are heated with a crystal of vanillin, when a violet or raspberry color shows the presence of formaldehyde, a faint trace, however, being indicated by a yellow color. The author found that piperonal or p-oxybenzaldehyde could be substituted for the vanillin, though not with quite so satisfactory results. This method of detecting formaldehyde was not found applicable to other food products than milk.

New method of rapid milk analysis, F. BORDAS and TOUPLAIN (*Ann. Chim. Analyt.*, *10* (*1905*), *No. 7*, *pp. 267*, *268*; *Rev. Soc. Sci. Hyg. Aliment.*, *2* (*1905*), *No. 2*, *pp. 163–168*).—Ten cc. of milk is added drop by drop to 25 cc. of 65 per cent alcohol acidified by acetic acid in a weighed sedimentation tube. After standing for a few moments this is centrifuged, the supernatant liquid decanted, and the precipitate washed twice in 50 per cent alcohol, using 30 cc. for this purpose.

Lactose is determined in the liquid obtained by means of Fehling's solution. Fat is determined by extracting the precipitate with alcohol and ether, centrifuging, and again extracting with ether, the decanted liquids being collected in a tared dish, evaporated, and the fat weighed. The casein remaining in a fine powder in the original sedimentation tube is then dried and weighed, after which it is incinerated and the ash determined.

New method of milk analysis, J. BELLIER (*Ann. Chim. Analyt.*, *10* (*1905*), *No. 7*, *pp. 268–276*).—In the gravimetric method described the absorbent material used is a medium fine sponge previously cut into small pieces and prepared by treating suc-

cessively with dilute hydrochloric acid, alcohol, ether, and water, and drying. The weight of the sponge then remains practically constant, the maximum loss in the subsequent operations being placed at 1 mg. The piece of sponge is weighed, moistened with distilled water, and made to absorb 5 cc. of milk. It is then dried at 80° C. to a constant weight, 3 hours being generally sufficient.

The total solids are then ascertained by loss in weight. The fat is then extracted in a Soxhlet apparatus and also determined by the loss in weight. The sponge containing the solids-not-fat is then subjected to fumigation with formaldehyde gas to render the proteids insoluble, and is then thoroughly washed with 50 per cent alcohol containing 5 per cent acetic acid and with distilled water to remove the milk sugar and mineral matter. The sponge is then dried and weighed, the loss in weight representing the proteids and also about 2 mg. of ash for an original sample of 5 cc. of milk. Ash is determined on a separate sample and milk sugar calculated by difference.

Analyses by the method described are given of 7 samples of cow's milk and a number of samples of human milk from normal and diseased subjects.

Chemical analysis and cryoscopy of milk, H. LAJOUX (*Ann. Chim. Analyt.*, *10* (*1905*), *No. 6*, *pp. 219–231*).—Cryoscopic determinations were made on 24 samples in the municipal laboratory at Reims.

The freezing point averaged about −0.55° C. and was apparently not influenced by the kind of food, the breed of cows, nor the density and fat content of the milk. The freezing point is, however, affected by the addition of water, and it is for the detection of this that the method is considered a valuable supplement to chemical analysis. For market milk a legal standard of 0.55 to 0.57° is suggested. For individual cows the freezing point may exceptionally be 0.54°. A freezing point between − 0.55 and 0° would, therefore, serve to indicate approximately the proportion of water added, bearing in mind, however, that pathological conditions of the milk or the addition of soda or other substances may affect the reading.

The Sichler "sin-acid" butyrometry, W. SCHNEIDER (*Chem. Ztg.*, *29* (*1905*), *No. 51*, *p. 690*).—Comparative tests of the Gerber and Sichler methods were made on goat's milk and cow's milk during a period of 6 months. In its present form the Sichler method is not considered equal to the Gerber method.

Sulphuric acid for the determination of milk fat by the Gerber method, M. SIEGFELD (*Molk. Ztg.*, *19* (*1905*), *No. 29*, *p. 758*).—While pure acid is not necessary for this purpose, badly contaminated acid was found to be very unsatisfactory.

The estimation of fat, L. LIEBERMANN (*Arch. Physiol.* [*Pflüger*], *108* (*1905*), *No. 10–12*, *pp. 481–488*).—According to the author, simple extraction with alcohol and ether does not give results which are comparable with the saponification method, unless the alcohol extraction is continued for days. Indeed, a complete extraction of the fat is hardly possible.

The estimation of fat in infant and invalid foods, C. B. COCHRAN (*Jour. Amer. Chem. Soc.*, *27* (*1905*), *No. 7*, *pp. 906–909*).—The method proposed consists in treating the sample of milk or milk products under suitable conditions with equal volumes of 80 per cent acetic acid and concentrated sulphuric acid, warming until the substance turns a coffee color, cooling, mixing with a small amount of ether, and heating with hot water until the ether vapor is removed. The layer of supernatant fat can then be measured and the proportion of fat calculated from the amount of material used.

The use of the centrifuge in the analysis of cocoa and chocolate, F. BORDAS and TOUPLAIN (*Rev. Soc. Sci. Hyg. Aliment.*, *2* (*1905*), *No. 1*, *pp. 92–110*).—Methods of analyzing cocoa and chocolate are described and analyses reported. The use of a centrifugal machine for determining fat and materials insoluble in water and insoluble in a mixture of water, alcohol, and ether is recommended. According to parallel determinations, the centrifugal method for determining fat (ether, carbon disulphid,

and gasoline being used as solvents), gives as satisfactory results as the Soxhlet extraction method.

The influence of atmospheric oxidation upon the analytical constants of fatty oils, H. C. SHERMAN and M. J. FALK (*Jour. Amer. Chem. Soc., 27 (1905), No. 5, pp. 605–608*).—Data are given for correcting the iodin number of oxidized fatty oils on the basis of the original specific gravity, or if this is not known on the average specific gravity of the oil under consideration.

Analysis of the Mexican plant Tecoma mollis, L. F. KEBLER and A. SEIDELL (*U. S. Dept. Agr., Bur. Chem. Circ. 24, pp. 6*).—Analyses by the methods of Dragendorff and Parsons were made of this plant, which is reported as extensively used in certain parts of Mexico in the treatment of disease.

The examination failed to reveal the presence of any alkaloid or other well-characterized constituent of medicinal importance. The virtues attributed to this plant are believed to be associated in some way with bitter ingredients which it contains. As applied to this material the Dragendorff method of analysis was considered preferable to the Parsons method.

Agricultural chemistry in the year 1904, W. ZIELSTORFF (*Chem. Ztschr., 4 (1905), Nos. 8, pp. 178–182; 9, pp. 198–202; 10, pp. 219–222; abs. in Chem. Centbl., 1905, I, No. 26, p. 1729*).—A review of the literature of investigations (mainly European) during the year relating to the nutrition of plants and animals.

METEOROLOGY—WATER.

Summary of weather data, 1894–1904, G. A. CROSTHWAIT (*Idaho Sta. Bul. 49, pp. 7, 8*).—Monthly and annual summaries of observations during 11 years, 1894–1904, on temperature and precipitation at Moscow, Idaho. The mean temperature for that period was 46.6°, the annual precipitation 22.11 in. The mean temperature of 1904 was 48.6°, the precipitation 15.39 in.

Weather data, 1903–4; summary for eleven years, 1894–1904, G. A. CROSTHWAIT (*Idaho Sta. Circ. 1, pp. 28, map 1*).—This bulletin is a collection of tables giving daily and monthly summaries of observations at Moscow during 1903 and 1904 on temperature, atmospheric pressure, precipitation, cloudiness, and wind movement. Summaries of observations on temperature and precipitation during 11 years at the same place are also given, as noted above.

Meteorological observations, J. E. OSTRANDER and C. H. CHADWICK (*Massachusetts Sta. Met. Buls. 199, 200, pp. 4 each*).—Summaries of observations on pressure, temperature, humidity, precipitation, wind, sunshine, cloudiness, and casual phenomena during July and August, 1905. The data are briefly discussed in general notes on the weather of each month.

Meteorological observations, G. GINESTOUS (*Bul. Dir. Agr. et Com. [Tunis], 9 (1905), No. 36, pp. 452–463*).—Tabular summaries are given of observations during March, April, and May, 1905, at a number of places in different parts of Tunis on precipitation, temperature, atmospheric pressure, humidity, evaporation, cloudiness, direction of the wind, and casual phenomena.

Meteorological and magnetic observations at the observatory of the College of Belen of the Society of Jesus, Havana, during the year 1904, L. GANGOITI (*Observaciones meteorologicas y magneticas hechas en el observatorio del Colegio de Belen de la Compañía de Jesus en la Habana, año de 1904. Havana: Avisador Comercial, 1905, pp. 74*).—A detailed report largely tabular and diagrammatic of the usual meteorological observations.

Meteorology of New Zealand: On the routes of high and low pressures, and the changes of pressure and wind movement resulting from them, R. A. EDWIN (*Trans. and Proc. New Zeal. Inst., 37 (1904), pp. 555–567, figs. 7*).—This arti-

cle gives a general discussion of the principles upon which atmospheric movements depend, especially the theory of the mechanical principle of atmospheric circulation, and defines "certain systems of pressure, their wind movements and routes."

Barometer and weather, van Bebber (*Arch. Deut. Seewarte, 27 (1904), No. 2, pp. 1-15; abs. in Science, n. ser., 22 (1905), No. 550, p. 54*).—The author discusses the use of the barometer in weather forecastings, refers to studies along this line, and traces the relation between barometer readings at Hamburg and the rainfall, temperature, and cloudiness for the year, for different seasons, and for individual months during the period 1876-1900.

A close relation between rainfall and falling barometer is shown. The average yearly temperature departures were negative at the higher pressures and positive at the lower. At low pressures the departures are positive in winter and negative in summer. In general the author concludes that a reasonably accurate judgment of existing and coming weather can be based on barometer readings, especially when the location of cyclonic and anticyclonic centers are shown.

An experience of 25 years leads the author to the conclusion "that no reorganization of weather-service work would be of any value if the present forecasts for a single day following are adhered to. These forecasts have not satisfied the agricultural interests, and will not satisfy them in the future. Nor will the forecasts be satisfactory unless the general public understands better than at present the basis on which weather predictions rest."

Investigation of the upper atmosphere by means of kites in cooperation with a committee of the Royal Meteorological Society, W. N. Shaw et al. (*Rpt. Brit. Assoc. Adv. Sci., 1904, pp. 17-20*).—This is a report of progress in a continuation of the investigations of this committee which have been previously noted (E. S. R., 15, p. 125). The observations here outlined were made in the summer of 1903, their object being "to ascertain if the behavior of the kites could be improved by alteration of shape, size, etc., more particularly with regard to uniformity of pull and stability in winds of varying force."

The general movements of the atmosphere in winter, P. Garrigou-Lagrange (*Compt. Rend. Acad. Sci. [Paris], 141 (1905), No. 4, pp. 283-285*).—The author briefly describes the results of an attempt to trace the general atmospheric movement of the entire northern hemisphere, especially during the winter of 1882-83, by superposition of daily barometric charts.

The use of cannons and bombs as a means of protection against hail, H. Dufour (*Chron. Agr. Vaud, 18 (1905), No. 14, pp. 330-334*).—The results obtained in the use of this method during 1902, 1903, and 1904 are briefly reviewed, the general conclusion being reached by the author that while results are not decisive they furnish some encouragement for the continuance of the practice.

It is pointed out, however, that, apparently, viticulturists have more confidence in the method than scientists, but that meteorologists are at variance in their opinions on the subject, one class denying absolutely the efficiency of the process, another holding that the results claimed are not explicable in the present state of science, and therefore require a long series of observations before final judgment can be rendered.

The water supply: Bacteriological examination of water from ponds, tanks, and cisterns, L. L. Lewis et al. (*Oklahoma Sta. Bul. 66, pp. 26, figs. 4*).—This bulletin reports work which was undertaken in order to obtain data showing the relative number of bacteria in water from ponds, tanks, and cisterns under conditions similar to those existing when the water is in use, special attention being given to the variations in the bacterial content of two small ponds such as are commonly used in Oklahoma as a source of water supply for farm animals.

The results of the bacteriological examinations show that the water from the ponds contained as a rule less bacteria than that of the tanks filled with pond water or from wells. The pond receiving drainage from the barn lots, and to which the cattle had

free access, showed a higher bacterial content than that which was fenced and received drainage from pasture land. The number of bacteria in the pond water was high after heavy rains and rapidly fell with clear weather. "Two conditions contribute to this purifying process in ponds, sunshine and sedimentation, the latter having a much greater influence in purifying the water than the former." As a result of such purification in the pond, which was fenced so that the water was not disturbed by stock, the actual number of bacteria present in the surface water was less than in some of the wells examined. The number of bacteria in the tanks was much higher than in the water of the wells from which they were filled, showing "that any water, however pure, when pumped from a well will soon show a large number of bacteria when sampled from a tank, on account of the trash, dirt, etc., that will accumulate in the tank, as well as from the saliva of animals drinking the water."

Attention is called to the danger of the spread of intestinal parasites through the agency of pond water. "If any of the stock are infested with worms the water from pastures collected into ponds soon becomes contaminated with the eggs and larvæ, and in this way are transferred to the alimentary canal of other animals, where they develop."

The methods of bacteriological examination used, of building ponds and cisterns, and of protecting them from contamination are described.

Miscellaneous water analyses, A. G. FORD (*Oklahoma Sta. Bul. 67, pp. 18*).—The results of partial analyses of 126 samples of water made at the station during the past 5 years are reported and discussed. Of these, 95 samples were from wells, 13 from springs, 5 from rivers or creeks, 2 from cisterns, and 11 miscellaneous. The methods used in analysis and in the interpretation of results are briefly explained, and methods of protecting water from different sources from contamination are described.

Filtration and sterilization of water, H. PILLAUD (*Jour. Agr. Prat., n. ser., 10 (1905), Nos. 30, pp. 109–111; 38, pp. 373–375, fig. 1*).—Apparatus and systems (thermal, chemical, and physical) for this purpose suitable for use on farms are described and tests of the efficiency of some of them are briefly reported.

The action of cupric sulphate upon the bacterial life contained in water, H. WATKINS-PITCHFORD (*Natal Agr. Jour. and Min. Rec., 8 (1905), No. 8, pp. 775–782*).—A series of tests of Moore's method (E. S. R., 16, p. 238) is reported, which leads to the conclusion that "in the sulphate of copper, used in proportions of 1 part of the salt to 75,000 parts of water, we possess an agent which promises to be both valuable and safe." Practical trials of the method on a large scale in purification of South African water supplies are advised.

Use of barium carbonate for the purification of water, E. E. BASCH (*Chem. Ztg., 29 (1905), No. 53, pp. 721, 722; abs. in Jour. Chem. Soc. [London], 88 (1905), No. 514, II, p. 515*).—Experiments on a small scale are reported, in which barium carbonate used in excess and thoroughly mixed with the water was found to be an effective means of reducing hardness.

The barium carbonate precipitates lime as carbonate and sulphuric acid as sulphate. It thus has a decided advantage over the ordinary method of using caustic lime to remove temporary hardness due to bicarbonates of lime and magnesia, and sodium carbonate to remove permanent hardness due to sulphates of these bases, since in this process sodium sulphate is formed which remains in solution with sodium chlorid and is objectionable for a number of reasons. The barium carbonate, however, acts slowly on account of its low solubility in water. For this reason apparatus has been devised which keeps the carbonate stirred up in the water and thus hastens its action.

Thirty kg. of barium carbonate to 10,000 liters of water daily, with the addition of 15 kg. every 14 days, is considered a sufficient amount for the treatment of ordinary waters. The precipitated slime may be partly removed from time to time, but it is

considered best to allow it to accumulate in considerable quantity since precipitation is more complete in its presence.

Purification and sterilization of drinking water by means of calcium peroxid, L. Freyssinge and R. Roche (*Rev. Internat. Falsif., 18 (1905), pp. 49–51; abs. in Jour. Chem. Soc. [London], 88 (1905), No. 514, II, p. 515*).—It is stated that water can be completely sterilized by adding 0.4 gm. of calcium peroxid per liter. The action is not instantaneous, but in most cases takes about 2 hours.

The process is hastened (requiring about 15 to 20 minutes) by the addition of a small amount of sodium hydrogen carbonate which rapidly decomposes the peroxid. The hydrogen peroxid as well as the precipitate of calcium carbonate formed by the decomposition of the calcium peroxid may be removed by filtering through manganese dioxid. The hardness of the water is generally reduced by this treatment.

SOILS—FERTILIZERS.

Studies on the properties of an unproductive soil, B. E. Livingston, J. C. Britton, and F. R. Reid (*U. S. Dept. Agr., Bur. Soils Bul. 28, pp. 39*).—The soil used in these experiments is described as "a brownish-yellow coarse sandy loam, 3 ft. or more in depth, resting upon material similar to the Susquehanna clay. Samples taken at intervals from the surface downward show a gradually increasing proportion of silt and clay."

The mechanical analysis shows that "the soil is rather peculiar in that it possesses relatively large amounts of coarse and of fine material, but only small quantities of medium-sized particles." Chemical analysis (by digestion in hydrochloric acid, sp. gr. 1.115) showed potash 0.135, lime 0.145, and phosphoric acid 0.11 per cent. The water extract of the soil contained calcium 11.7 parts per million of air-dry soil, potassium 22.7 parts, phosphate (PO_4) 7.6 parts, and nitrate (NO_3) 5.5 parts. The soil contained 3 per cent of organic matter and 0.1 per cent of nitrogen. Native and cultivated plants growing on the soil exhibited peculiar structures similar to those observed in case of a soil subject to drought.

A series of experiments was made with this soil in small wire baskets described in previous publications of the Bureau (E. S. R., 17, p. 227). In these experiments the influence of the water supply and of different manurial substances was studied. The results show that wheat seedlings were much stunted even when the water content was kept at the optimum (14–17 per cent) throughout the period of growth, indicating that the unproductive character of the soil is not due to lack of water.

It was shown that the soil was "improved to a great extent by the addition of fermented stable manure, green manure (consisting of the stems and leaves of cowpeas), sumac and oak leaves, tannic acid, pyrogallol, calcium carbonate, and ferric hydrate. . . . With the exception of nitrate of soda, ordinary fertilizers have no beneficial effect. When wheat seedlings are grown in aqueous extracts of this soil they make the same kind of growth as in the soil itself. The stunting power of the extract can be corrected by the addition of extract of stable manure, pyrogallol, calcium carbonate, ferric hydrate, and carbon black."

The authors conclude that these facts show that the soil "contains a water-soluble nonvolatile substance or substances, probably organic in their nature, which are toxic to wheat plants, causing a stunting of their growth. The toxicity of the soil is corrected by the use of stable manure, green manure, leaves of sumac, oak, etc., tannic acid, pyrogallol, calcium carbonate, ferric hydrate, and carbon black."

A method for the mechanical analysis of soils, T. Crook (*Econ. Proc. Roy. Dublin Soc., 1 (1904), No. 5, XIII, pp. 267–280, figs. 2*).—In the method here proposed the separations are performed by means of a modification of the Schöne apparatus, the essential features of which are (1) a constant-level water reservoir which can be adjusted to any desired height; (2) an elutriator which differs from the Schöne apparatus in being conical both above and below the cylindrical portion;

and (3) an outlet which can be fitted with delivery tubes of any desired diameter. The methods of standardizing this apparatus are described, as well as the different steps in a mechanical analysis.

The author emphasizes the importance of taking account of coarser constituents of the soil in order that the mechanical analysis may serve as a guide to the structure and physical properties of a soil as it exists in nature. With this object in view he begins with a few kilograms of soil from a typical position and picks out all stones larger than 5 cm. in diameter. One kg. of the soil from which these larger stones have been removed is passed through a sieve with meshes 1 cm. in diameter. The stones collected on the sieve are washed, dried at about 90°, and weighed. Five hundred gm. of the material passing this sieve is put through a sieve with circular holes 1 mm. in diameter. The material remaining on the sieve is washed, dried, and weighed. Twenty gm. of the material passing the sieve, dried at 90° C., is boiled in a porcelain dish for 1 hour with constant stirring and gentle pestling with a rubber-tipped class rod, and is used for elutriation in the apparatus described.

Mechanical analyses of soils and subsoils by centrifugal action; with notes on treatment of samples, J. R. KILROE (*Econ. Proc. Roy. Dublin Soc., 1 (1904), No. 5, X, pp. 223–230, figs. 2*).—The method proposed is a combination of those of Whitney and Bennigsen, and is thus described:

"Adopting the idea of an inverted flask, attach a tube firmly to it, so as to make this serve as a prolongation of the neck. Into the flask thus fitted, earth is introduced, and distilled water poured in, so as almost entirely to fill the neck with clear liquid. The tube is then corked (with india-rubber stopper), a sheath of tin is slipped down over the neck and secured by pliable copper wires to a leather base or cradle, which fits closely to the bottom of the bulb, and bears the extreme statical pressure resulting from the rotary motion. The flasks are then fixed securely on the centrifugal table . . . . with the bulbs inward and the tubes outward, the extremities being about 15 in. from the axis of rotation.

"When the table is revolved for a short time, at 900 revolutions per minute, the coarser particles become precipitated, and so consolidated that, at the close of the operation, when the flask is removed from the table and held with the bulbs downward, the sand and coarse silt remain in the tube, and the clay and fine silt, forming the fluid mixture, are found in the flask. The chief advantage of the apparatus is that the detachable tube admits of the easy removal of the sand and silt. . . .

"The detailed procedure, as practiced in the examination of soils and subsoils at the Geological Survey office, is as follows: In the case of fine homogeneous earths, a quantity of soil or subsoil, dried and averaged, is taken, and passed through a 2 mm. sieve; of this 20 gm., if a sandy soil, 25 if a loam, and 30 if a clay, are taken for treatment. It is boiled with distilled water for some hours, to loosen the clay from the sands and silts.

"The mixture is then thoroughly shaken to break up the compound particles and detach the clay from the sand particles. It is then transferred to the flask, and the latter nearly filled with distilled water to within an inch of the outer end of the connected tube. If this be carefully done, the neck is filled with clear water. The sheath is run down over the tube and neck of the flask, and fastened to the base of the flask. The bulb is then shaken to detach all particles from the bottom, and the whole inverted. The coarser sand and silt fall down through the clear liquid in the tube, and are thus free from clay particles."

Soil moisture investigations for the season of 1904, J. D. TINSLEY and J. J. VERNON (*New Mexico Sta. Bul. 54, pp. 27, figs. 4*).—This is a continuation of experiments of previous years (E. S. R., 15, p. 1060). As in the previous year the crop grown was wheat.

The results in 1903 having indicated that the application of water while wheat was heading and filling was more beneficial than its application before this time, the

experiments in 1904 were designed especially to further investigate this point. Different series of plats were irrigated after the wheat began to head, once a week, once in 2 weeks, and once in 3 weeks. A record of the amounts of water applied; meteorological conditions of the season; the relations between the amount of water applied, soil moisture, and yield; and the movement of the water in the soil is given. Owing to unfavorable meteorological conditions the yield of wheat was only about one-third of that of the previous season.

It was found that irrigating oftener than once in 3 weeks after the wheat began to head increased the yield, but scarcely enough to pay for the additional irrigations. "Twenty-four in. of water gave the greatest yield per inch of water applied, and while 35 and 29 in. of water gave greater yields than did 24 in., the increase per inch of water is very small. Twenty-four in. was the most economical amount." The conclusion is reached that 25 per cent is the optimum amount of water in this soil for the production of wheat and beyond this the wheat is very sensitive to an increase in the moisture content of the soil.

While variations in texture and the irregular distribution of the water through the soil made it difficult to obtain results accurately expressing the true moisture conditions of the soil, the indications are that "the plats as a rule did not gain materially in moisture below the second foot during the season and there were indications of a general loss in total moisture toward the end of the season. There was no indication of an appreciable loss of moisture from the percolation into the soil below the limits of the roots of the wheat."

Soil temperatures 1903–4, G. A. CROSTHWAIT (*Idaho Sta. Bul. 49, pp. 3–6*).—Tabular summaries of weekly observations at Moscow on soil temperatures during 2 years at 10 different depths varying from 1 in. to 6 ft.

Diffusion in acid and neutral media, particularly in humus soils, H. MINSSEN (*Landw. Vers. Stat., 62 (1905), No. 6, pp. 445–476*).—The literature of the subject is reviewed, especially the investigations of Blanck (E. S. R., 14, p. 848), and investigations by the author on diffusion are reported.

The results lead to the conclusion that Blanck's method is so defective and his results so unreliable that his conclusion that diffusion of water in acid soils is hindered by the presence of humus acids is not warranted. The author concludes that neither humus acids nor any other organic or mineral acids in dilute solutions interfere with the diffusion of water or salt solutions. The "physiological dryness" of moor soils can not, therefore, be ascribed to humus acids.

Experiments in fertilizing chernozem, V. V. WIENER (*Khozyain, 1904, Feb., Sup.; abs. in Zhur. Opuitn. Agron. (Russ. Jour. Expt. Landw.), 6 (1905), No. 1, pp. 48–50*).—The article contains the main results of 5 years' work at the Shatilov Experiment Station (Government of Tula) on the question of fertilizing chernozem.

The results are in the main of local and limited interest. A close direct connection was observed between the action of the fertilizers and the meteorological conditions in the sense that higher effects of the mineral fertilizers were observed in years of abundant yields with favorable meteorological conditions, when, according to a generally accepted opinion, chernozem has no need of fertilizers for the production of large crops. Deep and shallow plowing were equally favorable. The author concludes that the reputation of chernozem for great fertility is unmerited and that the use of fertilizers, especially phosphates, is very profitable.—P. FIREMAN.

Soil bacteriological studies, J. G. LIPMAN (*New Jersey Stas. Rpt. 1904, pp. 237–289, pls. 6*).—The importance of the biological processes in the soil is discussed, and studies of the physiology and morphology of members of the Azotobacter group, including three members—*Azotobacter vinelandii*, *A. beyerincki*, and *A. woodstownii*—discovered by the author, are reported.

The relative nitrogen-fixing power of these organisms, as well as of *A. chroococcum* and several smaller bacilli, designated *Bacillus 30a*, *B. 33*, *B. 34*, and *B. 35*, which

accompanied Azotobacter in crude mannite cultures, was studied alone and in association with one another or other organisms, in nutrient media of different kinds (mannite and sodium malate solutions) and in soils.

The analytical results in case of pure cultures show that in the case of *A. vinelandii* the fixation of nitrogen was at the rate of 4 to 5 mg. of nitrogen for every gram of mannite consumed, while in the *A. beyerincki* and *A. chroococcum* cultures the rate of fixation was less than 1 mg. of nitrogen per gram of mannite consumed.

"In the combinations, it appears that *Proteus vulgaris* did not appreciably affect the fixation by *A. vinelandii*, but that *B. new jersey* and *B. pyocyaneus*, both denitrifying bacteria, depressed it considerably, particularly in the case of the former. Of the accompanying small bacilli, *B. 30a* increased the fixation somewhat, *B. 33* depressed it, *B. 34* did not affect it, and *B. 35*, or *B. 35* and *B. 30a* together, increased it. On the other hand, where *B. 30a*, *B. 33*, *B. 34*, and *B. 35* were all inoculated together with *A. vinelandii*, there was no fixation at all by the latter."

A. beyerincki showed uniformly a slighter nitrogen-fixing power than *A. vinelandii*. The decay bacteria depressed the fixation of nitrogen. The decrease was least in the case of *Proteus vulgaris*. Where *B. 30a* was inoculated together with *A. beyerincki*, the fixation was greatly enhanced, the yield being 9.5 mg. as compared with the higher yield of the two inoculations with *A. beyerincki* alone. Where *A. beyerincki* was inoculated together with *B. 33*, the depression was greater than in any other combination.

"The nitrogen-fixing power of *A. chroococcum* in pure culture was practically the same as that of *A. beyerincki*. In the presence of other organisms, however, the former showed somewhat different relations. There was an increased fixation here in the presence of decay bacteria, as well as in the presence of *B. 30a*, *B. 33*, *B. 34*, and *B. 35*. In the presence of *Proteus vulgaris*, the yield of nitrogen was raised from 7.17 mg. to 8.55 mg.; in the presence of *B. new jersey* it was raised to 10.23 mg.; in the presence of *B. 30a*, to 9.16 mg.; in the presence of *B. 33*, to 8.55 mg.; in the presence of *B. 34*, to 9.31 mg.; and in the presence of *B. 35*, to 10.38 mg., the highest yield in the series. . . . There was practically no fixation of nitrogen by *A. woodstownii*, either when growing alone or together with the smaller bacilli. . . .

"The small bacilli did not increase the nitrogen content of the mannite solution to any appreciable extent. When, however, they were inoculated together with *A. vinelandii* they seemingly augmented the nitrogen-fixing power of the latter. . . . The evidence, both microscopical and macroscopical, pointed to the fact that the small bacilli can make more growth in malate solutions than in mannite solutions. The analytical data confirm this evidence."

In view of the results obtained "it is deemed justifiable to state that members of the Azotobacter group are capable of fixing atmospheric nitrogen when growing in pure culture, and that they are affected unfavorably by acid culture media until their growth is entirely stopped, when the acidity reaches a certain limit. Beyerinck's theory, therefore, that the fixation of Azotobacter is symbiotic is proved untenable, and the fact that the development of *A. chroococcum* in nitrogen-poor solutions was made possible by other bacteria indicates, probably, that the latter produced an alkali and decreased the acidity of the culture solution, thus enabling the Azotobacter to develop normally."

Chemical studies of mannite media in which *A. vinelandii* had been grown showed the presence of a small but appreciable amount of nitrogen, in both young and old cultures, not precipitated by lead acetate and a large proportion not precipitated by phosphotungstic acid or tannic acid. Similar studies of Witte's peptone show "that a large proportion of the peptone nitrogen is precipitated neither by the sulphates of the heavy metals nor by tannic acid. The nitrogen carried into the filtrate consists in part of amido-acids, or amido-acid derivatives."

Inoculation experiments are reported which included "one series of investigations on small quantities of soil inoculated with *A. vinelandii*, and kept in the incubator at a uniform temperature; and one series of investigations on cylinder soils inoculated partly with *A. vinelandii* and partly with *A. beyerincki*, and kept under field conditions."

In case of the pot soils there was less loss of nitrogen from the inoculated soils than from the uninoculated. In case of the cylinder soils "there was no decisive gain in the inoculated soils over the uninoculated. There was in all cases a loss of nitrogen during the summer that the soils had been kept bare, and the losses were greatest where manure had been used."

The formation of nitrates in the soil, W. A. WITHERS (*North Carolina Sta. Bul. 190, pp. 8*).—The sources of nitrogen and the conditions favoring nitrification are discussed and laboratory experiments to determine the rate of nitrification of sulphate of ammonia, dried blood, dried fish, tankage, bone, cotton-seed meal, and barnyard manure in different kinds of soils are reported. (See also E. S. R., 16, p. 737.)

"In some soils fish gave the most nitrates at the end of the experiment, in others sulphate of ammonia gave most, in others cotton-seed meal, and in others dried blood. Bone was nitrified least rapidly of the substances used. In some cases, where stable manure was applied in excessive quantities, there was a reduction rather than a gain in the quantity of nitrates, but in other experiments, where the amount was but a little larger than that applied in ordinary farm practice, the formation of nitrates proceeded well and there was no loss by reduction. . . . In some soils very small quantities of nitrates were formed from any of the materials, and in other soils large quantities of nitrates were formed from any of the materials, but each soil showed some material best adapted to it so far as the formation of nitrates was concerned. Some soils used by us nitrified ten times as well as others."

Investigations relative to the use of nitrogenous materials, E. B. VOORHEES (*New Jersey Stas. Rpt. 1904, pp. 191–233, fig. 1*).—This is a report of progress during 1903 in a series of experiments on this subject which has been carried on by the station for a number of years (E. S. R., 16, p. 453).

"The method of treatment has been outlined in previous reports. It includes the study of the availability of nitrogen in various nitrogenous materials, and affords a means for determining their relative value from the economic standpoint. It thus enables the farmer to decide for himself what forms of nitrogen are most desirable under given conditions. The study has also been continued of the composition of cow manure and of the changes in its composition due to leaching. The collection, treatment, and analysis of the manure samples were carried out as heretofore."

The crop grown in 1903 was corn (field and sweet) and marks the beginning of a new rotation.

The relative availability of the nitrogenous materials experimented with in 1903 was as follows:

Relative availability of the nitrogen in different nitrogenous materials.

	Field corn.	Sweet corn.
Sodium nitrate	110.0	100.0
Ammonium sulphate	99.8	83.9
Dried blood	59.2	89.3
Solid manure, fresh	25.7	63.0
Solid manure, leached	39.2	46.5
Solid and liquid manure, fresh	59.2	58.3
Solid and liquid manure, leached	43.2	48.5

Brief accounts of experiments with asparagus and in improving light lands on farms in the State are appended.

On the decomposition of lime nitrogen, F. Löhnis (*Centbl. Bakt.* [*etc.*], *2. Abt.*, *14* (*1905*), *Nos. 3–4*, *pp. 87–101; 12–13*, *pp. 389–400; abs. in Chem. Centbl.*, *1905*, *I*, *No. 26*, *pp. 1731*, *1732*).—A study of the action of bacteria in decomposing calcium cyanamid is reported which showed that in a medium of grape sugar inoculated with soil bacteria the nitrogen of the cyanamid was transformed to ammonia by bacterial action in the same manner as that of urea but at a slower rate.

A number of the organisms active in this transformation were isolated and studied, including *Bacterium putidum*, *Bacillus mycoides*, *Bacterium vulgare* var. *zopfii*, *B. lipsiense* n. sp., *B. kirchneri* n. sp., *Bacillus megatherium*, *Bacterium fluorescens*, *Bacillus subtilis*, *Bacillus ellenbachensis*, and *Bacillus vulgare*. The most active of these were *Bacterium kirchneri*, *B. lipsiense*, *B. vulgare* var. *zopfii*, and *Bacillus megatherium*. Of these only *B. kirchneri* has the power of producing ammonia from urea. Studies of the behavior of these organisms under varying conditions of aeration, temperature, and concentration of nutritive media are also reported.

It was observed among other things that the organisms which were comparatively active in decomposing the lime nitrogen set free only small amounts of ammonia from peptone and that aeration had no essential effect on their activity.

Urobacillus leubei and *Planosarcina pasteuri* also liberated ammonia from calcium cyanamid, but *Urobacillus pasteuri* had little effect.

Utilization of peat in the manufacture of ammonium sulphate, A. Doudlet (*Ann. Gembloux*, *15* (*1905*), *No. 8*, *pp. 437–440*).—This article refers to the various methods which have been proposed for the manufacture of ammonium sulphate, and describes and recommends that of Woltereck, which consists of treating the partially dried peat with a current of hot air and steam, maintaining the temperature at 450° C., the treatment resulting in the formation of ammonia, acetic acid, etc. The adaptability of the process to countries like Belgium, where the supply of peat is abundant, is pointed out.

On the loss of substances useful as plant food sustained in moss manure, T. Macfarlane (*Proc. and Trans. Roy. Soc. Canada*, *2. ser.*, *10* (*1904*), *Sec. III*, *pp. 61–69*, *pls. 2*).—Observations on the amount and value of the manure obtained in dry moss closets by methods previously described (E. S. R., 16, p. 349) are reported.

In one experiment the product for 3 persons during 6 months, using 20 lbs. of moss litter, weighed 70 lbs. The material contained 62.6 per cent of water, and the dry matter 4.88 per cent of nitrogen, 4.79 per cent of phosphoric acid, and 3.12 per cent of potash. On this basis the total annual product per person would be worth 18 cts.

In another experiment extending over 3 months and using 15 lbs. of litter, the total product weighed 60 lbs. and contained 67.5 per cent of water. The dry matter contained 3.33 per cent of nitrogen, 3.52 per cent of phosphoric acid, and 1.05 per cent of potash. The value of product per person annually was 17.4 cts.

In an experiment extending over 3 weeks, in which 410 gm. of the moss manure obtained in the previous experiments was kept moistened with urine, the amount of nitrogen so added being 18.09 gm., the loss of nitrogen was 15.48 gm. The addition of a mixture of bone superphosphate and double manure salt, magnesium sulphate, and gypsum reduced the losses to some extent, but the results indicate "that urea in decomposing under the above-described circumstances is not all resolved into carbonic acid and ammonia, but that a varying quantity of nitrogen escapes in the free state."

Concerning the agricultural value of sodium salts, H. J. Wheeler and G. E. Adams (*Rhode Island Sta. Bul. 106*, *pp. 111–153*, *dgms. 11*).—This is essentially an account of a continuation on the same plats during 1900 and 1901 of experiments of previous years (E. S. R., 17, p. 232), attention being directed especially to a study of the extent to which the liberation of plant food other than potash in soil might explain the beneficial effects of sodium salts which had been observed in many cases

even when the sodium salts were used in connection with full rations of potash. The after effects of the sodium and potassium salts up to 1904 have also been studied.

These experiments, begun in 1894, have been made on 48 twentieth-acre plats grouped in 4 series of 12 each. "Two of the series received sodium chlorid (common salt) and potassium chlorid (as commercial muriate of potash). The other two received potassium carbonate and sodium carbonate. One of the chlorid series and one of the carbonate series was limed in 1894, and the other series in each case remained unlimed until 1902, when an application of slaked lime was made to all of the 48 plats. . . .

"Four of the 12 plats [of each series] received full rations of the potassium salt; to one of these a quarter, to another a half, and to another a three-quarter ration of sodium salt was added. Four other plats received full rations of sodium salt; to one a quarter, to another a half, and to a third a three-quarter ration of potassium salt was added. One of the 4 remaining plats received a quarter ration of each salt, one a half ration of each, one a three-quarter ration of each, and the fourth a full ration of each. The plats in all of the series were manured alike with magnesia, phosphoric acid, and nitrogen.

"In the year 1900 Indian corn was planted upon the entire area of all of the plats, and in 1901 one or two rows of a number of different varieties of plants were grown, in order, if possible, to obtain further indications as to what varieties seemed most likely to be helped by sodium salts."

The latter included radishes, chicory, carrots, mangel-wurzels, squash, and soy beans.

"The results with Indian corn in 1900 show, so far as concerns the yields of ears, that it was doubtful if sodium chlorid (common salt) aided in raising the yield even when the amount of muriate of potash was reduced to 70 lbs. per acre. The same failure of sodium carbonate to prove of positive benefit was observed in connection with potassium carbonate when the amount of the latter substance was reduced so as to contain the same amount of potassium as 70 lbs. of the muriate of potash. Concerning the yields of stover, there were somewhat greater indications of benefit from the use of the sodium salts than in the case of the ears, yet the apparent advantage from their use was very slight."

In case of radishes, chicory, carrots, and mangel-wurzels, sodium salts were apparently beneficial when the amounts of potash salts used were small. In case of soy beans and squash sodium salts were of little or no benefit even in presence of small amounts of potash.

"In 1902, 1903, and 1904 no further applications of sodium or potassium salts were made, but each plat continued to receive annual applications of phosphoric acid and nitrogen. Where the large applications of potassium salts had been made previously, it was found that timothy and clover were much better able to persist than elsewhere. The influence of the previous applications of potassium salts still continued in a most striking manner even the third year, in all cases where large amounts were used at that time, as was fully demonstrated by the much greater yields of hay.

"Considerable evidence was afforded that the earlier applications of sodium salts were now helpful by way of increasing the crops of hay in those cases where the previous applications of potassium salts had been large." It is suggested that this may have been due to conservation of potash by soda in the soil.

Analyses of commercial fertilizers, M. A. SCOVELL, H. E. CURTIS, and W. H. SCHERFFIUS (*Kentucky Sta. Bul. 117, pp. 87–171*).—The results of analyses during 1904 of 630 samples of fertilizers are reported. Of these "111, representing 89 brands and 33 firms, fell so far below the guaranteed analyses in phosphoric acid, nitrogen, or potash, or any two or all three of these ingredients, that the deficiencies could not be accounted for by variations in sampling or analysis."

Attention is called to the advisability from the standpoint of economy of purchasing only high-grade fertilizers, and it is stated that "it is an utter waste of money to purchase potash or ammonia in fertilizers containing less than 1 per cent of these ingredients."

Analyses of commercial fertilizers and Paris green, W. C. STUBBS and C. H. O'ROURKE (*Louisiana Stas. Bul. 80, 2. ser., pp. 104*).—This bulletin is a detailed report on the fertilizer and Paris green inspection in Louisiana during the season 1903–4. It includes also the text of the State fertilizer law and the law of 1904 relating to Paris green. General notes on the nature, purchase, and valuation of fertilizers are included.

Inspection and analyses of commercial fertilizers on sale in the State, W. F. HAND ET AL. (*Mississippi Sta. Bul. 85, pp. 31*).—Analyses and valuations of 280 samples of fertilizers examined during the season of 1903–4 are reported, with brief notes on the general results of inspection and on valuation, and the text of the State fertilizer law as amended in 1904 to provide for the branding of fertilizers with reference to their grade.

Analyses and valuations of fertilizers, J. P. STREET, W. P. ALLEN, and V. J. CARBERRY (*New Jersey Stas. Rpt. 1904, pp. 43–98*).—This is a reprint of matter contained in Bulletins 176 and 177 of the station (E. S. R., 16, pp. 556, 761), with the addition of a list of manufacturers whose goods were sampled and analyzed during 1904, and data relating to the wholesale prices of fertilizing materials in New York during different months of the year 1903 and valuations for 1904.

AGRICULTURAL BOTANY.

Physiological investigations on young shoots of the grape, E. GRIFFON (*Rev. Vit., 24 (1905), No. 607, pp. 117–122*).—On account of the common practice of topping vines to promote fruitfulness, the author investigated the physiology of the subject.

It has been held by many that the presence of starch in the young growth is an indication that these shoots are living a sort of parasitic life at the expense of the remainder of the plant. The author studied the photosynthesis of the plant in relation to the age of different parts, the principal investigations being made with grapes, although a number of other economic plants were included in his studies. He claims that the presence of starch in a young rapidly growing shoot is not an indication of the ability on the part of the shoot to fix carbon dioxid, nor can it be considered as a measure of the energy of photosynthesis.

The absence of starch, on the other hand, does not indicate that a part of a plant is incapable of carbon dioxid assimilation. The suppression of the extremities of the vine is not correctly based on the ground of their being parasites, as there was found little evidence of such a habit of growth. The young leaves were found capable of assimilating carbon dioxid immediately after their expansion. The true explanation of the beneficial action of topping is that this process establishes a beneficial equilibrium between the remaining foliage and the forming fruit.

Recent investigations on the rôle of hydrocyanic acid in green plants, M. TREUB (*Ann. Jard. Bot. Buitenzorg, 2. ser., 4 (1904), pt. 2, pp. 86–147, pls. 9*).—Investigations by the author and others have shown the frequent occurrence of hydrocyanic acid in various tropical plants, its formation seeming to be dependent upon the simultaneous presence in parts of the plant of carbohydrates and inorganic compounds of nitrogen, probably in the form of nitrates.

When these conditions are present hydrocyanic acid is formed and the theory has been evolved that hydrocyanic acid is the first recognizable nitrogen compound in the plant, if not the first nitrogen compound actually formed by the plant. Among the plants reported as containing hydrocyanic acid was *Phaseolus lunatus* (E. S. R.,

11, p. 121). On account of the importance of this plant and the fact that it is, through its root tubercles, an active assimilator of nitrogen, studies were begun with it in 1897 and continued with various interruptions for several years.

The experiments, which are described in detail, show that sugar, most probably in the form of glucose, is indispensable to the formation of hydrocyanic acid in the leaves of *P. lunatus*, and evidence is produced showing that nitrates exert a direct influence on the production of hydrocyanic acid. The author, summarizing his work, again declares that hydrocyanic acid is the first recognizable product of the assimilation of nitrogen in the leaves of *P. lunatus*.

The assimilation of leucin and tyrosin by plants, L. LUTZ (*Bul. Soc. Bot. France, 52 (1905), No. 2, pp. 95–101, fig. 1*).—In a previous publication (E. S. R., 11, p. 316) the author stated that phanerogams could not assimilate leucin or tyrosin as their only sources of nitrogen. The frequent occurrence of these substances in seeds and the experiments of others have led to a repetition of the author's studies along this line.

Experiments are reported with cucurbit seedlings and a number of molds in solutions containing leucin and tyrosin as the only sources of nitrogen. Where leucin was added to the culture medium, gains of 35.8 to 40.8 per cent in nitrogen are reported for the cucurbits, while for tyrosin a gain of 11.9 per cent is given. Spores of Aspergillus and Penicillium sown in culture media made excellent growth, showing that both phanerogams and fungi can use these organic compounds as sources of nitrogen. For the fungi they are about equally efficient, but for the flowering plants leucin, being more soluble, is much better assimilated than tyrosin.

The assimilation of organic nitrogenous substances by plants, L. LUTZ (*Bul. Soc. Bot. France, 52 (1905), No. 4, pp. 194–202*).—A summary is given of the investigations of the author and others on the assimilation of organic nitrogenous compounds by plants, many of the more important papers having been noted elsewhere (E. S. R., 8, p. 843; 10, pp. 235, 414; 11, p. 316; 14, pp. 119, 422).

In all the author's experiments the flowering plants were grown in sand or similar cultures, the seed being first sterilized. The algæ were grown in Molisch's culture medium and the fungi in Raulin's liquid. For each kind of plant the only source of nitrogen was to be found in the compound under investigation.

Flowering plants, algæ, and fungi can take the nitrogen necessary for their growth from salts containing amin compounds. This appears to take place without transformation into nitric or ammoniacal nitrogen. Methylamin is an excellent source of nitrogen, but benzylamin is not, and phenylamin is poisonous. The algæ seem somewhat less subject to injury by phenylamin than flowering plants. Ammonia compounds, pyridin bases, and alkaloids are not directly assimilable, but they may become available in the presence of some form of assimilable nitrogen. The same rule applies for the alkaloids as for the amins, the less complex the molecule the more assimilable they are.

The instability of amid compounds limited their use to algæ and fungi. As with the amins, the amids of the fatty series are directly assimilable by plants, but those of the aromatic series are not adapted to plant growth. The investigations showed that asparagin and urea caused better growth than the form of nitrogen existing in Raulin's fluid. Leucin and tyrosin under conditions described above are assimilable by each class of plants studied. The nitriles are only slightly assimilable when used alone, but when used in connection with other forms of nitrogen are taken up to some extent by the plants.

Compounds of the aromatic series are either not assimilable at all or are poisonous to plants. Comparing the assimilability of the amin, amid, and nitrile compounds, it is stated that for compounds of equal molecular complexity the amins are the most assimilable, followed by the amids and nitriles. Hydroxalamin acted as slightly toxic to all plants tested.

The author believes it is practically demonstrated that many organic nitrogenous substances are directly assimilated by plants, and the common belief that ammoniacal fermentation takes place first, followed by nitric fermentation, is not in accord with what actually occurs in the plant.

The comparative assimilability by plants of ammoniacal salts, amins, amids, and nitriles, L. LUTZ (*Bul. Soc. Bot. France, 52 (1905), No. 3, pp. 159-162*).—Studies on the assimilability of these compounds as sources of nitrogen for Aspergillus and Penicillium are reported, comparisons being made with ammonium nitrate.

The fungi were sown in modified Raulin's solution, and in the same solution with various amins, amids, and nitriles substituted for the ammonium nitrate. The assimilability of the amins was in inverse proportion to the size of the molecule, while the amids were nearly the complement of the amins and the nitriles were only slightly assimilated. The comparative studies with ammonium salts show that of all nitrogenous bodies the amids are the most assimilable. In general, nitrogenous compounds are assimilable in proportion to the complexity of their molecule.

FIELD CROPS.

Annual report of the Alaska Agricultural Experiment Stations for 1904, C. C. GEORGESON (*U. S. Dept. Agr., Office Expt. Stas. Rpt. 1904, pp. 265-360, pls. 7*).—The work for the year is summarized, and a report on the grazing lands of the South Alaska coast, by C. V. Piper of this Department, included.

The grazing lands of the Yakutat Plains, the Kenai Peninsula, Kadiak Island, and Alaska Peninsula and adjacent islands are described, and their utilization is pointed out. The principal native grasses and forage plants are noted with reference to their occurrence and the soils and localities they occupy. The 3 most common forage plants of the entire region are bluetop (*Calamagrostis langsdorfii*), sedge (*Carex cryptocarpa*), and beach rye (*Elymus mollis*). The following analyses of these 3 plants were made by the Bureau of Chemistry of this Department:

Composition of Alaska forage plants.

	Moisture.	Ash.	Ether extract.	Crude fiber.	Proteids.	Nitrogen-free extract.
	Per cent.	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*	*Per cent.*
Bluetop	7.18	3.90	1.03	42.94	4.58	40.37
Sedge	5.85	10.65	2.12	25.72	10.32	45.34
Beach rye	11.92	7.51	2.26	30.31	12.71	35.29

The experience in keeping sheep, Angora goats, beef cattle, and dairy cows in different sections of this region are briefly reviewed. In the author's opinion the outlook for sheep raising is doubtful, but the keeping of goats and cattle seems promising. Notes on numerous grasses and other forage plants on the Alaska coast are given.

Work at Sitka Station.—The following composition of a dried sample of beach grass silage from the station's silo at Sitka was determined by the Bureau of Chemistry of this Department: Fat 3.32 per cent, protein 10.64, ash 6.89, crude fiber 34.64, and nitrogen-free extract 44.51 per cent. The ash sample contained 69.77 per cent of water. Analyses of 16 samples of soil from the Copper Center Station and of 1 sample from near the mouth of the Stikine River, made by the Bureau of Soils of this Department, are also reported.

The present condition and amount of growth of apples, cherries, plums, bush fruits, and ornamentals are briefly noted, as are also the results with vegetables and grasses. Tall meadow oat grass has so far been the most successful of the grasses

tried. Fertilizer experiments showed that a much better growth was made where a heavy dressing of caustic lime was applied. This was especially apparent on raw peaty soil seeded to common oats. Where a ton of caustic lime was applied per acre, together with 300 lbs. of muriate of potash, a uniform and fair growth of oats was obtained, while on the plats receiving the muriate of potash alone the plants turned yellow and died.

Work at Kenai Station.—The progress of work at Kenai is reviewed and notes on the results with the different crops are given. The use of 300 lbs. of superphosphate per acre in connection with growing cereals gave a much more even, uniform, and rank growth and a heavier yield than the same crops on unfertilized soil. A plat of common oats protected on all sides by timber stood from 40 to 48 in. high, while a similar plat fully exposed to the inlet winds reached a height of only 30 in. Of several winter grains tested winter wheat and Excelsior rye survived the cold season.

The milk produced by each cow of the station herd is recorded. The best cow produced a total yield of 5,437.5 lbs. in a milking period of 268 days.

Work at Copper Center Station.—At Copper Center numerous varieties of barley, oats, wheat, vegetables, and grasses were grown. Sixty-day and Finnish Black oats matured in part, but the wheats did not ripen. Barley, which generally ripens, also failed to mature this season, but the several varieties gave a good crop of hay. Manchuria, Lapland, and Mansury barley came nearest to ripening. The yields of different kinds of grain cut for hay ranged on unfertilized land from 763 to 1,907 lbs. per acre, and on fertilized land from 2,343 to 5,085 lbs. Of the grasses, timothy matured seed, while the seed of redtop, blue grass, and meadow foxtail was about matured August 15. The results of fertilizer tests again showed that newly cleared land is less productive than land which has been under culture.

Work at Rampart Station.—Barley and oats matured this season at this station, while at Copper Center, in a latitude of 3° 30′ farther south, the same varieties were killed. The general progress in the establishment of the station is described.

Cooperative experiments on Wood Island.—Five varieties of barley sown April 18 gave promise of ripening, while 3 varieties of oats made a good growth but did not mature. Timothy grew 3½ feet high and produced long full heads. A few reports of the results of the seed distribution in cooperation with the Bureau of Plant Industry of this Department are reproduced.

Daily records of soil temperatures at Sitka, Kenai, and Copper Center and meteorological records from several stations are given in tables.

Annual report of the Hawaii Agricultural Experiment Station for 1904, J. G. Smith (*U. S. Dept. Agr., Office Expt. Stas. Rpt. 1904, pp. 361–382, pls. 2*).—A general review of the activities of the station during the year is given and the results of investigations are reported.

An experimental crop of tobacco grown in 1904 produced about 1,000 lbs. of cured leaf, exceedingly variable in quality. Deli, Florida Sumatra, Java Sumatra, Connecticut Broad Leaf, Vuelta Abajo, Connecticut Havana, Florida Havana, and Spanish Zimmer were grown. The quality of the Cuban type was uniformly much better than that of the Sumatra. The crop was grown on new land in an untried locality, and numerous delays interfered with the work. The results indicate that the tobacco of this region colors well, tends to run to the dark shades, is likely to be mild in flavor, and has a good burn. More definite results are expected from the second season's work.

Chemical work for the station is outlined by the chemist, and a partial list of the injurious insects of Hawaii is presented by the entomologist. The horticulturist gives notes on the culture of the banana, mango, cacao, and avocado pear, and also on the black rot of cabbage. Successful experiments in budding the mango have shown that it is perfectly practicable to propagate it by this method in the islands.

Experimental shipments of avocado pears to Manila and to New York have shown that these fruits can be successfully shipped to these points.

Annual report of the Porto Rico Agricultural Experiment Station for 1904, D. W. MAY (*U. S. Dept. Agr., Office Expt. Stas. Rpt. 1904, pp. 383–424, pls. 5*).—A general review of the station work is given and the agricultural possibilities of the island are discussed.

Report of the entomologist and botanist, O. W. Barrett (pp. 387–406).—The plant collections, comprising variety tests with bananas, yautias, cassava, orchard fruits, forest trees, fiber plants, and miscellaneous crops are briefly described, and the new additions noted.

Tests of commercial fertilizers, coffee pulp, stable manure, and guano in yautia culture resulted in the highest yield from the use of about 30 tons of stable manure per acre, giving edible tubers at the rate of about 16 tons per acre, as compared with 8 tons on one of the check plats. The highest yield per plant, 3.22 lbs., was obtained in the plat receiving stable manure, and the lowest yield per plant, 1.6 lbs., in the check plats. A second crop of tubers was obtained from the same plants left standing after the first ripe roots had been removed.

Four varieties of cassava analyzed by the Bureau of Chemistry of this Department, showed a variation in starch content of from 21.50 to 31.69 per cent. Ceiba, the variety showing the highest percentage of starch, is one of the 3 best native sorts. The native "malanga" (*Colocasia antiquorum esculentum*) made a very promising growth, and the mature roots, according to an analysis made by the Bureau of Chemistry of this Department, contained 14.94 per cent of starch and 74.47 per cent of moisture. A yield of about 15 tons per acre of edible canna roots was obtained. These roots showed a starch content of 19.41 per cent, with 70.25 per cent of water. The prevalence and effects of certain insect enemies and fungus diseases are described.

The outlook for the culture of citrus fruits, pineapples, mangoes, and aguacates is summarized by the assistant horticulturist, H. C. Henricksen.

The station was successful in growing seedling *Castilloa elastica* from seed, and the behavior of some of the distributed trees indicates that Castilloa should be planted only in rich moist soil.

Report of the coffee specialist, J. W. van Leenhoff (pp. 406–410).—The average yields of an old coffee grove in 1903 were observed to be as follows: Ripe berries 887 lbs. per acre, coffee ready for market 180¼ lbs., productive trees per acre 746, and the product per tree 0.261 lb. The cost per 100 lbs. for harvesting and marketing the coffee was $2.26. Notes are given on a number of experiments begun in cutting coffee trees to stumps, renovating old coffee plantations, and establishing new plantings.

Bananas, yautias and economic fruits such as oranges, lemons, and figs, as well as rubber and eucalyptus trees, cotton, and varieties of yams and sweet potatoes, have been distributed in the coffee regions for soils not occupied by coffee.

Report of the tobacco expert, J. van Leenhoff (pp. 410–425, pl. 1).—This report is an abstract of Bulletin 5 of the station, which has already been noted (E. S. R., 17, p. 32).

Cooperative experiments in agriculture, C. A. ZAVITZ (*Ann. Rpt. Ontario Agr. and Expt. Union, 26 (1904), pp. 13–31*).—The organization of the Experimental Union is described, and the results obtained during 1904 are summarized and briefly noted.

Experiments were conducted during the season by 4,050 farmers, and the work carried out was along 35 distinct branches of field agriculture. The leading varieties of grain crops gave the following average yields per acre: Tartar King oats, 120 tests, 50.82 bu.; Mandscheuri Six-rowed barley, 33 tests, 36.23 bu.; Guy Mayle Hulless barley, 31 tests, 29.43 bu.; Wild Goose spring wheat, 19 tests, 19.48 bu.; Common

emmer, 7 tests, 56.85 bu.; Red spelt as compared with emmer, 31.58 bu.; New Canadian Beauty field peas, 22 tests, 30.03 bu.; Silver Hull buckwheat, 4 tests, 23.38 bu.; Marrowfat field beans, 10 tests, 30.33 bu.; Imperial Amber winter wheat, 3 tests, 22.47 bu.; and King Philip corn, 9 tests, 55.99 bu.

The leading varieties of field roots and fodder crops gave the following yields per acre: Yellow Leviathan mangels, 5 tests, 29.31 tons; New Danish Improved sugar beets, 9 tests, 31.29 tons; Magnum Bonum Swede turnips, 4 tests, 22.17 tons; Redtop White Globe turnips, 1 test, 33.48 tons; Mammoth Intermediate Smoot White carrots, 2 tests, 16.16 tons; Henderson Eureka fodder corn, 2 tests, 21.22 tons; Early Amber sugar cane sorghum, 1 test, 18 tons; grass peas in comparison with vetches, 4 tests, 5.90 tons; and Dwarf Essex rape, 1 test, 25.72 tons. Dwarf Bonanza rape gave a yield almost as large as Dwarf Essex.

The leading varieties of hay crops were Japanese Barnyard millet, Mammoth red clover, lucern as compared with sainfoin and Burnet, and tall oat grass tested with several other common grasses. The results with sowing hairy vetches, winter rye, and crimson clover in the fall show that hairy vetches gave a yield of 6.8 tons and winter rye of 4.3 tons of green crop per acre during the last 2 seasons, while crimson clover was badly winterkilled in each of the 2 years.

The average yields of Empire State and American Wonder potatoes, 2 late varieties grown in 62 tests, were 224.5 and 221.8 bu. per acre, respectively. Of medium early varieties Rose of the North stood first, with an average yield of 200.4 bu. per acre in 55 tests, while among the early varieties, Early Andes in 163 tests ranked first with 170.8 bu. Hilling potatoes gave better results than level cultivation, which is considered due to a cool, damp season. The results of 17 tests show that seed potatoes coated with land plaster yielded 228.2 bu., as compared with 213.2 bu. per acre for untreated seed.

In 1904 experiments with fertilizers were confined to swedes, and the yields obtained per acre for the different methods of treatment were as follows: Check plat 24 tons; 160 lbs. of nitrate of soda per acre, 26.1 tons; 160 lbs. of muriate of potash, 26.7 tons; 320 lbs. of superphosphate, 28.1 tons; 213 lbs. of complete fertilizer, 29.3 tons; and 40,000 lbs. of cow manure, 32.5 tons.

In 8 tests with sweet corn Mammoth White Cory ranked first in yield, quality, and earliness. This variety required only 71 days to produce ears ready for table use. Field corn planted in hills yielded 2.14 tons of ears per acre, while corn in drills yielded 1.58 tons. In total crop the average of 4 tests showed but little difference between the 2 methods of planting.

Report on the manuring of seeds hay, 1904, W. ALLAN (*Edinb. and East of Scot. Col. Agr. Bul. 5, pp. 21*).—Fertilizer experiments in connection with growing different grass mixtures were conducted at 21 centers.

Nitrogen was used at the rates of 20, 30, and 40 lbs. and phosphoric acid and potash at the rate of 40 and 30 lbs., respectively. Nitrogen proved to be the most effective element, the best results being obtained where a mixture of nitrate of soda and sulphate of ammonia was used. When the 2 substances were applied alone, nitrate of soda gave better results than sulphate of ammonia. The largest quantity of nitrogen used gave a larger yield and better financial returns than the smaller quantity.

When applied alone nitrogen gave satisfactory results, but potash and phosphoric acid each given alone were not very effective. The largest yields and the greatest profits in the entire series of tests were obtained from the use of complete applications.

Culture and fertilizer tests on heath soils, B. HARDT (*Deut. Landw. Presse, 32 (1905), No. 29, pp. 253, 254*).—Experiments were conducted for 4 years to determine the effects of lime and marl on new heath soil, and to ascertain the possibility of growing oats under such soil conditions.

The rotation of crops by seasons was as follows: Lupines, oats and serradella, oats and clover, clover, and clover. Both lime and marl at the rate of 2,500 and 5,000 kg. per hectare, respectively, proved very effective and highly profitable. The gross as well as the net returns were in favor of marl, and the use of lime in 2 applications gave better results than applying the entire quantity at one time. The yields of oats obtained were satisfactory. The method successfully employed for the reduction of the heath soil is described.

Soiling crops, 1904, G. A. BILLINGS (*New Jersey Stas. Rpt. 1904, pp. 342–366, pls. 4*).—Summer soiling was carried on this season from May 14 to October 20, 160 days.

A herd equivalent to 43 full-grown animals was supplied with roughage from a continuous rotation of forage crops. The data show that 221.89 tons were grown at a cost of $429.21, or at an average of $1.93 per ton. The feeding and manurial value of the crops is shown, and the data deducted indicate that 46 tons of clover hay furnished 11,316 lbs. of protein, 2,116 lbs. of crude fat, and 64,952 lbs. of carbohydrates; 56 tons of mixed hay, 11,312 lbs. protein, 2,912 lbs. crude fat, and 77,168 lbs. carbohydrates; and 227 tons of corn silage, 7,718 lbs. protein, 3,632 lbs. crude fat, and 77,180 lbs. carbohydrates.

It is further shown that the total tonnage of soiling crops furnishes nitrogen equivalent to 5.15 tons of nitrate of soda, phosphoric acid equivalent to 1.11 tons of acid phosphate, and potash equivalent to 1.89 tons of muriate of potash, and that the manurial value of this crop is also equivalent to 9.9 tons of barnyard manure, 3.16 tons of nitrate of soda, and 0.98 ton of muriate of potash. A comparison of the manurial and feeding value, estimating barnyard manure at $1.50 per ton, nitrate of soda at $45, and muriate of potash at $42, shows that the value of the soiling crops for green manure would be $331.86, or $97.35 less than the feeding value.

The rotation furnished a continuous supply of forage. The average yield per acre for all the crops, including alfalfa but not including mixed grasses, was 11.99 tons per acre. It is pointed out that the protein produced by one acre of alfalfa yielding 17.5 tons of green fodder is equivalent to the quantity of protein in 6.4 tons of clover hay, or about 5 tons of wheat bran. On the average for 6 years alfalfa yielded 19.18 tons per acre, equivalent to 72 tons of clover hay, according to the nutrients contained in the 2 crops.

Of the different crops grown alfalfa was found to be the most economical. Barnyard millet, pearl millet, Thoroughbred White Flint corn, and Southern White corn, being about equal in yield, ranked next to alfalfa in the average production of forage. General notes on the different crops are given. The results of an experiment in seeding alfalfa at different periods were decidedly in favor of seeding between the 1st and the 15th of August.

The inoculation experiments of the season gave results in favor of the cylinder not inoculated. The results are not considered as showing that inoculation has been a failure, but that the cylinders not inoculated obtained the alfalfa bacteria from some source other than the use of a soil solution or soil as applied in this experiment. The application of a soil infusion was much more effective than the use of the soil itself. Different kinds of soil showed a variation of 74 per cent in responding to inoculation, Freehold marl in Monmouth County being the least affected by inoculation, and Woodbine sand in Cape May County making the greatest gains. Nitrate of soda at the rate of 147 lbs. per acre, costing $3.31, gave a loss of 135 per cent in favor of inoculation.

Of 3 varieties of corn compared to ascertain their value for silage Southern White in rows 3 ft. apart and at intervals of 9 in. in the drill gave the most satisfactory results, both in respect to quality and quantity. The yield of this variety was 11.84 tons per acre, while Hickory King produced 7.8 tons, and Thoroughbred White Flint, which was exceptionally good in quality, 8.77 tons.

Top-dressing with nitrate of soda increased the yield of both wheat and rye, though with profit only in the latter case.

Alfalfa in Michigan, C. D. Smith (*Michigan Sta. Bul. 225, pp. 133–148, figs. 3*).—This bulletin reviews the history of experiments with alfalfa at the station and throughout the State, summarizes the results obtained, and from the data secured presents conclusions with reference to the culture of the crop.

At the station alfalfa seemed to give as good results on light sand as on well-drained clay. Although artificial inoculation was not used at the station, the roots of the plants were practically in all cases provided with nodules, but from some parts of the State it was reported that nodules were not present, and it is therefore considered best to inoculate the seed or soil when sowing.

It is recommended that 20 lbs. of seed be used per acre when the germination is above 80 per cent, and larger quantities when it is below 80 per cent. In the southern part of the State sowing in May seems to be preferred, while in the portion permanently covered with snow during the winter sowing in August is thought to be best.

Tests with seed bought in the market, Utah and Colorado grown seed, sand lucern, and Turkestan, showed that Turkestan gave smaller yields than the others but proved hardier. Sand lucern apparently stood the winter as well as Turkestan, and Utah and Colorado grown seed gave results which differed but little. Clipping the crop in October, when the aftergrowth since August 30 was fully knee-high, and leaving the clippings as a mulch was a serious injury to the crop of the following season, and indicated that under the conditions alfalfa should not be mowed later than the last week in August.

Analyses of samples from 3 cuttings show that the composition of the cuttings made June 7 and July 11 differed but little, while the third, made August 30, was lower in ash, higher in total protein, but much reduced in true proteids, to which the hay owes its feeding value.

Of 76 culture tests with alfalfa made by farmers in the State, 32 were absolute failures, 24 were partially successful for a single year, and 16 for 2 or more consecutive years. Winterkilling, June grass, and dodder, are given as the chief enemies of the crop in Michigan.

Legumes other than alfalfa, C. D. Smith (*Michigan Sta. Bul. 227, pp. 165–184*).—Culture tests with a large number of leguminous crops are briefly reported and an analytical key to vetches is given.

The results with lupines, kidney vetch, goat rue, crimson clover, and vetches indicate that these crops are of some value as green manures, especially on sandy soils. Crimson clover, serradella, sainfoin, and Japan clover gave some promise as a food supply for stock. Sweet clover, fenugreek, *Astragalus sinensis*, sulla, peanuts, chick-pea, and lentils are apparently of no value for Michigan.

The tests at the station with *Lathyrus sylvestris* indicate that this crop is of little value, either as a fodder plant or for green manure. Iron, New Era, Whip-poor-will, and Black Eye cowpeas are recommended for plowing under to enrich Michigan soil in nitrogen. These varieties ripen seed only in unusually warm seasons with frosts late in the fall. Of the soy beans tested, Medium Green, Early Black, and Yellow produced abundant forage, and Ogemau, Ito San, and Government 9413 are good types for seed production.

Hairy vetch at the station has not been a success as a forage crop. *Vicia picta*, flowering early in July and fruiting in the middle of August, produced a large yield of seed but only a small amount of green forage, while *V. canadensis*, *V. angustifolia*, and *V. peregrina* yielded abundant foliage and a smaller amount of seed. *V. disperma*, *V. biennis*, *V. gerardii*, and *V. globosa* also produced considerable green forage. *V. faba* is considered totally unsuited to Michigan. It is reported that vetch has become a weed difficult to exterminate on the college farm and elsewhere.

An analytical study of the roots and upper portions of the plants of Medium Green and Ogemau soy beans, New Era cowpeas, *V. globosa*, second crop June clover, and new seeding June clover showed that on the basis of normal yields of forage per acre Medium Green soy beans yielded 152.29 lbs. of nitrogen per acre; the cowpeas, 61.90 lbs.; the vetch, 77.10 lbs.; the second crop clover, 51.47 lbs., and the new seeding clover, 49.06 lbs.

On September 15, 1904, 13,590 lbs. of soy beans were harvested and put into the silo. The silage taken from the silo the last week of April, 1905, had a peculiar and unpleasant odor. When weighed out it amounted to 11,285 lbs., and had the following composition: Water 68.97 per cent, ash 5.69, ether extract 2.97, crude fiber 9.09, protein 3.28, and carbohydrates 10 per cent. It was fed to dairy cows.

"Inasmuch as the soy beans do not grow tall and do not therefore stay bound in the bundle with the corn when cut with the harvester, and inasmuch as repeated experiments at this station show that the vines of the Red Speckled and of the Southern Prolific beans cling to the corn and are harvested with it, it is suggested that one or the other of these legumes be used instead of soy beans for enriching in protein the corn in the silo."

Trials with alfalfa, J. H. Sheppeed (*North Dakota Sta. Bul. 65, pp. 550–556, pls. 2*).—The results of 4 years' trials with alfalfa, and for the most part previously reported in former publications of the station, are reviewed.

The experiments at the station have indicated that alfalfa should be sown without a nurse crop on well prepared land at the rate of 15 lbs. of seed per acre. The common commercial strains of alfalfa seed were found not to be well adapted to the conditions of the region, and this has induced the station to breed hardy strains. In 1904 the yield of hay from the first mowing of Turkestan alfalfa seeded in 1901 was at the rate of 3,600 lbs. per acre, and the second growth, which had been hindered by extremely dry weather, gave 1,000 lbs. of hay per acre. A plat of the same variety seeded in 1902 yielded 4,200 lbs. of hay per acre on June 21, and 1,880 lbs. from the second cutting.

Grimm alfalfa showed a good stand in 1904, but did not grow as high as the Turkestan. The yield of hay from the first cutting was 3,720 lbs. per acre. The second growth, although not quite mature when killed by frost, was harvested for seed. It is believed that the trials indicate that alfalfa may ultimately prove a successful crop in the State.

Experiments in clover growing, J. H. Sheppeed (*North Dakota Sta. Bul. 65, pp. 543–550, pls. 2*).—The clover trials made by the station during 12 years are reviewed.

It was found that seeding clover, or clover and timothy, with a grain drill gives much greater assurance of a stand than broadcasting. With one exception during 9 years, medium red clover seeded with a nurse crop passed through the first winter without killing out. Allowing the second growth to remain as a winter protection gave good results in preventing winterkilling and in reenforcing the stand by means of the new seed.

It was observed that the average stubble field was in most seasons efficient as a winter protection. Inspection after each of 11 winter seasons did not reveal a case of heaving by frost. Where an ice sheet covered the plants, however, the clovers, alfalfa, timothy, and redtop were killed out, while brome grass and the weed quack grass had withstood this adverse condition.

Satisfactory results have been obtained from using 15 lbs. of clover seed per acre, and a mixture of 5 lbs. of red clover seed and 8 lbs. of timothy has given a mixture of from one-half to three-fourths of timothy plants in the resulting stand. Ten lbs. of Mammoth clover with 4 lbs. of timothy seed have given an average of more than three-fourths clover in the hay. The results for 4 years show a difference of only

91 lbs. in the yield of hay from medium red clover and from a mixed crop of clover and timothy.

Red clover also gave promise of good seed production, while clover from southern-grown seed or from most of the foreign sources was less satisfactory. Red clover alone and grown with timothy as a mixed hay crop gave in 10 trials an average yield of 3,376 lbs. of hay per acre. The average yield of hay from Mammoth clover for 2 years was 3,635 lbs.

Notes are given on trials with alsike and white clover, berseem, and melilotus. Alsike proved more resistant to the winter than Mammoth clover.

Corn. Field tests, J. N. HARPER (*Kentucky Sta. Bul. 118, pp. 19, pls. 13*).—The results with 15 varieties of corn grown in 1903 and 1904 are reported.

With a few exceptions, the same varieties were grown each year. In 1903 the yields ranged from 27.9 bu. per acre for Iowa Silver Mine, to 35.7 bu. for Boone County White obtained from Indiana. Boone County White from Tennessee yielded 33.5 bu. per acre. Cocke Prolific, which stood second in yield, and Mosby Prolific ranking next to the lowest, were the latest varieties, ripening September 28, while Iowa Silver Mine was ripe September 10. Mosby Prolific led in the yield of fodder with 5,994 lbs. per acre.

In 1904 Champion White Pearl stood last with a yield of 34.6 bu. per acre, and Boone County White from Indiana first, with 50.6 bu. Boone County White from Tennessee produced 46.7 bu. per acre this season. Champion White Pearl, Iowa Silver Mine, Riley Favorite, and Leaming Yellow began to tassel July 12, while Mosby Prolific, Sanders Improved, Cocke Prolific, and Hannah did not begin to tassel until July 23, and Roseland White not until July 27. In yield of fodder Roseland White, which stood second in yield of grain, ranked first with 4,222 lbs. per acre, being followed by Mosby Prolific with 4,171 lbs. A general discussion is given on the culture of corn and the different varieties tested are described.

Experiment station work in corn culture, J. I. SCHULTE (*U. S. Dept. Agr., Office Expt. Stas. Rpt. 1904, pp. 493–544*).—A summary of experiments in corn culture by the different experiment stations of the country.

Soil improvement for the Illinois corn belt, C. G. HOPKINS (*Illinois Sta. Circ. 96, pp. 16, figs. 5*).—The experiments reported were conducted on a dark-brown silt-loam prairie soil, which had been in pasture from 1876 to 1894, and in corn from 1895 to 1897. The land had been divided into 7 strips or series of 10 one-tenth-acre plats each, and the 3 series numbered 100, 200, and 300 were irregularly cropped but chiefly with clover, oats, and cowpeas, from 1898 to 1900, while the other series continued in corn.

The following systems of cropping were begun in 1901: A 3-year rotation of corn, oats, and clover on series 100, 200, and 300; a 2-year rotation of corn and oats on series 400 and 500; and corn only on series 600 and 700. The different plats receive different fertilizer treatment. Lime is given in the form of ground limestone at the rate of 2,000 lbs. per acre once every 6 years. Nitrogen in the form of dried blood is applied annually to certain plats in series 600 and 700 at the rate of 100 lbs. per acre.

On the series 100 to 500, nitrogen is supplied only by growing leguminous crops or catch crops, or by the use of barnyard manure. To supply phosphorus 600 lbs. of steamed bone meal is given once in 3 years in the 3-year rotation, and 400 lbs. every 2 years in the 2-year rotation and also in the continuous corn series. This furnishes annually 25 lbs. of phosphorus per acre. On some plats an equal money value of rock phosphate is substituted for the bone meal. Potassium sulphate or chlorid is given in quantities supplying 40 lbs. of potassium per acre each year.

The tabulated results show that, in 1904, 4 duplicate plats in the 3-year rotation gave an average increase of 31.5 bu. per acre over the corresponding plats in the 2-year series. On the plats growing corn continuously lime produced a gain of 5 bu. per acre, lime and nitrogen of only 4 bu., but lime, nitrogen, and phosphorus a gain

of 32 bu. In the 2-year rotation a gain of at least 11 bu. per acre, and in the 3-year rotation an increase of 10 bu. in corn and oats, and of 100 per cent in the yield of clover, is considered due to phosphorus.

The results of pot experiments with wheat showed that with clover turned under, rock phosphate gave a greater increase than the gains made by the clover and rock phosphate separately. Similar results were secured with clover and steamed bone meal, also with bone meal and potassium, and with rock phosphate and potassium. With other combinations this was not the case. The potassium apparently increased the availability of the phosphorus in the bone meal and the rock phosphate. Slightly better results were obtained with rock phosphate than with bone meal.

The latest corn yields on the university soil experiment fields, partly under test since 1876, indicate the great value of suitable crop rotations, but that these alone do not maintain fertility. Directions for soil management are given.

Report on the comparative merits of varieties of oats, 1903-4, R. B. Greig and J. Hendrick (*Aberdeen and No. of Scot. Col. Agr. Bul. 2, pp. 37*).—These experiments, conducted in Morayshire and at Ross and Cromarty, were made for the purpose of determining the grain and straw producing power of different oat varieties, their comparative milling quality, and the composition of the grain and straw.

The following varieties were grown in the Morayshire experiment: Potato, Newmarket, Storm King, Sandy, Waverly, Goldfinder, Banner, and Siberian. Potato and Sandy are two well-known old varieties which were included for comparison with the newer sorts. The tests were carried out on 3 different farms. Banner was the best grain producer on light land and the best average grain producer on all the farms. Storm King, Potato, and Sandy, mentioned in the decreasing order of yield, stood at the foot of the list.

Banner produced 33 bu. more of first quality grain than Sandy and 20 bu. more than Potato. The average total yield of Banner was 88 bu. and that of Sandy 63.25 bu. In weight of straw produced Potato ranked first, while Banner did not rank very high in this respect. Siberian and Newmarket showed themselves good general purpose, or intermediate varieties, in the production of grain and straw. The earliest variety, Storm King, required 136 days to mature and Goldfinder, the latest, 160 days. Banner and Sandy stood nearest the average in the length of growing period.

In the Ross and Cromarty trials the same varieties, with the exception of Siberian, which was replaced by Hamilton, were grown on 7 different farms. The average total yield of grain was in favor of Hamilton. A comparison of the results on 5 of the farms shows that Hamilton gave an average yield of 79.75 bu., as compared with 69 bu. for Potato; and in these tests Banner and Potato produced the same quantity of grain, but Potato furnished the larger yield of straw. The season was not favorable, and the average weight per bushel of grain as compared with that of the original seed showed a reduction in all varieties except Banner.

In these tests Sandy and Potato ranked high as grain producers and also stood among the 3 first in the yield of straw, Hamilton standing second. The percentage of oatmeal obtained from each variety at each of the places is given in a table. Sandy and Newmarket ranked first with 57.8 and 57.6, respectively, while Hamilton on the average of 4 farms furnished only 53.4 per cent. The percentages of husk and kernel and the composition of the kernels of the different varieties, as well as the composition of the straw, is given in tables. The percentage of kernel ranged from 71.27 in Storm King to 77.13 in Sandy.

Varieties of potatoes, W. Bruce (*Edinb. and East of Scot. Col. Agr. Bul. 6, pp. 4*).—Six varieties of early and 7 varieties of late potatoes were tested at 3 different farms in 1904. In each case Pink Blossom, Factor, Up-to-Date, Twentieth Century, and British Queen gave the best results when both quantity and quality are considered. Langworthy is unequaled in quality, but proved to be low in yielding power.

The manuring of swedes and potatoes, 1904, C. B. JONES (*Armstrong Col., Newcastle-upon-Tyne, Agr. Dept. Bul. 1, pp. 18*).—Cooperative fertilizer experiments with swedes and turnips were conducted to ascertain the fertilizer requirements of the crops and of the different soils, to compare the value of barnyard manure and commercial fertilizers and of basic slag and superphosphates, and to determine the best application of commercial fertilizers to be made in combination with barnyard manure.

The best average results were obtained from the use of 1 cwt. of nitrate of soda, ¾ cwt. of sulphate of ammonia, 4 cwt. of superphosphate, 2¾ cwt. of slag, and ⅞ cwt. of muriate of potash per acre. This application supplied 35 lbs. of nitrogen, 100 lbs. of phosphoric acid, and 50 lbs. of potash. Superphosphate gave a slightly better yield than basic slag, but was not quite so profitable, while a mixture of the two was more profitable than either applied alone. Barnyard manure was not as effective as commercial fertilizers, and their use in combination was unsatisfactory.

For potatoes potash was the most important element, and sulphate and muriate of potash were generally more satisfactory than kainit. The results also indicated that where commercial fertilizers alone are used a complete application, consisting of 1⅛ cwt. of nitrate of soda, ⅞ cwt. of sulphate of ammonia, 3 cwt. of superphosphate, and 1 cwt. of muriate of potash per acre, furnishing 40 lbs. each of nitrogen and phosphoric acid and 60 lbs. of potash, is to be recommended. Barnyard manure gave better results this season than commercial fertilizers. The combined use of barnyard manure and commercial fertilizers is considered profitable for potatoes, and an application of 12 tons of barnyard manure, 1⅛ cwt. of nitrate of soda, ⅞ cwt. of sulphate of ammonia, 3 cwt. of superphosphate, and 1 cwt. of muriate of potash is suggested for use.

In a fertilizer test with mangels, reported by W. T. Lawrence, 1½ cwt. of nitrate of soda was more effective than an application of ¾ cwt. of nitrate of soda, 1 cwt. of superphosphate, and 1½ cwt. of kainit, the money value of the two applications being the same.

Quality in potatoes, J. W. GILMORE (*New York Cornell Sta. Bul. 230, pp. 501–525, figs. 11, dgm. 1*).—This bulletin compares the estimates of quality in potatoes in this country and Europe, and reports the results of investigations to determine the principal factors influencing the flavor of potatoes and their mealiness when boiled. Similar work in France, previously noted, is reviewed (E. S. R., 9, p. 263).

It is pointed out that in the United States a tuber of a starchy flavor, white and floury in color, and mealy when cooked is desired, while in France, as the published data seemed to indicate, potatoes retaining their form, yellowish in color, and soggy after boiling are preferred. The trade estimates of quality as based on size, surface aspects and shapeliness, and variety considerations are explained. The market calls for tubers ranging from 2 to 3 in. in length and weighing from 5 to 10 oz.

In the North light yellow or whitish-skinned tubers are often preferred, while in many parts of the South a pink skin is liked best. Generally a more or less netted skin with a corky appearance or touch is more desirable than a smooth and clear skin. Tubers with deep eyes and otherwise uneven on the surface are avoided and those of oval, flat-round, and elongated-oval shape selected. As potatoes are grown principally for table consumption in the United States, it is suggested that mealiness in cooking, color, and flavor be considered as the chief factors in estimating the quality.

The results of 2 years' work indicate that good cooking quality in potatoes depends largely upon (1) the daily range of soil and atmospheric temperature during the growing period; (2) the degree of ripeness of the tuber when the plant dies; and (3) the physical condition and type of the soil. The different parts of the tubers were studied and the bearing of the internal and external characteristics upon the quality is noted. It was found in boiling tubers of 4 different varieties that in 3 cases the

loss in moisture ranged from 1.87 per cent to 6.29 per cent, while in the fourth there was a gain of 0.48 per cent. In baking tubers of 3 varieties the loss in moisture ranged from 12.79 to 20.76 per cent.

The investigations on the depth and time of planting, and the temperature of the air and of the soil in their relation to quality, pointed out that the seed should be planted 5 to 6 inches deep in good soil, in order to provide room enough between the seed and the surface of the ground for the development of the number of tubers the plant is capable of producing. The tubers growing from 1½ to 4 in. deep were of more uniformly good quality than those growing either deeper or shallower. The results seemed to show that good quality is developed under a uniform soil temperature of 65 to 75°.

It was further found that long tubers which grew sloping in the ground showed a difference in cooking quality between the 2 ends, the stem end cooking more mealy than the bud end, which in these instances is generally nearer the surface of the soil. Incidentally the station observed that in 1904 a fine sandy loam produced potatoes of good quality, while under identical conditions a poorly drained clay loam yielded potatoes which remained firm and soggy after boiling and were very poor in flavor.

Irrigation experiments of 1905, C. F. ECKART (*Hawaiian Sugar Planters' Sta., Div. Agr. and Chem. Bul. 14, pp. 17, dgm. 1*).—These experiments were begun in 1901 (E. S. R., 15, p. 960).

The harvest of 1905 formed a ratoon crop from the planting of 1901. The data for the ratoon crop of 1903 are also given. The Lahaina variety produced the largest weight of cane for both crops with 3 in. of water per week, the average yield being greater by 43,415 lbs. per acre than on the plat receiving only 1 in. per week. The plants given weekly applications of water produced the following yields of cane per acre: One in. per week, 134,491 lbs.; 2 in. per week, 160,395 lbs.; and 3 in. per week, 177,906 lbs. As compared with the use of 1 in. per week, the average figures for 2 in. of water applied every 2 weeks and 3 in. applied every 3 weeks show a loss in yield per acre of 2,730 and 14,030 lbs., respectively.

The plant crop of Rose Bamboo was greatest where 3 in. of water per week was used, and the ratoon crop where 2 in. were applied. Comparing the average yields for the 2 crops, the 2-in. per week plat gave 32,873 lbs. and the 3-in. per week plat 16,604 lbs. of cane more per acre than where only 1 in. per week was applied. The general average for the 2 varieties and the 2 crops shows but a small difference in yields of cane between the plats receiving 2 and 3 in. per week.

The method of irrigation and the different amounts of water applied were apparently without effect on the quality of the juices. The largest yields of sugar, as a rule, were secured from the heaviest yields of cane, but in 2 instances, owing to a lower percentage of sucrose in the juice, plats ranking first in yield of cane did not produce the largest yields of sugar. Lahaina produced the greatest amount of sugar with 3 in. of irrigation water per week, and Rose Bamboo with 2 in.

The plant and ratoon crop of Lahaina with 1 in. of water per week, or 1,632,219 gal. in addition to 1,926,502 gal. of rainfall, gave an average yield of 22,560 lbs. of sugar per acre. As compared with this result, 2 in. of water per week gave a gain of 3,758 lbs. of sugar, and 3 in. a gain of 7,862 lbs. per acre, or 1 lb. of sugar for each additional 448 and 418 gal., respectively. The average results of the plant and ratoon crops of Rose Bamboo show a distinct loss in sugar production when 3 in. instead of 2 in. of water per week were used. The plant cane crop of Lahaina showed a gain of only 2,333 lbs. of sugar on increasing the irrigation from 1 in. to 2. in. per week, and an average gain for the 2 crops of 7,862 lbs.

The results in general call attention to the different water requirements of the 2 varieties and the necessity of basing conclusions upon more than one crop test.

Fertilizer experiments, 1897–1905, C. F. ECKART (*Hawaiian Sugar Planters' Sta., Div. Agr. and Chem. Bul. 15, pp. 57, dgms. 10*).—These experiments, which have been previously noted (E. S. R., 15, p. 960), are conducted on 20 plats, including 2 check plats.

Lahaina and Rose Bamboo sugar cane are grown, 10 plats being devoted to each variety, and the essential plant-food elements, furnished either singly or in combination, are each applied at the rate of 100 lbs. per acre. Analyses of the station soil and of average soils on the 4 principal islands are reported. The data secured during the 8 years are tabulated in detail and discussed.

The results with respect to purity of juice for both varieties show that the highest purity, 90.69 per cent, was obtained on the unfertilized plats, and the lowest, 88.29 per cent, on the plats receiving a complete application with the nitrogen in the form of sulphate of ammonia. The highest sucrose content, 18.26 per cent, was also secured on the unfertilized plats, and the lowest, 16.40 per cent, on the plats given a complete fertilizer with the nitrogen in the form of dried blood. The average yields of sugar for the 2 varieties, together with the percentage of gain or loss from fertilization, are given in the following table:

Comparison of plat yields by four-year periods.

Fertilization.	Yields of sugar per acre.			Gain or loss from fertilization.	
	First period.	Second period.	Difference for second period.	First period.	Second period.
	Pounds.	*Pounds.*	*Per cent.*	*Per cent.*	*Per cent.*
No fertilizer	21,458	15,974	25.6		
Nitrogen	25,047	19,348	22.8	+16.7	+21.1
Phosphoric acid	22,241	13,633	38.7	+ 3.6	−14.7
Potash	24,593	14,182	42.3	+14.6	−11.2
Nitrogen and phosphoric acid	26,464	20,533	22.4	+23.3	+28.5
Nitrogen and potash	29,119	21,478	26.2	+35.7	+34.5
Complete fertilizer	27,379	23,438	14.4	+27.6	+46.2

These experiments have shown that lands capable of producing 11 tons of sugar per acre without fertilization, may be profitably fertilized under favorable climatic conditions and a sufficient water supply. Mixed fertilizers produced a greater percentage of gain as the soils suffered a gradual exhaustion. Rose Bamboo cane seemed to require a larger supply of phosphoric acid in the soil than Lahaina, while Lahaina responded more to an increased supply of potash than Rose Bamboo. Both varieties showed considerable gain from the use of nitrogen, in which the soil was below the average for the islands.

On land much richer in phosphoric acid than the average soil, Rose Bamboo gave larger yields when phosphoric acid and nitrogen were applied together than when nitrogen was given alone, but Lahaina under the same conditions gave about equal yields. On soil containing about the same quantities of potash as an average island soil both varieties gave increased yields when this element was applied with nitrogen. It was also found that the separate use of phosphoric acid in soluble forms on soil already rich in this element may result in a loss of sugar, and that apparently the chances of loss are greater with Lahaina than with Rose Bamboo, where both make an equally thrifty growth under normal conditions.

Separate applications of potassium sulphate to lands under cane also sometimes decrease the yields of cane, and the danger of loss seems greater with Lahaina than with Rose Bamboo. A particular element given alone may produce negative results, but it may be very effective in increasing the yields when applied with some other element. The unfertilized areas produced the purest juice, and, in general, the

plats receiving incomplete fertilizers yielded juices of greater purity than those treated with complete applications.

Wheat growing, F. C. BURTIS and L. A. MOORHOUSE (*Oklahoma Sta. Bul. 65, pp. 35*).—Wheat experiments at the station were begun in 1892. The results up to 1901 have been previously noted (E. S. R., 12, pp. 846, 850), and those secured since that date are reported in this bulletin. A summary for the entire period is given.

A half-acre plat receiving 7.5 tons of barnyard manure the first year of the test and 5.5 tons the second year yielded from 6 consecutive crops 82.9 bu. of wheat, as compared with 53.1 bu. on a like plat without manure. The first and second years the manured plat yielded 18.6 and 18.7 bu. more per acre, respectively, than the unmanured plat, but the last year there was a difference of only 3.1 bu. in its favor. Nearly 2½ bu. of wheat was obtained for each ton of manure applied per acre. In isolated experiments of this kind an average yield of 32.4 bu. from manured land and of 14.4 bu. per acre from unmanured land was obtained in 1894, and of 27.5 bu. from manured land and 14.5 bu. from unmanured land in 1899. These experiments were made on practically virgin soil.

In a test covering 5 consecutive years plats plowed the middle of July averaged 27.1 bu. per acre; plats plowed the middle of August, 24.2 bu., and those plowed the middle of September, 22.1 bu. In July the ground was free from weeds and in better condition for plowing than later in the season. The early plowing also formed the best seed bed.

Experiments on the time of seeding, carried on for 5 seasons from 1899 to 1904, gave an average yield of 24.28 bu. per acre on plats seeded September 10 to 20, 27.49 bu. on plats seeded October 10 to 20, and 17.38 bu. on those seeded November 10 to 20. The late-seeded plats, generally severely damaged by rust, produced the poorest quality of grain. Seeding late in November gave in one experiment an average of only 5.4 bu. per acre, the grain weighing only 45 lbs. per bu. The best results were secured from seedings made from September 20 to October 10.

The results with different quantities of seed per acre show that 5 to 6 pk. per acre usually gave better yields than 3 to 4 pk., but differed but little in yield from the use of 8 pk. In general, moderately thick seeding, or the use of about 6 pk. per acre, is considered safest.

In 2 years' work on pasturing wheat the plats not pastured averaged 2.45 bu. per acre more than plats pastured until March 1, 3.5 bu. more than plats pastured until the end of March, and 9.66 bu. more than those pastured to the middle of April. Late pasturing retarded ripening and made the wheat more subject to rust. When wheat is to be pastured, seeding 10 days earlier is recommended if later seeding is not necessary to avoid insect attacks.

The following varieties, most of them tested from 8 to 10 years, are considered good varieties for Oklahoma: "*Soft smooth wheats*—Early Red Clawson, Fultz, and German Emperor; *soft bearded wheats*—Fulcaster, Missouri Bluestem, and New Red Wonder; *hard smooth wheats*—Red Russian and Oregon Red; and *hard bearded wheats*—Sibley New Golden, Turkey, Weissenburg, Crimean, and Theiss." None of these varieties belong to the durum wheats.

Soil treatment for wheat on the poorer lands of the Illinois wheat belt, C. G. HOPKINS (*Illinois Sta. Circ. 97, pp. 22*).—The management of this particular class of soil is discussed and 4 years' results on 4 soil experiment fields in southern Illinois are reported. The plan of these experiments has been previously described (E. S. R., 15, p. 469). In 1905 an average yield of 29 bu. of wheat was secured on treated soil, and only 9 bu. on untreated soil.

On the Odin field in 1904, an undrained plat on which leguminous crops are grown and lime and phosphorus applied, produced 21.6 bu. of wheat per acre, of which 7.9 bu. are credited to the land and 13.7 bu. to the treatment. On the corresponding tile-drained plat 21.5 bu. per acre was secured, 6.7 being credited to the untreated

land and 14.8 bu. to the soil management. It is estimated that 1.8 bu. of this increase of 14.8 is due to the growing of leguminous crops, 1.1 bu. to the use of lime, and 11.9 bu. to the phosphorus applied.

On the Cutler field on undrained land the same treatment increased the yield of wheat from 7.9 to 17.6 bu. as an average for 3 years. On the plats receiving potassium in addition, the average was further increased by 4.6 bu., which was a more marked effect than that produced on the other fields.

The data secured in 1904 on the Cutler and DuBois experiment fields, where nitrogen was applied at the rate of 100 lbs. per acre in the form of dried blood, in place of growing leguminous crops, show that the land produced 6.2 bu. while the lime increased the yield 3.3 bu., the nitrogen 0.5, the phosphorus 16.6, and the potassium 0.6 bu., giving an average of 27.2 bu. of wheat per acre for 3 tests. It is believed that the first beneficial effect of leguminous crops on this soil was not due solely, or even largely, to the fixation of nitrogen, but rather to the liberation of phosphorus and to the improved physical condition of the soil as brought about by the chemical action of the decaying organic matter of these crops.

The results on the Vienna soil experiment field showed that in 1904 the yield was increased from 6.7 bu. on the untreated soil to 10 bu. on soil growing leguminous crops and treated with lime, and to 14.8 bu. when phosphorus was also given. In 1905, where lime had been applied to correct soil acidity and leguminous crops had added nitrogen and decaying organic matter, the yield was increased from 1.3 bu. on untreated soil to 18.2 bu. per acre with leguminous crops and lime treatment; and where phosphorus was added a further increase of 7.4 bu. was obtained.

It is estimated that during the 3 years the untreated land produced 8.4 bu., the growing of leguminous crops gave an increase of 10.1, the lime treatment an increase of 10.4, and the phosphorus treatment an increase of 19.5 bu., or a total yield of 48.4 bu. The results of 4 years' experiments with pot cultures on unglaciated hill soil showed that an appreciable increase in yield was made only when nitrogen was supplied either in commercial form or by means of growing leguminous crops.

A summarized statement is given showing the yields and value of the wheat produced on the different soil experiment fields. The average yield of wheat in 1903 was 1.9 bu. per acre on the untreated land and 11.9 on the treated land, while in 1904 the yields were 7.6 bu. and 10.5 bu., respectively, or a total of 18.1 bu. on the treated land. In 1905 the treated land produced 28.9 bu. and the untreated land only 9 bu. In 12 tests covering 3 years' work the untreated land yielded on an average 6.1 bu. and the treated land 19.6 bu., the use of leguminous crops and the application of lime and phosphorus being responsible for this increase of 13.5 bu. The cost of the soil treatment, allowing 50 cts. an acre a year for ground limestone and \$2.50 an acre a year for the cost of 200 lbs. of steamed bone meal, is given at \$3 per acre, but it is pointed out that if raw rock phosphorus at \$8 a ton is substituted for the steamed bone meal the total annual expense for materials may be reduced to \$1.70 an acre.

Data on the effect of the soil treatment on corn, oats, and clover indicate that during the first 3 years on the different fields the use of leguminous crops, lime, and phosphorus increased the yield of oats 13.2 bu. per acre. As a result of this treatment an average increase of 13.3 bu. of corn was secured in 6 tests made in 1904, and an increase of 1.14 tons per acre of field-cured clover hay as due to this method of soil management was obtained in 1905 in 5 different trials. The value in the increase in each of the crops was more than enough to pay for the annual cost of the materials.

An experiment showing the comparative value of steamed bone meal and finely ground rock phosphate is noted in the abstract of Circular 96 (see p. 356).

HORTICULTURE.

Report of the horticulturist, B. D. Halsted (*New Jersey Stas. Rpt. 1904, pp. 291–340, pls. 4*).—An account of greenhouse experiments with tomatoes and cauliflower, observations on the weather during the year, and data for the yields of asparagus, small fruits, and vegetables on the permanent plats at the station. The latter has been a prominent feature of previous reports (E. S. R., 16, p. 463). The winter of 1903–4 was especially severe and caused considerable injury to small fruits. The rainfall was unusually abundant throughout the season.

From work done at the station in the greenhouse with tomatoes for a number of years, it is estimated that the expense of caring for a house 100 by 20 ft. is about $300 a year. The average yield of marketable fruit per square foot for 6 years has been 32.33 oz. and the average price 24.3 cts. per pound. The net profit from a house of this size is placed at $428.55 a year.

On the basis of the station work, the following method of growing the crop is advocated: Soil for the benches should be made up of 3 parts turfy loam, 2 parts manure, and 1 part sand, and 2 sq. ft. allowed per plant. The best varieties for forcing are Lorillard and Best of All. These should be 7 or 8 weeks old when set out and trained to single stems. The best fertilizer for tomatoes is solid and liquid cow manure, fresh and directly from the stables, applied to the surface at the rate of 244.64 oz. per 100 sq. ft., or where subwatering is practiced at the rate of 214.28 oz. liquid manure per 100 sq. ft. To prevent root gall frozen sterile earth is used. For dropsy good ventilation and not too much water and heat on dull winter days is recommended. The Aleurodes are controlled by spraying with a mixture made of 1 lb. whale-oil soap and 6 gal. of water added to 1 lb. of tobacco stems in 2 gal. of water. For rot, clean, well-ventilated houses, uniformly heated to 65° F. at night and 75 to 85° F. during the day. Before the houses are filled they are smoked for 2 days with sulphur to kill any spores from the crop of the previous year. The benches are then filled with frozen earth and the plants set, after which they are smoked with tobacco powder to kill whatever insects may be brought in with the plants. Many of the details on which the above conclusions are based are recorded in tabular form and otherwise.

The culture of cauliflower in the greenhouse has been less profitable than that of tomatoes. The average price for 3 years' sales has been at the rate of $1.44 per dozen or 15.8 cts. per square foot of space, while with tomatoes the returns have been 48.6 cts. per sq. ft. With this crop, however, less expensive houses are required and much less care and attention. The only crop of cauliflower which has been found profitable is that which matures heads in April from plants set in the benches in December.

The temperature for this crop should range from 50° F. at night to 70° F. on bright days. Plants give the best returns when allowed about 290 sq. in. each of bench surface and allowed about 42 oz. of manure per 100 sq. ft. on solid beds made up of 16 in. of either sand or soil, and 22 oz. when shallow beds 8 in. deep are employed. The crop is not seriously troubled with diseases or insects. Phosphate of potash has been found superior to muriate of potash and phosphoric acid for this crop. Manure should be used to supplement commercial fertilizers for cauliflower.

On the permanent asparagus plats Palmetto still stands as the best average variety. Unirrigated plats have given better yields than irrigated plats. Selected crowns have not proved superior to ordinary crowns. The largest total and early yields have been obtained on the plat fertilized with barnyard manure at the rate of 20 tons per acre.

Cuthbert was the only variety of raspberry during the year which yielded fruit. The yields obtained with the different fertilizers are tabulated, but no conclusions drawn. Of the blackberries the largest total and early yield was secured on the

manured plat, the plat fertilized with complete fertilizer standing second. The early yield was a little larger on the irrigated plats, but the total yield was much greater on the unirrigated. Agawam and Taylor came through the winter in best condition.

The manured plat of gooseberries has also given better results both with and without irrigation than any combination of commercial fertilizers. With currants the manured plat also stood first. With strawberries, the plat receiving the complete fertilizer with an additional amount of nitrate of soda after blossoming stood first. In both early and total yields the irrigated plats led over the unirrigated. In early yield Glen Mary led with Bubach second.

The yields of apples, peaches, standard and dwarf pears, plums and cherries on plats which are being treated with different fertilizers are recorded but no conclusions drawn. Pears are grown as dwarfs, as dwarfs by cutting, and as standards. Kieffer dwarfs by cutting bore during the year an average of 493 fruits per tree, weighing 152 lbs. 9 oz., while Kieffer standards bore 938 fruits, weighing 252 lbs. 2 oz. per tree. On an acre basis, however, it is calculated that the dwarfs would give an increased yield of 45 per cent due to closer planting than the standards, besides they are preferable from the standpoint of harvesting and of beauty of tree. Being more compact, the branches are also less likely to be broken down by the weight of the fruit.

Bartlett and Lawrence varieties also stand in favor of dwarfs against the standards, but a difference between dwarfs proper and dwarfs by cutting has not yet been definitely established. The Lawrence variety dwarfs by cutting came into bearing a year later than the dwarfs proper.

Report of the botanist, B. D. HALSTED, E. J. OWEN, and J. K. SHAW (*New Jersey Stas. Rpt. 1904, pp. 447–553, pls. 12, figs. 3*).—A leading feature of the work of the year has been the crossing of plants and the growing of hybrids secured in earlier work (E. S. R., 16, p. 464).

The Voorhees Red sweet corn, originated by the station, was distributed to farmers in considerable quantities, and notes from them on the character and quality of the corn as grown during the season are reported. From these reports it appears that the corn is medium large, usually bears 2 ears, and the quality good to excellent. Further notes are given on the cross between Black Mexican and Country Gentleman sweet corn. In these reciprocal crosses the male parent has controlled to a large extent the character and color of the ear.

A study was made of a large number of varieties of sweet corn obtained from different seedsmen throughout the country. These were grown at the station, and notes are given upon their tendency to intercross, especially that of Black Mexican, together with a proposed classification of sweet corn. Some data are incorporated on experiments with conspicuously colored varieties of sweet corn and their tendency to intercross. The Malakhov sweet corn, introduced by this Department from Russia, was sent to a number of growers in the State. This corn appears to have small stalks, with from 1 to 4 ears per stalk. The quality was reported excellent or good.

A second crop of sweet corn was grown in one instance from the matured seed of the first crop. The output of ears of the second crop was small and no seed matured. Apache corn, grown by the Indians of the arid regions of the Southwest, produced an ordinary crop, and it is thought that it may be of some value as a breeder with eastern sorts, especially for corn grown in sandy soils on dry situations.

Six kinds of squashes have been intercrossed and the fruits of some of the results obtained are illustrated, as well as the seeds. The Jersey Belle eggplant, originated by crossing New York Improved Spineless and Early Long Purple, has been grown another season, producing plants very uniform in color and other characteristics.

This variety is considered valuable because of its earliness and the large proportion of fruit which is without seed.

A test was made of a large number of tomatoes. The yields obtained on different dates are tabulated, and the fruiting season, size of fruits, popularity, and other characteristics of the different varieties noted. A scale of points for judging the merits of ordinary tomatoes was devised and its use is illustrated in scoring the varieties grown. In this score card 50 points are given to the fruit and 50 to the plant. The score for the different points is allotted as follows: Size of fruit 4, shape 4, surface 7, skin 3, color 3, cells 7, flesh 7, flavor 5, seeds 5, and decay 5. For the plant the scale is: Form 5, vigor 10, foliage 10, product 15, and disease 10.

A proposed classification for tomatoes is also given, and various varieties classified according to the scheme. A second crop of tomatoes was grown from the seed of some of the earliest varieties to mature. This second crop attained full size, maturing seeds.

Tests were made of bush and pole Lima beans, green-pod bush beans, and wax beans. Classifications are given for green-pod beans and for wax beans, with illustrations of the pods and beans of the different varieties tested. For each variety the weight of vines, weight of pods, number of pods, seeds per pod, and popularity are noted. Considerable work was done in the crossing of beans during the season, but it will require another season to determine the success of the crosses, since beans are easily self-fertile.

Data are also tabulated for weight of vines and pods, and number of pods and seeds in 3 varieties of peas, in which seed of each variety obtained from Canada was compared with the same variety when grown in New York.

Further notes are given on the colors of the blooms of salsify hybrids under cultivation and from self-sown seed. The proportion of each of 9 lawn grasses sown in the mixture in 1896 is noted for each of the years since that date. Likewise, the proportion of weeds on the plat of soil which has been undisturbed since 1897 are recorded.

In a test of Early Snowball cauliflower seed from Denmark, the State of Washington, and an eastern locality, the best results were obtained from the seed grown in the State of Washington.

In experiments with tulip bulbs, American-grown bulbs gave finer flowers and were longer in bloom than foreign bulbs. Notes are given upon *Aralia cordata* as a salad plant, nasturtiums, and the report blanks used by this Department in descriptions of tomatoes.

The usual notes upon the weather are given, showing the rainfall, temperature, and sunshine for the growing season of each of the past 16 years. The condition of crops and the relation of fungi to weather, as shown in the weather and crop bulletins issued weekly by the State weather service during the growing season, are noted with special reports from correspondents in 21 different counties of the State, showing the winter injury to vegetables, fruits, and field crops in various sections.

Results of experiments in production and marketing fruits and vegetables, and canning fruits and vegetables on a small scale, at the North Louisiana Experiment Station, D. N. BARROW and E. J. WATSON (*Louisiana Stas. Bul. 81, 2. ser., pp. 36, pl. 1, figs. 2*).—In order to obtain results of commercial importance and also to encourage farmers in the neighborhood to engage in the shipping of fruits and vegetables, a number of vegetables were grown at the station during the season in considerably larger quantities than heretofore. These were shipped in cooperation with the farmers of the neighborhood in carload lots.

From seven-eighths of an acre of tomatoes 236 crates were shipped and about 60 crates were canned. The average net return was about 50 cts. per crate, and the cost of growing an acre from seed bed to market was placed at $50. From one-eighth

of an acre in cabbage 16 crates weighing about 175 lbs. per crate were obtained. The cost of production is placed at $40 per acre. The season for string beans was unfavorable. From one-fourth of an acre 18 bu. was obtained. The price received averaged 50 cts. per bushel net; and the cost of growing an acre is placed at about $20.

From one-eighth of an acre of radishes 820 bunches containing 6 to 10 radishes per bunch were obtained. The first planting of bush Lima beans proved unsatisfactory. From the second planting made the first of June 24 bu. of dry shelled beans were obtained, worth $2 per bushel. The expense of growing muskmelons is placed at $30 per acre and watermelons at $20 per acre. From 3 to 5 salable watermelons were obtained per hill. The melons were of good size, averaging 24 lbs. per melon. No shipments were made.

Squashes cost about $20 per acre. Early Bush yielded about 70 bu. and Crookneck about 66 bu. per acre. One small shipment of Early Bush netted about 75 cts. per bushel crate. One-eighth of an acre of okra was grown but no shipments were made of this crop. Considerable quantities, however, were successfully canned, the resulting product being of high quality. By keeping the mature pods pulled off the crop lasted through the entire season. About 60 bu. per acre was obtained.

Peas were grown only on small areas. They did so well, however, that one small shipment was made which sold for 50 cts. per bushel. The yield of onions was at the rate of 86 bu. per acre which had a market price of $1.50 per bushel. The results of variety tests with a number of the vegetables mentioned above are included in the notes, as well as the results of variety tests with peaches, plums, apples, pears, strawberries, and figs.

In the canning experiments two $10 outfits were used, each having a capacity of 300 2-lb. cans and 200 3-lb. cans per day. With these 2 outfits the cost of canning 600 2-lb. cans of tomatoes daily was placed at $21.40. The net price for the canned product was 70 cts. per dozen or $35, leaving a balance of $13.60 per day. The cost of 400 3-lb. cans of peaches was $20.40. These sold for $1.75 per dozen, or a total of $58.33, leaving a net balance of $37.93 per day.

Pears were found even more profitable than peaches, since a bushel of pears filled an average of 24 3-lb. cans, while a bushel of peaches filled only 16 3-lb. cans. It is believed that canning may be profitably employed in utilizing the surplus that can not be profitably shipped to market.

Where king watermelon reigns supreme (*Cal. Cult., 24 (1905), No. 19, pp. 435, 450, fig. 1*).—The author of this article made a trip to the Glendale-Burbank melon section in the region of Los Angeles, and describes the methods of watermelon culture followed in that district.

The vines are planted 12 by 12, 10 by 14, and 8 by 16 ft. apart, each of these different distances having adherents. The Chilean White is the variety chiefly grown. In addition a few Georgia Rattlesnakes and Kleckley Sweets are grown. Before planting the seeds are soaked for about 12 hours in warm water and most growers sprout them before planting.

Sprouting is accomplished by digging through a pile of warm manure down to the ground, spreading the seeds in sacks so that they are about 1 in. deep, covering them with warm manure, and leaving them there until sprouted, after which they are planted immediately. Where manure is scarce a fire is sometimes built on the ground to warm it. The ashes are then scraped away and the seeds buried in the warm earth, being covered as before with manure to prevent the escape of heat. One large grower sprouts his seed by placing them in Mason jars and keeping them in warm water. By this latter method it requires on an average about 36 hours to sprout the seed, the time varying with the temperature of the water.

The seeds are planted mostly in raised hills or on backfurrows. Cultivation consists in keeping the weeds down and preserving a dust mulch. The vines are also compacted in the center of the rows as much as possible to shade the melons and

thus prevent sunburn. The chief disease is blight and this is kept under control by planting the melons on new ground at least every second year. Plant lice are controlled by spraying with soap mixtures.

Fall and winter culture of Pé-tsaï, J. CURÉ (*Rev. Hort. [Paris], 77 (1905), No. 6, pp. 148, 149*).—The author gives his results in the winter culture of Pé-tsaï or Chinese cabbage. The plant appears to be nearly as hardy as ordinary cabbage.

Water cress supplies (*Gard. Mag. [London], 48 (1905), Nos. 2685, p. 237; 2686, p. 252*).—An investigation was made, under the auspices of the London County Council, of the water cress beds grown within a radius of 50 miles of London.

One hundred and fifty beds ranging from less than a quarter of an acre to upwards of 40 acres in extent were visited. Of this number 35 beds were not liable to pollution and 67 beds were probably polluted, the water used in the majority of the cases on these beds being about equal in quality to that of the Thames. There were 27 beds that were actually polluted and 11 beds in which there was a gross actual pollution. The possibility of thoroughly cleansing the cress grown in polluted water was investigated.

The results indicate that thorough washing will remove a large proportion of the impurities, but "that no ordinary amount of washing could be relied on to rid cress grown in polluted waters of all undesirable microbes. This may be due either to bacteria so firmly adhering to the exterior of the plant as to resist being swept away during the washing process, or to the cress harboring microbes within its structure, or to a combination of these causes." Under normal kitchen conditions it is believed that the chances for cleaning the water cress would be less favorable than exists in a laboratory.

An apple orchard survey of Orleans County, G. F. WARREN (*New York Cornell Sta. Bul. 229, pp. 461-499, figs. 15*).—This is the second report on this subject. The first report dealt with orchard conditions in Wayne County, New York (E. S. R., 17, p. 41).

The present report presents the results of a similar survey of Orleans County. In this county 564 orchards, containing 4,881 acres, or a little more than one-fourth of the total area in apples in the county, were personally examined with reference to topography, soils, varieties, tillage, drainage, fertilizers, cover crops, pruning, spraying, yields, markets, prices, income per acre, etc. From 70 to 90 per cent of the fruit grown in Orleans County is barreled and sold, while in Wayne County the greater part is evaporated.

Generally speaking, better cultural practices are observed in the apple orchards in Orleans County than in Wayne County. It is believed that greater profit would be obtained by orchardists in Orleans County if greater attention was paid to sorting and grading the fruit and more extensive use made of the apple evaporator.

Briefly, the survey shows that Baldwin and Rhode Island Greening are the leading varieties of apples grown in the county. The 5-year average yield of orchards cultivated 10 years was 86 per cent greater than for orchards 10 years in sod. Apples from tilled orchards have brought slightly better average prices than from orchards in sod. One-fifth of the orchards in sod have given as good results as the average tilled ones, but no method of sod treatment has been found to equal tillage in average yield or income. Cover crops are used in about 3 per cent of the area examined, red clover and buckwheat being the favorite crops for this purpose.

The average income per acre from well-cared-for orchards was as follows: Unsprayed, $103; sprayed once, $139; sprayed twice, $143; sprayed 3 times, $184. In 1904 most of the unsprayed orchards showed about 90 per cent of scabby fruit, while over half of the orchards sprayed 3 times were practically free from scab.

The best orchards were found on loamy soils. Good apples were also grown on quite sandy soil. A loss of 8 to 10 per cent of apple trees was found to be due to poor drainage. The gross income in over half the orchards has averaged over $100 per

acre during the past 5 years. The data in the bulletin supplement that obtained from Wayne County and serve to confirm the recommendations there given as to the best cultural practices to follow.

The avocado, a salad fruit from the Tropics, G. N. COLLINS (*U. S. Dept. Agr., Bur. Plant Indus. Bul. 77, pp. 52, pls. 8*).—The author visited certain parts of Mexico, Central America, and the West Indies, and gives the results of his observations in these regions with reference to the avocado.

The origin, history, and botanical affinities are discussed, and the types found in Guatemala, Porto Rico, Mexico, Costa Rica, Cuba, and Hawaii are noted. The culture of the avocado is considered at length and an account given of some experiments in shipping avocados from Hawaii to New York City. Five crates were thus shipped experimentally in cold storage. They were 30 days in transit. The majority of the samples suffered considerably from the long trip, but some lots were found in good condition, demonstrating that with better knowledge of methods of handling these fruits can be successfully shipped in cold storage providing they are not too long in transit.

Especial interest is attached to the thick-skinned avocados found in Guatemala. These varieties promise to withstand shipment much better than the thin-skinned varieties, and the culture of these in Porto Rico, it is hoped, will aid materially in establishing a profitable industry in that island. The food value of the avocado is discussed by C. F. Langworthy and compared with that of a number of other fruits.

Cooperative experiments with small fruits, H. L. HUTT (*Ann. Rpt. Ontario Agr. and Expt. Union, 26 (1904), pp. 31-38*).—The kinds of small fruits which were sent out by the college to experimenters during the year are given, together with the cultural directions which accompanied them.

The influence of American stocks on the quality of wine, E. HOTTER (*Ztschr. Landw. Versuchsw. Oesterr., 8 (1905), No. 5, pp. 565-571*).—The effect on the composition of the fruit and on the quality of wines obtained from European grapes grown on their own roots and on American stocks was studied. Nine European varieties were thus compared. The fruit of 7 kinds on American stock contained more acid and 2 kinds less acid than when grown on their own roots. Five varieties of European grapes on their own roots one year and 6 varieties another year contained slightly more sugar than the same varieties on American stocks.

Relative to the wine made, that from grapes on their own roots contained more phosphoric acid than that from grapes on American roots. The results were the same whether the grapes were fermented with the stems or not, or whether the must was pressed immediately or after a considerable period. Tables are given which show in considerable detail the composition of fruit and the wine obtained from each variety of grape during the 2 years of the investigation.

Chinese fruits, G. E. ANDERSON (*Mo. Consular Rpts. [U. S.], 1905, No. 294, pp. 52-54*).—An account of the kinds and value of different fruits most commonly grown in China. For the most part they appear to be much inferior to American fruits.

The persimmon, which is highly esteemed in China, is thought to be less astringent than the American persimmon. It grows large and is a good keeper. The author states that probably the best all-round fruit in China is the pomelo. This resembles the American fruit in size, shape, and color, but is sweeter and has less of the bitter quality, while the flesh is more perfectly separated into sections, as in the case of oranges. It has better keeping qualities than the orange and is strongly recommended to American horticulturists.

The preparation of fruit pulp (*Bot. Dept. [Trinidad], Bul. Misc. Inform., 1905, No. 46, pp. 174-176*).—The method of preparing fruit pulp in France for shipment to England, to be manufactured into jams, is given for a number of different kinds of fruit, such as black currants, cherries, raspberries, apricots, plums, and the like.

An experiment was made to determine the length of time that black currants will keep in cold storage when packed at different stages of maturity. When gathered while still green, 15 to 18 days before maturity, they kept perfectly for 1 month and then gradually withered and dried. When gathered some 5 or 6 days before maturity, they kept perfectly for 46 days and were good for 12 days later. Gathered when quite ripe they kept fresh for 26 days, but 9 days later they showed slight signs of withering.

Cold storage for the preservation and transportation of food and horticultural products, VALVASSORI (*Bul. Mens. Off. Renseig. Agr.* [*Paris*], *4* (*1905*), *No. 5, pp. 532–542*).—The author visited a number of cold storage houses in Milan, Frankfurt, Cologne, and Berlin, and gives brief descriptions of the different plants, and in some instances an account of the temperatures observed in the preservation of different products.

At Milan lily of the valley rhizomes are placed in cold storage in May. They are drawn out and forced according to the needs of trade. After withdrawal they produce flowers in about 15 days. The usual period of forcing is from October to January. Lilacs are also kept in cold storage and withdrawn for forcing toward the end of October. They may be withdrawn, however, at any other time in the year.

Other plants retarded in cold storage to be withdrawn when needed are asparagus, strawberries, azaleas, rhododendrons, *Kalmia latifolia*, *Hydrangea paniculata*, *H. hortensia*, Spiræa, etc. In this establishment ripe cherries put in cold storage in June kept well until August; temperature not stated. At Cologne grapes on the stem maintained at a temperature of zero kept in prime condition for 4 months. At Hamburg lily of the valley was kept at a temperature of - 6°.

A new coffee from central Africa, A. CHEVALIER (*Compt. Rend. Acad. Sci.* [*Paris*], *140* (*1905*), *No. 8, pp. 517–520*).—A botanical account is given of *Coffea excelsa*, a tree which grows 18 to 60 ft. high.

Analyses are given of the soil on which it flourishes. The soil is especially rich in nitrogen and soda, and contains only very small amounts of potash, phosphoric acid, and lime. The coffee seeds are small and rounded, taking about 10 to a gram. A wild tree 5 years old measured 8 meters in height and contained 600 fruits. The following analysis is given: Water at 100° 7.66, caffein 1.89, nitrogen 3.11, fat 12.58, and ash 3.75 per cent. The coffee is classed as among the best sorts known at the present time.

How walnuts grow, J. L. BOWERS and F. GILLET (*Pacific Rural Press*, *69* (*1905*), *No. 22, p. 340*).—Two different views are given by these writers on how walnuts sprout and how the seed should be planted in the ground. Mr. Bowers states that nuts should be planted with the point down. Mr. Gillet maintains that walnuts like all nuts should be planted with the suture or seam perpendicular to the line of the horizon—that is, lying on the seam, and never on the face or with the small or big end down.

Home-grown bulbs, A. J. PIETERS (*Amer. Florist*, *24* (*1905*), *No. 888, pp. 908, 909*; *Gardening*, *13* (*1905*), *No. 307, p. 297*).—An account is given of a test on the trial grounds of this Department of certain varieties of narcissus raised in Virginia, in comparison with the bulbs from 3 European houses.

The Virginia-grown bulbs gave decidedly the best results. The bulbs of Emperor gave magnificent flowers, being as large as any seen from the best imported stock. *Narcissus princeps* was also very satisfactory, and *N. poeticus poetarum* just as good as any others, although neither obtained the high standard of Emperor.

FORESTRY.

Report of the chief of the Bureau of Forestry of the Philippine Islands, G. P. AHERN (*Philippine Bur. Forestry Rpt. 1904, pp. 68, pls. 25, map 1*).—This is an account of the inspection service and forest management in the various districts of the Philippine Islands, with a statement of the licenses granted, amount of timber cut, the results secured in the timber-testing laboratory, the forest products of the islands for the fiscal year ended June 30, 1904, average Manila prices of timber and lumber, etc.

Some work is being done in the growing of tropical and deciduous fruits, forage plants, and the maintenance of forest nurseries. The details of physical tests of 13 Borneo woods are also included in the report.

Report on the examination of a forest tract in western North Carolina, F. W. REED (*U. S. Dept. Agr., Bur. of Forestry Bul. 60, pp. 32, pls. 6, map 1*).—This report gives the results of a careful examination of a tract of about 16,000 acres lying in the mountains of western North Carolina.

The prevailing timbers in different parts of this tract are mapped, the products which they will yield noted, and specific directions given regarding their management as a source of revenue and the maintenance of the present natural beauty of a large portion of the tract. The bulletin is an illustration of the method of the Bureau of examining private forest lands and extending expert advice in their management.

History of Austrian forestry, LASPEYRES (*Ztschr. Forst u. Jagdw., 37 (1905), Nos. 1, pp. 30–42; 2, pp. 113–124*).—In commemoration of the 50-years' reign of Francis Joseph, Emperor of Austria, a jubilee history of the development of agriculture and forestry in Austria for the years 1848 to 1898 was written. One of the 5 volumes deals with forestry. The extracts from this work given in this article relate to the development of the forest industry and its constitution, the use of the forest, sylviculture, forest management and protection, transportation of forest products, and forest engineering.

Investigations on the influence of kiln-drying at different temperatures on the percentage germination of pine seed, HAACK (*Ztschr. Forst u. Jagdw., 37 (1905), No. 5, pp. 296–312, dgms. 9*).—A report is given upon the results of an investigation upon the germinative ability of pine seeds gathered at different periods in the fall and kiln-dried at different degrees of temperature.

In these experiments seed gathered late in the fall germinated as well as seed gathered the following March. Seed gathered the middle of August had a whitish unripe appearance, was subject to mold, and gave a percentage germination of 80 to 92. A month later the seeds were more nearly ripe and gave a percentage germination of 90 to 98. It is believed that by the beginning of November of every year pine seeds have reached their full germinative ability.

Seeds mechanically removed from the cones early in the season without drying gave a higher percentage germination and germinated in half the time required for dry seeds. March-gathered seed, kiln-dried at a temperature of 65° C. 7½ hours, gave a percentage germination of 78 to 87. When kiln-dried at 61° C. for 2 hours and the temperature then gradually decreased to 55° C. for 9 hours the percentage germination was 94 to 97.

With the more sappy cones gathered in December kiln-drying at 65° C. decreased the percentage germination to 20 per cent. Even the seedlings that did grow when the seed was dried at this temperature presented a stunted appearance. It was determined that the maximum temperature at which these sappy fall cones may be kiln-dried is 60° C. for 2 to 3 hours, decreasing then to 55 to 56° C. The optimum temperature for such cones is placed at 49° C. Naked seeds were found able to withstand without injury to their germinative ability a much higher temperature and for a longer period than seeds in the cones.

The following general deductions are drawn by the author from the experiment: Pine seeds are very sensitive to a high degree of heat. Between the permissible and injurious temperatures lie so few degrees that extra care is necessary in kiln-drying these seeds. The greatest danger lies in kiln-drying moist cones. For this reason cones which remain longer on the tree and are, therefore, riper and drier are to be preferred for seed purposes, and not for the reason sometimes given that the seed in early-picked cones is less able to germinate.

Natural grafting, L. S. HOPKINS (*Amer. Inventor, 14 (1905), No. 2, p. 33, figs. 2*).—Illustrations and descriptions are given of two natural grafts between adjacent sycamore trees.

Thinning spruce, SCHWAPPACH (*Ztschr. Forst u. Jagdw., 37 (1905), No. 1, pp. 11–30*).—The right method of growing spruce has long been considered a settled question by German foresters. Observation in Austrian forests, however, where the use of small timbers necessitated the thinning of spruce much earlier than usual led to the discovery that from the standpoint of greater growth and larger profits early thinning, which gave opportunity to the remaining trees for better crown development, was very desirable.

The details of the investigation are recorded at considerable length, based upon which the following conclusions are drawn:

(1) By growing spruce in dense stands the crown is stunted and food elaboration therefore impaired. (2) The method of growing spruce close together in youth, and first thinning in middle age, does not use the site to the full capacity and results in a loss to the owner. (3) A stunted spruce crown regains its vigor very slowly and on poor sites not at all. Consequently late thinning exercises no considerable influence on the accretion.

(4) A rational treatment of spruce forests requires, therefore, avoidance of too close planting, say from 4,000 to 6,000 plants per hectare, and (5) the gradual decrease of this number through frequent thinnings as soon as the branches begin to die off to a height of 12 to 15 ft. (6) The aim in thinning must be the production of the greatest possible number of well-developed stems with crowns fully developed on all sides and the trees as equally distributed over the area as possible, constant attention being given to the breaking up of the groups. (7) The live portion of the crown should never average less than 30 per cent of the height of the tree.

The regulation of the spacing in planting and thinning spruce forests, MARTIN (*Ztschr. Forst u. Jagdw., 37 (1905), No. 7, pp. 419–427*).—The author briefly reviews the paper by Dr. Schwappach above and gives supplemental data along several lines drawn largely from German sources.

The data given do not show any stunting of the crown resulting from too close planting, and the author believes that no hard and fast rules as to spacing in planting and in thinning spruce can be formulated. From an economic standpoint thick planting where there is a considerable demand for small timber, as in Germany, may be of as great value as a less number of larger trees.

The effect of forest cover upon stream flow, W. B. GREELEY (*Forestry and Irrig., 11 (1905), Nos. 6, pp. 163–168; 7, pp. 309–315, figs. 4*).—A discussion of the general factors governing stream flow. In addition to the effects of forest cover, the varying influences of precipitation, topography of the drainage basin, and its geological character are discussed.

Investigations in connection with the Reclamation Service covering 3 years were made with reference to these factors in 2 tributaries of the Hudson, Esopus Creek, and Wallkill River. The catchment area of Esopus Creek has only about 15 per cent of cleared land on it. In the Wallkill Basin, on the other hand, about 85 per cent of the land is cleared. Precipitation and climatic conditions in the two basins are practically the same.

The grade of the slope of the Esopus Basin is 13.05 per cent or twice as steep, and the fall of the river is 59.6 ft. per mile, or about 6 times as rapid as that of the Wallkill. The topography of the basin is also much more simple and direct. There are no natural reservoirs in the Esopus Basin, while 42.52 sq. mi. or 5.04 per cent of the total area of the Wallkill Basin is occupied by lakes, ponds, or swamps.

The characteristic geological features of the Wallkill Basin are deep layers of fine loamy, marly soils of large absorptive capacity, while in the Esopus Basin there is only a thin layer of soil which tends to shed water immediately rather than to store it.

Studying the weekly deviation of these 2 streams from 1901 to 1903, inclusive, it was found that the percentage deviation from the average weekly mean flow was 78.24 per cent for the Wallkill and 83.69 per cent in the case of the Esopus. It is thus shown that the combined influence of moderate topography, natural reservoirs, and favorable geological conditions of the Wallkill are stronger in promoting evenness of stream flow than the compact forest of the Esopus. The difference, however, is small, the forest cover overcoming in a very large degree the unfavorable effects of steep topography, hard and dense surface rocks, and marked deficiency in natural storage facilities.

It is concluded, therefore, from the evidence in hand that temperature and precipitation being equal, the relative regularity of stream flow is determined first by the topographic and geological conditions, and second by the character and extent of forest cover.

Fire protection in the teak forests of Burma, R. S. Troup (*Indian Forester, 31 (1905), No. 3, pp. 138–146, dgms. 2*).—The author made a careful study of the growth and reproduction of teak on an area of 37 acres, which had had fire protection since 1872–73, and another area of 24 acres lying alongside, which had had no fire protection and which was burnt over annually.

From the data obtained it is shown that in moist, mixed, fire-protected forests the bamboo grows so rapidly as to depress and severely injure teak trees, while with annual burning the bamboo is suppressed sufficiently to permit of the very satisfactory growth of teak. The locality chosen for this experiment is believed to be typical of hundreds of square miles in Burma, and it is believed that fire protection over such areas is decidedly injurious to the development of teak.

In Vol. 31, No. 7, pp. 383–388, of the same publication, a number of discussions on the above paper appear, some of which confirm the author's views, and others point out that in the very dry teak forests of Burma, where the cover is much lighter, fire protection is of undoubted value in aiding the young teak plants to establish themselves.

Discovery of maniçoba rubber forests in Brazil, H. W. Furniss (*Mo. Consular Rpts.* [*U. S.*], *1904, No. 287, pp. 52–57*).—The author states that extensive forests of "maniçoba" or Ceará rubber (*Manihot glaziovii*) have recently been discovered in the interior of Brazil, particularly in Bahia.

Methods of maniçoba rubber culture are discussed, with an account of milk production and of extracting and collecting the latex. The quality of this rubber seems to be very high. It is believed that it could be profitably introduced into the southern part of the United States, and especially into Porto Rico and the Philippines. Statistics are given on the exports of the Bahia rubber to different countries of Europe and the United States during each of the years 1901 to 1904.

Rubber tapping in the botanic gardens, Singapore (*Agr. Bul. Straits and Fed. Malay States, 4 (1905), No. 5, pp. 144–154*).—Tabulated data are given which show the yields obtained from trees of different sizes tapped in the morning as compared with those tapped in the evening. There were 15 trees in each experiment and 5 experiments were made. The trees in the different experiments varied in circum-

ference from 3 to 7 ft. On the whole, the morning tappings gave about 10 per cent better results than evening tappings.

Terms used in forestry and logging (*U. S. Dept. Agr., Bur. Forestry Bul. 61, pp. 53, map 1*).—The various popular and technical terms used in forestry and logging are defined and in many instances their equivalents given in German and French. The work was prepared by the Bureau of Forestry in cooperation with the Society of American Foresters.

Forestry terms in French, English, and German, J. GERSCHEL (*Vocabulaire Forestier Français-Anglais-Allemand. Paris and Nancy: Berger-Levrault [1905], 4. ed., pp. 203; rev. in Rev. Eaux et Forêts, 44 (1905), No. 2, pp. 48, 49*).—Previous editions of this work have been in the German and French languages. In the present edition the work has been enlarged to include English forestry terms.

DISEASES OF PLANTS.

Minnesota plant diseases, E. M. FREEMAN (*St. Paul: The Pioneer Press, 1905, pp. XXIII+432, pl. 1, figs. 211*).—The author's chief aim in this book is to disseminate knowledge of the destructive parasites of useful plants, to assist all concerned with the cultivation of plants to a more intelligent and thorough understanding of the habits of these parasites, and to point out established methods of combating such diseases. The object of the work is educational rather than immediately practical, the author thinking the practical combating of diseases will follow a better conception of their cause and importance.

After describing fungi in general, chapters are devoted to their physiology, reproduction, etc., fungi as causes of disease, different kinds of fungi, diseases due to causes other than fungi, etc. The economics of prevention and cure are discussed, formulas for fungicides are given, and spraying apparatus described, after which specific diseases are described under the heading of diseases of timber and shade trees, field and forage crops, garden crops, orchards and vineyards, greenhouse and ornamental plants, and wild plants.

The author has unavoidably omitted some diseases, while others, although not yet observed in the State, are included on account of their importance. A number of plant diseases are also described which are economically of minor importance but which are illustrative of certain classes of diseases that otherwise could not be treated.

The author has drawn freely on experiment station literature for information regarding diseases and their prevention. The work is especially commendable on account of its appearance and the excellence of its illustrations, most of which are new.

A report on plant diseases of the State, J. L. SHELDON (*West Virginia Sta. Bul. 96, pp. 69–99, pls. 6*).—Popular descriptions are given of a number of diseases of cultivated plants, the information being based upon the author's investigations while traveling about the State and also upon a large number of replies to letters sent out asking for information relative to diseases. The arrangement is alphabetical by host plants.

Annual report of the literature of plant diseases for 1903, M. HOLLRUNG (*Jahresbericht über die Neuerungen und Leistungen auf dem Gebiete der Pflanzenkrankheiten. Berlin: Paul Parey, 1905, pp. VIII+374*).—A review is given of the literature relating to plant diseases and insect injury to plants for the year 1903, which includes references to more than 2,200 articles either by abstract or title. The arrangement of the material and method of treatment is similar to that in previous volumes (E. S. R., 14, p. 1091).

Notes on the Erysiphaceæ of Washington, W. H. LAWRENCE (*Jour. Mycol., 11 (1905), No. 77, pp. 106–108*).—A list is given of the species of powdery mildews col-

lected by the author in the State of Washington, with critical notes regarding the different species, the host plants, etc.

The Ustilagineæ, or smuts, of Connecticut, G. P. CLINTON (*Conn. State Geol. and Nat. Hist. Survey Bul. 5, pp. 45, pls. 7*).—A list of smuts known to occur in Connecticut is given, based chiefly on collections made by the writer during the past 3 seasons, which are contained in the herbarium of the Connecticut State Station. The list embraces descriptions of 12 genera and 50 species.

Cultures of Uredineæ in 1904, J. C. ARTHUR (*Jour. Mycol., 11 (1905), No. 76, pp. 50–67*).—The author gives a report upon investigations of plant rust which cover studies from 1899 to 1904. In these studies the grass and sedge rusts hold a prominent place, but a number of others have been included.

Successful cultures which have not hitherto been reported are given as follows: *Melampsora bigelowii* grown from teleutospores on *Salix amygdaloides* sown on *Larix decidua; Puccinia tomipara* from teleutospores on *Bromus ciliatus* sown on *Clematis virginiana; Puccinia stipæ* from teleutospores on *Stipa spartea* sown on *Aster multiflorus, A. ericoides*, and *A. novæ-angliæ; Puccinia sorghi* from æcidiospores on *Oxalis cymosa* sown on *Zea mays;* and *Puccinia podophylli* from æcidiospores on *Podophyllum peltatum* sown on same host.

The cedar apple fungi and apple rust in Iowa, L. H. PAMMEL (*Iowa Sta. Bul. 84, pp. 36, figs. 11*).—During the past few years apple rust has become so prevalent in Iowa that the author was led to investigate the subject and presents the results in this bulletin.

The relationship between the cedar apples caused by Gymnosporangium upon junipers, and the Rœstelia stage occurring on a number of rosaceous plants is described. Lists are given showing the connection between different species of Gymnosporangium and Rœstelia, after which the author describes at some length *G. globosum, G. macropus, G. clavipes, G. nidus-avis*, and *G. clavariæforme*. The distribution of these species is indicated and the relationship between the two forms pointed out.

A number of inoculation experiments made by the author and others are described, showing the results of the transfer of spores from the cedar apples to the leaves of different varieties of apples, to crab apples, service berry, etc. Decided differences are noted in the degree of susceptibility possessed by different varieties of apples, and for the control of the rusts the author recommends the planting of resistant varieties and the removal of the cedar trees about orchards.

Report of the mycologist, J. B. CARRUTHERS (*Admin. Rpts. Roy. Bot. Gard. Ceylon, 1904, Ed., Sci., and Art, pt. 4, pp. 5, 6*).—Notes are given on the gray blight of tea, caused by *Pestalozzia guepini*, the root disease of tea (*Rosellinia radiciperda*), and diseases of rubber, cacao, and betel pepper.

On the occurrence of Peronospora parasitica on cauliflower, H. VON SCHRENK (*Mo. Bot. Gard. Ann. Rpt., 16 (1905), pp. 121–124, pls. 3*).—It is stated that cauliflower plants grown in a greenhouse in the Missouri Botanical Garden during 1903 were almost universally attacked by the mildew, *Peronospora parasitica*.

The fungus made its appearance suddenly, and within a week had affected practically every plant in the greenhouse and threatened the entire destruction of all cauliflowers. Acting upon various suggestions for the control of this fungus a number of sprays were used including copper sulphate, ammonium copper carbonate, and potassium sulphid. In order to make the solutions more adhesive small quantities of glue were added and it was found to form a very effective way of holding the solutions on the leaves of the cauliflower.

Good results were obtained with all the sprays with the exception of ammonium copper carbonate, which while killing the fungus caused other injuries to the leaf which are mentioned in another place. The fungus disappeared during the spring months, and the following winter the beds of the greenhouse were carefully treated

with lime. Since that time there has been no further attack upon the cauliflower in this house.

Intumescences formed as a result of chemical stimulation, H. VON SCHRENK (*Mo. Bot. Gard. Ann. Rpt., 16 (1905), pp. 125–148, pls. 7*).—As mentioned in another place, while spraying cauliflowers for the crucifer mildew, *Peronospora parasitica*, with ammonium copper carbonate certain injuries were noted on the leaves. These were more abundant on the lower surface than on the upper, and consisted of various irregular swellings and distortions. The experiments carried on showed that similar intumescences were produced by means of weak solutions of other copper salts, and that they were entirely independent of the soil or atmospheric conditions.

They are considered a result of the stimulating activity of chemical poisons sprayed upon the leaf in weak solutions. This activity is probably due to the formation of compounds within the cells, either in combination with the copper salts or compounds which are a result of the stimulus observed by the spray. This is evidenced by the presence of large amounts of oxidizing enzyms as a result of extra stimulus exerted by the salts sprayed upon the leaf surface. A bibliography of 40 papers is appended to the report.

A disease of cauliflower and cabbage caused by Sclerotinia, G. G. HEDGCOCK (*Mo. Bot. Gard. Ann. Rpt., 16 (1905), pp. 149–152, pls. 3, fig. 1*).—For several years a disease of cauliflower and cabbage has been observed at the Missouri Botanical Garden and in the vicinity, which is manifested by a dark rot of the plants accompanied by numerous tiny black specks.

The disease was at first thought to be a form of the bacterial rot, but a more careful examination showed that the interior of the cauliflower stems was uniformly filled with mycelium of the fungus which was identified as *Sclerotinia libertiana*. The rot produced by this fungus is more watery and the diseased tissues are not so dark as in the case of the bacterial rot of cruciferous plants.

Inoculation with the ascospores from the apothecia and the mycelium from pure cultures produced the typical rot of the cauliflower. Control plants, wounded but not inoculated at the same time, remained free from the disease.

A disease of cultivated agaves, G. G. HEDGCOCK (*Mo. Bot. Gard. Ann. Rpt., 16 (1905), pp. 153–156, pls. 3*).—A number of small plants of *Agave utahensis* were potted during the spring of 1904 and placed in the large collection of the Missouri Botanical Garden. In a short time many of the plants were found dying from a disease which first attacked the older leaves.

A study of the fungus showed that it belonged to the species Colletotrichum and inoculation experiments showed that it could be readily transferred. The disease has a striking appearance, the tissues penetrated by the mycelium showing either a circular or elliptical spot which at first is dark in color, changing as the tissues die, to brown or gray. Under humid conditions the leaves turn brown and rot rapidly.

Bordeaux mixture of the ordinary formula proved beneficial in preventing the spread of the fungus to adjacent plants.

Fungus galls, H. VON GUTTENBERG (*Beiträge zur physiologischen Anatomie der Pilzgallen. Leipsic: Wilhelm Engelmann, 1905, pp. 70, pls. 4; rev. in Nature [London], 72 (1905), No. 1867, pp. 339, 340*).—In this work the author describes the effects caused by 5 different fungi on as many host plants.

Both fungi and hosts belong to widely separate families and include Albugo on shepherd's purse, Exoascus on alders, Ustilago on maize, Puccinia on Adoxa, and Exobasidium on Rhododendron. The author attempts to explain the various anatomical changes occurring in the fungus galls from a physiological standpoint. These changes, in his opinion, are mostly due to a change of function which the tissues assume under the influence of the parasite for its exclusive benefit.

In the main, the author considers the fungus as controlling the development of the host plant, but in the case of the corn smut it is shown that where the intracellular

hyphæ pass through cells they become inclosed in a cellulose tube which may subsequently become more or less thickened. The changes produced in the nuclei of hosts, the development of haustoria, etc., are described, and on the whole the work treats of the subject from a somewhat new point of view.

Ripe rot, or anthracnose, of banana (*Agr. News [Barbados], 4 (1905), No. 83, p. 189*).—A brief note is given on a ripe rot or anthracnose of bananas, an account of which has been previously presented (E. S. R., 15, p. 486).

Thrips and black blight, H. A. BALLOU (*Bot. Dept. [Trinidad], Bul. Misc. Inform., 1904, No. 44, pp. 132-135*).—A report is given of investigations carried on by the author on the thrips of cacao and the black blight.

The thrips (*Physopus rubrocinctus*) has been known in Grenada for a number of years, and where present in abundance is associated with the black blight. This blight is due to the fungus Capnodium, which finds its most favorable conditions for growth in the secretions of scale insects. A list of trees is given upon which the black blight was conspicuous, among them being the mango, breadfruit, sapodilla, guava, limes, and oranges.

No serious attack of black blight has been observed on cacao or nutmeg, and it is believed that until scale insects attack these plants the black blight will not. The control of the fungus is a rather simple affair, and consists of spraying to destroy the various scale insects.

Pod diseases of cacao (*Agr. News [Barbados], 4 (1905), No. 83, p. 189*).—There are said to be 3 pod diseases of cacao, only 2 of which are of serious importance in the West Indies. These are the Trinidad pod disease, caused by the fungus *Phytophthora omnivora* and the brown rot due to *Diplodia cacaoicola*. Both of these diseases are described, and precautionary measures of burning or burying the pods are recommended.

Witch broom disease of cacao (*Agr. News [Barbados], 4 (1905), No. 78, p. 105*).—This disease, which has been considered a very destructive one, the author claims is a consequence of poor development of trees, the roots frequently being set in ground that is perfectly saturated with water for several months at a time. The result of planting in such a situation is a weak growth, making the trees particularly susceptible to fungus attack. It is also observed that trees that are more than 35 years old are also subject to the fungus by reason of their impaired vitality.

Disease in immortelles (*Bot. Dept. [Trinidad], Bul. Misc. Inform., 1904, No. 44, p. 148*).—For some time complaint has been made that cacao shade trees were dying in certain regions, the tree most affected being the immortelle, *Erythrina umbrosa*.

Diseased specimens which were examined showed the presence of abundant fungi, but as yet the character of the fungus has not been determined. The investigations seemed to show that this species of tree is poorly suited to the soil and situation where the disease has appeared, and probably some other shade tree should be substituted for it.

A disease of black oaks caused by Polyporus obtusus, P. SPAULDING (*Mo. Bot. Gard. Ann. Rpt., 16 (1905), pp. 109-116, pls. 7, map 1*).—A disease caused by the fungus *Polyporus obtusus*, which was quite destructive locally to several species of oak trees, is described.

The fungus seems to be confined to North America and its distribution is indicated. So far as known it occurs only on species of oak belonging to the black oak series, and seems to be associated with the attacks of an oak-boring insect which is believed to be *Prionoxystus robiniæ*. The spores of the fungus are apparently blown into the entrances of the burrows, where they germinate and the fungus grows following the burrow until the heart of the tree is reached. Here the heartwood becomes affected, and the rot extends through the wood of the trunk until the top is broken by the wind or the weight of the tree.

All gradations in the severity of the disease are found, and as it progresses in the heartwood the sapwood becomes affected and is no longer able to carry on its proper functions in relation to the tree. Ordinarily the heartwood of these trees is naturally dark in color, but when affected by the fungus it turns a light yellowish tint and in the last stages becomes nearly white. It retains its fibrous appearance but breaks much easier than does the healthy wood. No suggestion is given for the control of the fungus.

Willow canker, T. JOHNSON (*Sci. Proc. Roy. Dublin Soc., n. ser., 10 (1904), II, pp. 153–166, pls. 3*).—The author reports having observed in the autumn of 1899, in specimens of willows sent for examination, black spots which rendered the osiers useless for basket making.

These spots, which have a canker-like appearance, are easily recognized externally and may reach through the shoots to the pith. They cause weakening of the stems, which break at the least attempt to bend them. A study of the fungus showed that the disease was caused by *Physalospora gregaria* and associated with it were the two other stages which are distinguished as *Tetradia salicicola* and *Macrodendrophoma salicicola*.

Judging from analogy the author believes that all 3 fruiting stages are capable of infecting healthy willows. Poor undrained bogs and a prevalence of weeds would favor development, and every care should be taken not to plant diseased sets from an infected holt. Land chosen for osier growth should be well drained and if bog land should be treated with lime, potash, and phosphoric acid. If the disease appears, all attacked sets should be dug out and burned. A weak solution of formalin, 0.5 per cent, it is believed would be useful as a spray to keep the fungus from spreading.

Glassy fir, H. VON SCHRENK (*Mo. Bot. Gard. Ann. Rpt., 16 (1905), pp. 117–120, pls. 2*).—A description is given of specimens of balsam fir which were received during the winter at the laboratory, and which exhibited peculiar smooth spots at various points in cross sections.

Some of these areas extended from the heart to the sapwood, while others formed irregular circumscribed spots. A great deal of balsam fir is used for pulp wood in the region from which these specimens were obtained, and it was claimed that this appearance indicated a defect in the wood. Investigations showed that this appearance is quite frequent during winter months, and it is suggested that it is due to freezing.

To secure experimental evidence to corroborate this belief, the author saturated a number of specimens of loblolly pine, after which they were subjected to temperatures below zero and partially sawed through when in a frozen condition. After thawing, the pieces were cut completely in two for examination, and the portions that had been cut while in the frozen condition exhibited a condition analogous to that mentioned in the fir. It is believed that this defect is due to freezing and cutting when there is a superabundance of water in the trunk of the tree.

Corticium chrysanthemi, C. B. PLOWRIGHT (*Brit. Mycol. Soc. Trans. 1904, pp. 90, 91, pl. 1*).—The author reports having noticed a number of years ago chrysanthemums planted for permanent ornamentals which had died off, and in each case a white fungus growth was present on the lower part of the stems. Recently his attention has been called to this same trouble, and a careful examination was made to ascertain the cause of the disease.

The stems show a white hymenium on the living and dead stems at the level of the ground, matting the earth and the shoots together so that the gardener may at once recognize the trouble he has to deal with. The only treatment seems to be the burning of the diseased plants and the use of only healthy cuttings. A technical description of the fungus is given.

Concerning the root rot of cotton.—In the note on the root rot of cotton by V. Mosseri (E. S. R., 17, p. 45) an error was committed in stating that the disease in

Egypt differed from that known in this country. The author in the course of his paper shows them to be identical, but calls attention to the fact that the fungus known in the United States as *Ozonium auricomum* is not the same as that species found in Europe. In discussing treatment the general possibilities of securing immune strains through selection are pointed out and a variety of bananas immune to root knot is described. The banana is not subject to root rot.

ECONOMIC ZOOLOGY—ENTOMOLOGY.

The international code of zoological nomenclature as applied to medicine, C. W. Stiles (*Pub. Health and Mar. Hosp. Serv. U. S., Hyg. Lab. Bul. 24, pp. 50*).—The international code is taken up seriatim, and each article is discussed and recommendations given. A detailed synonymy is presented for *Tænia solium, T. saginata, Dipylidium caninum, Dibothriocephalus latus,* and *Echinococcus granulosus.*

Report of the entomologist, J. B. Smith (*New Jersey Stas. Rpt. 1904, pp. 557–652, pls. 10, figs. 4*).—San José scale was unusually abundant during the season and caused great damage. Notes are given on the prevalence of *Pseudococcus aceris,* elm-leaf beetle, cabbage worms, onion maggot, potato beetle, bollworm, strawberry weevil, etc. Insecticide treatment of cottony maple scale is rather unsatisfactory. Summer applications of soap and kerosene and winter washes are partly effective.

The second brood of codling moth should be combated with bands, but the banding method should be combined with spraying, destruction of infested fruit, and all other known precautions. Cranberry insects are also briefly noted.

A detailed account is given of attempts to introduce the Asiatic ladybird into New Jersey and other localities. Only a portion of the beetles survive the winter even in Georgia. The beetle is apparently unable to keep the San José scale in check. Notes are presented on *Tenodera sinensis* as a predaceous insect.

A test was made of potassium sulphid, sulphite of soda, and Con-Sol for destroying San José scale on peach trees. Potassium sulphid and lime proved most effective. This remedy seems not to injure peach foliage when applied in summer and kills the scale insects. Sulphite of soda was of no avail, and Con-Sol was comparatively ineffective.

Lime-sulphur wash was almost a complete failure in New Jersey during the winter of 1903–4 as used by fruit growers. A study was made to determine the causes of failure, and various recommendations are made regarding the composition and preparation of the wash. Caustic soda was thoroughly tested as an insecticide and the results were not encouraging. Salimene and Universal insecticide and scale killer also proved to be of little or no value. Crude oil and kerosene continue to give good results. Kill-O-Scale is quite effective but too expensive. Pyrol tree and plant spray neither killed the scale nor injured the foliage. Horticultural Compound proved effective against plant lice but not against San José scale. Rose-leaf tobacco extract gave fairly good results as a remedy for grape-leaf hoppers and scale insects.

Third annual report of the chief inspector (*Ohio Dept. Agr., Div. Nursery and Orchard Inspection Rpt. 1904, pp. 34*).—During the year 1904 the inspector carried on the usual work of his office in the control of harmful pests in nurseries and orchards. Nurseries were inspected, fumigation was carried out on a large scale in houses built for that purpose, and orchard inspection was undertaken wherever it appeared to be necessary. During the year serious injuries were suffered from cankerworm, San José scale, elm-leaf beetle, grape-blossom bud-gnat, and other insects. A copy is given of the nursery and orchard inspection law of the State.

The arrowroot worm (*Agr. News [Barbados], 4 (1905), No. 76, p. 74*).—*Calpodes ethlius* is said to cause serious damage to arrowroot, cannas, and related plants. The use of Paris green and London purple appears to give the best results. Certain birds, including the common blackbirds of the Barbados, feed upon these pests.

FOODS—HUMAN NUTRITION.

The milling and chemical value of the grades of wheat in the Manitoba Inspection Division, crop of 1904, C. E. SAUNDERS and F. T. SHUTT (*Canada Cent. Expt. Farm Bul. 50, pp. 20*).—Studies are reported on the character and milling qualities of a number of varieties of Manitoba wheats.

The milling value of the grades of wheat, C. E. Saunders (pp. 5–12).—The 7 samples of high and low grade wheats, 2 of feed wheats, and 1 of frosted wheat included in the investigation, it is believed represent fairly the grades shipped from Fort William, Manitoba.

The results of the milling tests showed that the amounts of straight-grade flour and total flour decreased from the higher to the lower grades of wheat, while the amounts of low-grade flour and of shorts and bran increased. The changes were fairly regular, though the differences between any 2 grades were more noticeable as the lowest grade was approached.

The large proportion of low-grade flour obtained from the poorest samples of wheat is, in the author's opinion, a clear indication of their inferior character. The straight flours from the different grades of wheat were much alike in color when dry, though that from the lower grades was less creamy and of a grayish tint. In the author's opinion all the flours tested, except those ground from the feed wheat, were suitable for bread making.

As regards the price of wheat, "it is evident that what may be called the single milling value of the different grades can never fix the prices that will be paid for the wheat. The highest grades will probably always command enhanced prices, while the value of the lowest grades will be determined by their utility for feeding purposes and not for milling. For some of the intermediate grades it seems possible that millers could afford to pay relatively higher prices than those which have lately prevailed if greater attention were given to the grinding of such wheat and special efforts made to find the most advantageous markets for the products."

A chemical study of the grain and flour of the grades of wheat, F. T. Shutt (pp. 13–20).—Analyses of the different grades of wheat included in the investigations noted above and of the flours ground from them are reported, and the composition discussed in relation to the relative value of the different wheats.

"We find a great similarity in composition between these wheats, especially among the higher members of the series, as regards all the more important constituents, i. e., those which affect the bread-making quality, and we should presurmise, therefore, that the grading has been based upon the relative yield of first quality flour (of which color is an important factor) rather than upon the essential differences in what might be termed the relative strengths of the wheats.

"As regards quantity of flour, we have shown that in such a series the weight of the kernel and the weight per bushel, and to a minor degree the fiber, indicate the relative flour yield. Our results in these determinations are in excellent accord, supporting the supposition that the grading of the wheats has been made primarily from the standpoint of yield of first quality flour.

"The percentage of protein in the wheat undoubtedly is a measure of the strength of the resultant flour, but if we except . . . [a sample of feed wheat and one of frosted wheat] we scarcely think it would be justifiable to use differences in protein content such as we have met with between these wheats (frequently less than 0.25 per cent) as a basis for the arrangement of the wheats in their order of merit. And the same holds true for the data regarding gluten and gliadin. It is highly significant, therefore, that the resultant flours were found so uniform in quality for bread making."

Dietetics in relation to hospitals for the insane, W. O. ATWATER (*U. S. Dept. Agr., Office Expt. Stas. Rpt. 1904, pp. 473-492*).—Investigations noted from a previous publication (E. S. R., 16, p. 688) are summarized and general problems connected with institution dietetics are discussed, particularly hospitals for the insane.

Labels on adulterated and imitation foods, R. M. ALLEN (*Kentucky Sta. Bul. 119, pp. 23-41*).—The State pure-food law, which has been in operation 6 years, requires that food shall be so labeled that its true character may be known.

Such publicity, according to the author, has "about stopped the use of formaldehyde in milk and boric acid in meat. It is stopping the use of aniline dyes in fruit products and saccharin in canned corn. It is stopping the use of salicylic and benzoic acids in jellies, preserves, ciders, and grape juices. Imitation products are being labeled for what they are, and if the consumers will purchase with ordinary care they can protect health and obtain fair values in the purchase of foods."

In many instances the labels are not as plain as they should be, and the information which the law demands shall be made public is printed in such a way that it is not likely to be read or is expressed in terms with which the public is not familiar. Some of the terms used are explained, and sample labels are reproduced so that labels of this character may be understood. The bulletin also contains a discussion of antiseptics and coloring matter.

The protective value of proteids and their decomposition products on trypsin, H. M. VERNON (*Jour. Physiol., 31 (1904), No. 5, pp. 346-358*).—The following statements are quoted from the author's summary of his investigations:

"The protective value of various substances upon trypsin was estimated by keeping pancreatic extract with 0.4 per cent sodium carbonate and a known percentage of the substance for 1 hour at 38° C., and determining the amount of trypsin thereby destroyed. As a rule the protective value depends almost entirely upon the power the substance possesses of neutralizing the alkali, and so rendering it incapable of reacting upon the ferment.

"Most proteids have practically the same protective value, about 45 per cent of the trypsin of an extract being destroyed per hour in presence of 0.4 per cent of proteid, 27 per cent in presence of 1 per cent, 12 per cent in presence of 2 per cent, and 7 per cent in presence of 4 per cent of proteid. When no proteid was present 56 per cent of the ferment was destroyed. Hydrated proteids have a slightly greater protective value than native proteids, and the decomposition products of proteid hydrolysis a slightly greater one still. . . .

"In certain cases there is a combination between ferment molecule and proteid. Thus egg albumen possesses a most marked antitryptic action, the digestive power of the ferment being reduced to 29 and 2.9 per cent of its normal value in the presence of 0.05 and 1 per cent of the proteid, respectively."

ANIMAL PRODUCTION.

Relative values of feeding stuffs, H. P. ARMSBY (*Pennsylvania Sta. Bul. 71, pp. 16*).—Feeding stuffs have commonly been compared on the basis of digestible nutrients and on the basis of energy values. The author does not believe that such values are satisfactory, but is of the opinion that the work required to eat and assimilate, which is known to vary with different feeding stuffs, should also be taken into account.

With the respiration calorimeter for experiments with animals (E. S. R., 15, p. 1036) such factors can be studied, and the bulletin summarizes the results of experiments with steers made to compare timothy hay, clover hay, and corn meal, both for maintenance rations and for production. The following table shows the absolute and relative values of these feeding stuffs as computed on the basis of digestible

nutrients and fuel value, and also the maintenance value and production value on the basis of the results obtained with the respiration calorimeter:

Fuel values, maintenance values, and production values per pound of several feeding stuffs.

	Computed from digestible nutrients.	Actual fuel value.	Maintenance value.	Production value.
	Calories.	*Calories.*	*Calories.*	*Calories.*
Absolute values:				
Timothy hay	875	777	489	259
Clover hay	901	742	270	....
Corn meal	1,525	1,308	1,016	697
Relative values:				
Timothy hay	1.00	1.00	1.00	1.00
Clover hay	1.03	0.96	0.56	....
Corn meal	1.74	1.68	2.11	2.73

As will be noticed, both the production and maintenance values are decidedly lower than the values computed from digestible nutrients or from fuel value.

"Coarse fodders in particular were found to have much lower values, for maintenance as well as for fattening, than concentrated feeds, the relative values of the former as compared with the latter being greatly overestimated in the feeding tables in common use."

The author calls attention to the fact that the results at present available are not numerous and therefore that deductions are suggestive rather than final.

"On the other hand, however, it is believed that the distinctions which . . . [the figure obtained] show between the digestible nutrients, the fuel values, the maintenance values, and the production values, as well as the differences between different classes of feeding stuffs, in these respects are significant. In other words, it is believed that the differences are too great to be explained by experimental errors.

"When we find, for example, that on the basis of digestible nutrients 174 pounds of timothy hay are the equivalent of 100 pounds of corn meal, while the actual experiment on the animal shows that for maintenance 211 pounds and for fattening 273 pounds of timothy hay are required to equal 100 pounds of corn meal, we are dealing with differences too large to be accidental and too important to be ignored in the practical computation of rations.

"Furthermore, these results show that the only safe basis for a comparison of the values of feeding stuffs is the actual experiment upon the animal, in which the real gain or loss of flesh and fat is accurately determined. In other words, the only way to ascertain the nutritive effect is to actually determine it."

On the basis of available data, the production value per 100 pounds has been computed for a number of the common American feeding stuffs. Some of these values are as follows:

Production values per 100 pounds of a number of feeding stuffs.

Feeding stuff.	Total dry matter.	Total crude fiber.	Digestible. Proteids.	Digestible. Carbohydrates.	Digestible. Fat.	Production value.
	Pounds.	*Pounds.*	*Pounds.*	*Pounds.*	*Pounds.*	*Calories.*
Green fodder and silage:						
Alfalfa	28.20	7.40	2.50	11.20	0.41	10,806
Clover, red	29.20	8.10	2.21	14.82	0.69	14,528
Corn fodder	20.70	5.00	0.41	12.08	0.37	11,024
Corn silage	25.60	5.80	1.21	14.56	0.88	14,260
Timothy	38.40	11.80	1.04	21.22	0.64	17,809
Hays:						
Alfalfa	91.60	25.00	6.93	37.33	1.38	34,413
Clover, red	84.70	24.80	5.41	38.15	1.81	34,748
Soy-bean	88.70	22.30	7.68	38.72	1.54	38,656
Timothy	86.80	29.60	2.05	43.72	1.43	33,562

Production values per 100 pounds of a number of feeding stuffs—Continued.

Gluten Feed, dry	91.9	6.4	16.09	54.22	5.35	79,422
Linseed Meal, new process	90.1	8.8	29.26	38.72	2.90	74,677
Wheat Bran	88.5	9.0	10.21	41.23	2.87	48,233

In connection with the data summarized, protein requirements and other factors are briefly considered.

Second report on feeding-stuff inspection, B. W. Kilgore, C. D. Harris, J. M. Pickel, and W. M. Allen (*Bul. N. C. Bd. Agr., 25 (1904), No. 11, pp. 67, figs. 15*).—The State feeding-stuff law is quoted and analyses, both chemical and microscopical, carried out under its provisions, are reported of 500 samples of wheat bran, middlings, ship stuff, corn and oat feed; rice, peanut, and saccharin feeds; gluten meal and feeds, chops, distillers' grains, hominy meal or feeds, corn-and-cob feeds, linseed meal, cotton-seed feeds, cotton-seed meal, dried beet pulp, mixed and mill feeds, mill sweepings, soy beans, wheat screenings, cane seed and corn feed, starch meal, graham wheat, stock feed, oats (whole and ground), meal and bran, and flour.

Some of the conclusions drawn regarding the extent of adulteration of some of the feeding stuffs follow: In the case of wheat bran 75 per cent of the samples examined were not up to the standard as regards protein content. The 20 samples of rice feeds examined were all found to be up to the standard. The peanut feeds included a feed for chickens, a feed for pigs, screenings, meal, middlings, and bran. Peanut meal, middlings, and bran, though differing in name, were all found to be made up of ground peanut hulls. Of the 84 samples of cotton-seed meal examined, 18 were below the legal standard.

The examinations which have been made, the authors state, show that the following adulterants are used to a considerable extent in making up the stock feeds sold in North Carolina: Corn, bran, rice chaff, ground corncobs, peanut hulls and middlings, oat hulls and dust, mill sweepings, screenings, cotton-seed hulls, and similar products. The composition of these materials is spoken of with the object of calling attention to their low nutritive value.

Investigation regarding succulence, F. W. Robison (*Michigan Sta. Spec. Bul. 32, pp. 15*).—Believing that the amount of energy required to assimilate feeds should be taken into account in determining their true feeding value, and that the proportion of succulent material would have an important bearing on this question, two series of experiments were undertaken with cows in which the digestibility of protein was determined on the basis of nitrogen in fresh feces, nitrogen in dried feces, and feces corrected for the proportion of metabolic products present. Foods, urine, and feces were analyzed, and the balance of income and outgo of nitrogen also determined.

In estimating metabolic products in feces, the ether, alcohol, water, and limewater method was employed. In periods 1 and 4 of the first series of tests, the food con-

sisted of a basal ration of clover, hay, oats, straw, bran and corn and cob meal, the nutritive ratio being 1 : 12.2. In the second period, wet sugar beet pulp was introduced into the ration, the basal ration being so changed that the dry matter of the total ration and the nutritive ratio remained constant. In the third period, the basal ration remained the same as before while the amount of sugar beet pulp was increased, the cows receiving all they would consume. In the second series of tests the conditions were the same except that in the fourth period dry sugar beet pulp was used in place of wet pulp, the dry matter and nutritive ratio of the ration being kept the same as in periods 1 and 2.

The coefficients of digestibility were in general lowest when the analytical data based on the fresh feces were taken into account, and highest when the corrections for metabolic products were introduced, but in no case were constant differences observed which could be attributed to the rations fed. The loss of nitrogen when the feces were dried ranged from .3 to 9.5 per cent and the amount of metabolic nitrogen of feces from 8.6 to 15.4 per cent, the variations being apparently caused by individual peculiarity or other conditions not determined. As regards the balance of income and outgo of nitrogen, the results varied from a loss of 4.4 grams per day with one of the cows fed a basal ration in the first series of tests to a gain of 12.1 grams per day with one of the cows fed the sugar beet pulp ad libitum.

"It is very noticeable that foods are utilized differently by different individuals. Two cows, although both are healthy and normal in every respect, will not utilize the same amount of nutrients in a given feed.

"In the first experiment both cows showed a slight increase in digestibility when beet pulp wet was added to the ration. In the second experiment one cow gave a slight increase, while the other showed practically no change. These figures are, however, so slight when an average is taken that they can not be said to prove an increase of digestibility due to the succulent feed.

"In all of the experiments a consideration of digestibility based on the nitrogen as found in the feces before drying, shows that former figures of digestibility of succulent feeds are given at least 5 per cent too high. Different feeds show varying percentages of volatile nitrogen in the feces, and inasmuch as it appears with the undigested food it should be taken into consideration, else our coefficients of digestibility are considerably too high. . . .

"Whatever the effect of succulence on the apparent digestibility of a food, which in these instances seems to be practically nil, it seems quite positive that a succulent food is digested at less expense than a dry food. In this way a succulent food should work antagonistic to a food rich in fiber and in the same capacity as grain. If an increase of cell oxidation is accompanied by an increase of metabolic nitrogen in the feces . . . then surely the expenditure of energy on a food high in factors of succulence is less than on a dry food. The above being true, it follows that the net available energy, other factors being equal, is greater in a succulent food than in a dry one."

The utilization of beet leaves, D. MEYER (*Fühling's Landw. Ztg., 54 (1905), Nos. 3, pp. 91–95; 4, pp. 145–152*).—The superior value of ensiled and dried beet leaves as compared with the green material is pointed out. According to the author, the dried leaves are generally considered the most satisfactory, though he believes that ensiling should receive more attention. Experimental data which have to do with the subject are summarized and discussed.

Mixed farming, R. W. PEACOCK (*Agr. Gaz. N. S. Wales, 16 (1905), No. 4, pp. 335, 336*).—Brief notes are given regarding the crops raised and the stock kept at the Bathurst Experimental Farm.

Especial attention is directed to providing a succession of grazing crops for sheep. "For winter feeding, rape, black tares, and early-sown wheats are principally to be relied upon. For spring feeding, rape, crimson clover, tares, prairie grass, and

sheep's burnet are valuable. For summer and autumn feeding, lucern, cowpeas, and stubble paddocks furnish the bulk of the food. By such practice it is possible to keep the ewes and lambs in good condition, and also allows of the lambs being marketed at profitable prices."

Feeding farm animals, T. BUTLER and B. W. KILGORE (*Bul. N. C. Bd. Agr., 25 (1904), No. 11, Sup., pp. 36*).—The composition and digestibility of feeding stuffs and related questions are discussed with special reference to the feeding of farm animals under local conditions.

To simplify the calculation of rations a table is given showing the amount of digestible nutrients furnished by different quantities of a number of feeding stuffs. Feeding standards are quoted, and rations suggested which meet the requirements of the standards. For a horse at light work a ration of 12 lbs. corn fodder, 2 lbs. cowpea hay, 5 lbs. corn, and 1 lb. cotton-seed meal is suggested, and for severe work 10 lbs. corn fodder, 5 lbs. cowpea hay, 10 lbs. corn, 2 lbs. cotton-seed meal.

"The horse is not able to digest coarse dry foods to the best advantage, and, moreover, large quantities of hay are objectionable where the horse is to do severe or fast work, because an overfull stomach interferes with respiration, which must be increased as the work is increased. In the opinion of the writer, therefore, both the rations for horses, given above, would be improved by slightly decreasing the hay and increasing the grain.

"Any difficulty experienced in getting a horse to eat the cotton-seed meal, when he has not been accustomed to doing so, may usually be overcome by grinding the corn and mixing the corn meal and cotton-seed meal. Cotton-seed meal is used in these rations to supply the necessary protein to repair the worn-out muscles instead of increasing the pea-vine hay for the reason given above and because any of the leguminous hays seems to cause too great a looseness in the bowels of hard-working horses. It is used in preference to oats and wheat bran because it is much cheaper."

For milch cows the authors believe that 5 lbs. of cowpea hay can replace 4 lbs. of wheat bran, since locally the wheat bran is expensive. As regards pig feeding it is stated that, "when a field of cowpeas, alfalfa, or peanuts is not available it will probably pay to balance the corn ration with wheat middlings or dried blood if either can be purchased at a reasonable price, unless some other protein food is available or the fattening period is to be an extremely short one."

Present methods of beef production, V, H. W. MUMFORD and L. D. HALL (*Illinois Sta. Circ. 94, pp. 4*).—The principal deductions which were drawn from replies to a list of questions sent to a number of Illinois cattle feeders regarding the breeding of beef cattle for market are as follows:

Only 12 per cent of the cattlemen represented raise all the cattle they fatten and but 35 per cent raise a part and buy the remainder. "With reference to the cattle involved, only 16 per cent are marketed by men who raise all the cattle they sell and 18 per cent by those who raise part and buy part of their cattle." Pure-bred sires were kept by 87 per cent of the correspondents who it is stated raise their own cattle, while the remainder report the use of grade bulls. Pure-bred cows were kept by 19 per cent of the cattle raisers and grades by 35 per cent, while 46 per cent did not state whether pure-breds or grades were used.

Forty-two per cent of the replies state that heifers are bred to produce market stock at 24 months. A number preferred 1 to 2 years and a very few more than 2 years. "The spring season is chosen by four-fifths of the correspondents as a time for the dropping of the principal crop of calves. The remainder are divided in their preferences among the summer, winter, and fall seasons, and but 2 per cent plan to have the calves dropped at 2 seasons, spring and fall.

"One-fifth of those who reply castrate calves when less than 1 week old; one-half castrate before the calves are over 1 month old; four-fifths castrate when less than 3 months old. Only 5 per cent of the correspondents delay the operation later than 6

months of age. . . . The length of suckling period recommended for calves intended for baby beef varies from 1 week to 10 months. Three-fourths of all the replies, however, recommend periods from 5 to 7 months in length. . . .

"A summary of the replies concerning the length of suckling period for calves not intended for baby beef shows that approximately three-fourths of all the replies name periods from 5 to 7 months in length." Of the concentrated feeds for the production of baby beef, corn was placed first in nearly half of the replies and oats in one-third, with bran, oil meal, corn and oat meal, barley, cotton-seed meal, gluten meal, wheat, and rye ranking next in the order named.

The comparison of the data relating to the feeding of calves and yearlings indicates that "concentrated feeds are generally regarded as most important in the feeding of calves, while for yearlings roughages seem to be considered of most consequence. . . . Corn is more highly regarded for yearlings than for calves, while the reverse is true of oats. The grinding of corn, however, appears to be considered more necessary in the case of yearlings. Clover hay is ranked much more highly for calves while for yearlings straw, varieties of hay other than clover, and corn-stalk fields are mentioned more prominently."

In general, the information gathered indicated that feeding beef cattle for market is a minor factor in Illinois cattle-feeding operations. (For earlier work see E. S. R., 16, pp. 805, 1112.)

The making of Prime Scots beef (*Breeder's Gaz., 47 (1905), No. 18, pp. 861–863, figs. 4*).—A descriptive article regarding the breeding and feeding for market of the best grade of beef cattle produced in Great Britain and known as "Prime Scots." The animals are marketed when 1 or 2 years old; are pastured in summer and fed during the winter on straw and roots. In many cases cake or grain is given for 3 months before marketing and at all times the animals are fed with great care.

Comparison of methods of preparing corn and clover hay for fattening steers, H. W. Mumford (*Illinois Sta. Bul. 103, pp. 43–93, figs. 11*).—This experiment was made to compare the economy of feeding corn on the ear, in the shock, shelled, and ground as corn meal and as corn-and-cob meal, and the advantages of chaffing clover hay. The economy of supplementing corn with nitrogenous feeds like gluten meal and linseed meal, when an abundance of clover hay is fed, was also studied. Corn silage formed a part of the coarse fodder of one lot.

One hundred and thirty 2-year-old steers were used, which were divided into 10 lots; and each lot was followed by pigs. The steers were fed in open sheds, the yards adjoining being paved with brick except in the case of one lot.

After a week's preliminary feeding the test began November 28 and continued for 186 days. Until full feed was reached in the fifth month the amount of corn supplied per day was gradually increased. The maximum amount fed was not far from one-third of a bushel per head per day. The nitrogenous feed consisted of gluten meal in the first half of the experiment and linseed meal in the last half, the change being made for the sake of variety. To the lots receiving this supplement it was fed in about the proportion of 10 lbs. per bushel of corn, the greatest amount being given to the lots receiving the corn-and-cob meal.

The largest gain, 2.45 lbs. per steer per day, was noted with the lot fed corn-and-cob meal, nitrogenous grain feed, and chaffed hay. Nearly as large gains (2.32 to 2.38 lbs.) were made by the lots fed unchaffed hay and the nitrogenous feed with corn-and-cob meal, corn meal, or ear corn. Considering all the lots the average daily gain was 2.25 lbs. per steer per day. The dry matter required per pound of gain ranged from 10.35 lbs. with the lot fed silage and corn meal to 13.42 lbs. with the lot fed shocked corn and ear corn.

The cost of a pound of gain ranged from 5.9 cts. with the lot fed ear corn without the addition of nitrogenous concentrates to 7.9 cts. with the lot fed corn meal and

chaffed hay. "The cheapest gain was made where the labor element in preparing the feed was reduced to the minimum." Data regarding shrinkage in dressing and the weight of hide, percentage of fat, etc., were recorded in connection with the slaughter test made at the close of the trial.

The greatest gain of the pigs, 1,115 lbs., was made by 7 pigs following the 10 steers fed shelled corn in the paved yard. The smallest gain, 63 lbs., was made by the pig following the 10 steers fed silage and corn meal.

Some of the author's conclusions were, in effect, as follows: Corn silage ranks with ear corn, corn meal, and corn-and-cob meal in its ability to make rapid gains on fattening cattle. Corn meal and corn-and-cob meal appear to be about equally efficient in producing quick finish. More rapid gains were secured in this test with whole than with shelled corn and equally as good as with meal. A reasonably quick finish may be secured without the feeding of an excessively heavy grain ration.

"The feeding of a nitrogenous concentrate to supplement corn undoubtedly stimulates the appetite and increases the capacity of the steer for consuming to advantage large quantities of concentrates. Hence this system of feeding is to be recommended where a quick finish is desired." Corn meal was more efficient than corn-and-cob meal or shelled corn, but not more efficient than ear corn. Chaffing the hay and mixing with a ground concentrated feed did not materially increase the efficiency of the grain for beef production, although by this system of feeding there is less likelihood of the steers getting off feed or of scouring.

As regards profit to the cattle feeder, the 3 rations which gave the best results were ear corn supplemented with oil meal and gluten meal, shocked or fodder corn and ear corn, and ear corn without additional concentrated feed, the 3 rations being so nearly alike that it would be unwarranted to say that either would prove superior. The 3 rations which gave the smallest net profits were shelled corn (fed in an unpaved yard), corn-and-cob meal, and corn meal fed with chaffed hay.

"The results of this experiment are so striking that it appears that the grinding of corn for feeding choice 2-year-old steers during the winter season is not warranted. The profits of feeding ear corn are fully twice as large as those secured in feeding corn meal or corn-and-cob meal. . . . [However,] it should not be assumed that it does not pay to grind corn for cattle that are being fattened in summer on grass. . . .

"The feeding of silage in moderate quantities is not necessarily conducive to heavy shrinkage in shipping or small percentages of dressed beef. The reader is cautioned not to conclude that since the feeding of silage was not followed with as large profits as the feeding of several other rations, that it has no place in beef production. Its use in growing young cattle and as a part of the ration of the breeding herd promises well in the hands of the experienced feeder, but to just what extent it may be profitably used for these purposes remains to be determined by future investigations.

"Many who advocate the feeding of ear corn to cattle if hogs follow, advocate the feeding of meal if for any reason it seems desirable to eliminate the hog. The results of this experiment do not warrant such a conclusion. After eliminating the hog from the cattle-feeding operations here presented the feeding of broken-ear corn was followed with larger profits than the feeding of meal."

As regards the gains made by the pigs, "the most striking points of importance brought out . . . [by the results of the test] are the relatively small amount of pork produced from the droppings of the silage-corn-meal-fed steers; the large gains made by the pigs following the shelled-corn-fed steers; and the fact that the pigs following the ear-corn-fed (without nitrogenous concentrates) steers made larger gains than did those in the lot where ear corn was so supplemented. . . . The amount of gain made by hogs following steers appears to be largely regulated by the amount of undigested corn in the droppings of the steers in an available form for the hogs to recover; therefore larger gains are made by hogs following steers fed corn

only than where it is supplemented with oil meal and gluten meal, thus rendering it more efficient for beef production."

Influence of rations upon the hydration of body tissues in cattle, A. Gouin and P. Andouard (*Compt. Rend. Soc. Biol. [Paris], 58 (1905), No. 17, pp. 813-815*).—Rations rich in carbohydrates (molasses) and nitrogenous rations were found to produce marked differences in water content of the tissues. The bearing of such facts on the study of animal nutrition is discussed. The authors intend to continue their observations along this line.

Raising calves on separator milk, H. T. French (*Idaho Sta. Bul. 48, pp. 17, figs. 5*).—The author studied the feeding value of skim milk with 5 scrub calves, dropped from February 25 to April 8, 1902.

The calves were separated from their dams within 48 hours after birth, and were given 2 feeds of whole milk daily for 5 to 7 days. At the end of that time warmed separator skim milk was gradually substituted for the whole milk. From the start whole oats were fed with the skim milk, the amount at first being not more than a tablespoonful, which was placed in a box in front of the calf after it had taken the milk. The animals readily learned to eat the oats, and at the end of 3 or 4 weeks, according to the author, ate about a pint a day.

When on full ration the calves ate not far from a gallon of skim milk at a feed, and the author cautions against feeding too large amounts. The calves were fed in stanchions, and learned to drink the milk readily. After they had eaten they were turned into a box stall and had access to a good quality of hay and to fresh water. When the calves were 4 to 6 months old the skim-milk ration was gradually withdrawn and the oat feeding continued. Early in May they were turned on pasture. In the fall they were placed in stalls and given a ration of hay and carrots.

From the beginning of the experiment until February 9, 150 days, the average daily gain was 1.59 lbs. per calf, and the cost of feed per pound of gain, not including pasturage, 2.13 cts. At the close of this period the feeding test was continued for a year, the ration during the winter consisting of corn silage, hay, and carrots, and during the summer of pasturage, supplemented during a part of the time by clover, mixed rye, and vetch, and alfalfa as soiling crops. During the fall and early winter oats were added to the ration, and green corn, and later carrots. When 2 years of age the calves were slaughtered, the average weight being 1,013 lbs.

Considering the test as a whole, the average daily gain from birth was 1.46 lbs. During the summer when flies were very troublesome it was found desirable to pasture the calves at night and keep them under cover during the day. From 6 to 12 months is considered the critical age for calves fed skim milk. The animals "develop a stomach out of proportion to the rest of their body, and their coat is not quite as smooth as it is when calves run with their dams. However, the calves have learned how to eat and digest coarse feed in larger quantities than calves reared on whole milk. The digestive organs are better developed for practical feeding, from this period on to maturity, than in calves fed whole milk."

The deductions which the author drew from the test follow: "It is possible to raise calves profitably on separator milk by substituting whole oats in place of the butter fat which has been removed. . . . We have found that an oat with a thin hull is best. . . . Calves fed in this way will do better on coarse feed alone than those raised on whole milk. Early maturity is not hindered by this method of feeding. The value of butter fat saved was more than 4 times the value of the oats consumed. There was $18 profit per head over and above cost of feed. The steers were sold as 'baby beef' at an average age of twenty-two and one-half months. The steers made an average gain of 2 lbs. per day during a portion of the time (128 days) on coarse feed alone."

Soy beans, middlings, and tankage as supplemental feeds in pork production, J. H. Skinner (*Indiana Sta. Bul. 108, pp. 15-32, figs. 4*).—Believing that corn

meal should be supplemented by some more concentrated feed, middlings, soy-bean meal, and tankage were tested for this purpose, using 4 lots of 4 crossbred pigs each. The feeding stuffs used were analyzed.

On the corn meal alone the average daily gain per pig in the 3 months of the test was 2.18 lbs. and the feed eaten per pound of gain 5.57 lbs. With the lot fed corn meal and middlings 1:1 similar values were 4.35 lbs. and 3.43 lbs. With corn meal and soy beans 2:1 the average daily gain was 4.78 lbs. and the feed eaten per pound of gain 3.11 lbs., and with corn meal and tankage 5:1 the values were 4.15 lbs. and 3.31 lbs.

In the case of the corn-meal ration the nutritive ratio was 1:13.3. On the rations containing wheat middlings, soy-bean meal, and tankage it was, respectively, 1:8, 1:5.1, and 1:5.2. The cost of feed per pound of gain was not far from 3.5 cts. on an average with all the lots fed corn meal supplemented by concentrated feed and was a little over 5 cts. on corn meal only.

"Corn alone is not a desirable feed for hogs; especially is this true in the case of young growing pigs and breeding stock. This was evidenced in the test under consideration by the small gains, poor appetites, lack of bone, poorly developed carcasses, harsh skin and hair, and a sharp, rasping, complaining squeal rather than the contented grunt so well recognized by swine growers. Perhaps the greatest need for some adjunct to corn on the average farm occurs during the winter months, in the case of fall or winter pigs and brood sows, as they usually have access to more or less grass, clover, etc., during the summer. . . . It takes favorable conditions and good feeding to make a profit [on corn meal only] on the late fall pig. Too frequently they are carried through at a loss, much of which might be avoided by a more judicious use of corn. Doubtless less corn and more of other feeds, such as milk, shorts or middlings, soy beans, tankage, and oil meal would greatly increase the profit on fall pigs.

"Middlings among other feeds is generally recognized as a desirable feed to combine with corn. In this test it proved to be the most profitable so far as money return was concerned. It is quite commonly used and has proved very effective in other tests. It is generally appreciated by swine growers, but high priced and difficult to secure.

"Tankage, although less widely known, has desirable qualities. In this test it did not give as favorable results as middlings or soy beans. This was doubtless due, in part, to the fact that one pig in the lot receiving tankage did not seem to make efficient use of the feed consumed during a portion of the time. . . .

"Soy beans are not commonly used in pork production. This is doubtless due to lack of knowledge of their characteristics and value."

Poultry suggestions for the amateur, C. K. GRAHAM (*Connecticut Storrs Sta. Bul. 36, pp. 12, figs. 9*).—The kind of eggs which should be selected for hatching, packing eggs for shipment, nests for setting hens, incubators, care of young chicks, and other related topics are discussed.

Poultry experiments, G. M. GOWELL (*Maine Sta. Bul. 117, pp. 93–116*).—The station work in breeding laying stock is reviewed; the proposed work which has to do with the amount of floor space required by poultry and related topics is outlined; the poultry houses at the station, including one recently built, are described; sample pedigree charts like those used in breeding tests are given, and the results of several tests on breeding and feeding are reported.

The author's experience convinces him that the use of trap nests is very desirable in selecting poultry in connection with breeding for improved stock, but suggests that where this is not practicable early maturity in pullets may be a basis for such selection. This was shown by a lot of 29 April-hatched pullets selected because they had begun to lay in the latter part of August. From September 1 until April 30

following these birds laid on an average 115 eggs each at a calculated profit of $3.01 per bird.

"While the egg yields of this group of birds were very satisfactory, the money returns from them were particularly so, for the reason that they did their work during that part of the year when prices were highest. . . . Early maturity in pullets is generally accompanied by physical vigor and when the function of such birds is to produce eggs, and they give evidence of it, they are certainly the best of their race to breed winter egg producers from, if we accept past experiences in breeding as our guides."

Eggs from hens over a year old have given larger chicks and larger mature birds than those from younger stock, yet in chicks from eggs laid by vigorous pullets showing early maturity "we have never been able to discover any lack of constitution or vigor . . . and know no reason why they are not desirable as workers."

At the station work has been carried on with the same family of Barred Plymouth Rocks for 25 years, and methods of feeding have been developed which are considered satisfactory. Throughout the year each pen of 22 chickens received 1 pt. of wheat early in the morning, a half pint of oats at 9.30 a. m., and a half pint of cracked corn at 1 p. m., these grains being scattered in litter. At 3 p. m. in winter and 4 p. m. in summer they were given all the mash they would eat up clean in half an hour composed of wheat bran, corn meal, wheat middlings, linseed meal, gluten meal, and beef scrap 2:1:1:1:1:1, with one-fourth of its bulk of soaked clover leaves and heads added. Cracked bone, oyster shell, grit, and water were always supplied, and each pen was also given 2 large mangels daily. "Very few soft-shelled eggs were laid, and so far as known not an egg has been eaten by the hens during the last 5 years."

The records which have been kept show that 50 to 55 lbs. of the dry meals were eaten per hen per year on an average in addition to 18.2 lbs. wheat, 6.4 lbs. cracked corn, 5.8 lbs. oats, 5.9 lbs. oyster shells, 3.2 lbs. dry poultry bone, 2.9 lbs. mica grit, and 40 lbs. of mangels. The straw required for litter has averaged 36 lbs. per bird per year. The average egg yield has been about 150 eggs each. "The amount of food required by the birds kept in this house [where the temperature was at all times above the freezing point] . . . was always less during the winter season than where birds were kept in the colder houses."

The value of cracked corn and beef scrap compared with the moist mash mentioned above was tested with 300 pullets divided into 2 equal lots. The moist mash was fed toward evening, as was also the dry cracked corn, which was supplied ad libitum in troughs. The dry beef scrap was kept within reach of the poultry at all times. The cost of feed and straw of the lot receiving the mash was $1.73 per bird per year and of the lot receiving dry feed $1.69. The yearly egg yield was 151 per chicken on moist and 149 on dry feed. So far as could be judged by egg yield, appearance, or health, no marked difference could be noted in the two lots. When the birds helped themselves to beef scrap they ate on an average 14.7 lbs. per year, as compared with 8.7 lbs. in the case of those receiving this feed as a part of the mash. "The quantity of oyster shell, bone, and grit eaten by the birds having a constant supply of beef scrap was markedly less than when the supply of scrap was limited to that contained in the mash."

The value of dry feed was further tested with 550 pullets, which were not selected with special reference to their egg-laying qualities. A dry mixture of the materials used in the mash mentioned above was constantly kept before the birds in troughs with slatted fronts so that they could help themselves at will. At first they were not used to the dry mixture and ate of it sparingly, but later ate it readily. Whenever feeds of cracked corn and oats were supplied to them "the birds were always ready and anxious for them and would scratch in the litter for the very last kernel

before going to the troughs where an abundance of food was in store." The average number of eggs laid from November 1 to April 30 was 76 per bird. The dry feeding has been found economical as regards time and waste, but the author does not consider the data extensive enough for final deductions.

The desirability of replacing a mash with dry grain and beef scrap feed supplied from separate troughs was tested with 1,400 young chickens.

"The results were satisfactory. The labor of feeding was far less than that required by any other method we have followed. The birds did not hang around the troughs and overeat, but helped themselves—a little at a time—and ranged off, hunting or playing and coming back again when so inclined to the food supply at the troughs. There was no rushing or crowding about the attendant as is usual at feeding time where large numbers are kept together. While the birds liked the beef scrap they did not overeat of it. The birds [both cockerels and pullets] did well under this treatment."

From June to October the chickens ate about a pound of beef scrap to 10 lbs. of cracked corn and wheat. According to the author, "it would seem that we had not been far wrong in our previous feeding, as the birds used just about the same relative amounts of scrap to other food, when they had liberty to do so, that we had formerly mixed in for them."

No special difficulty, it is stated, is experienced in keeping the troughs clean, as they are provided with roofs which project 2 in. on either side. The troughs used at the station are 6 to 10 ft. long, with sides 5 in. high and slats above. The lath slats are 2 in. apart, the total height of the trough being 16 in.

The system of feeding chickens followed at the station is outlined. For 2 or 3 days after hatching they are supplied with a mixture of infertile eggs (shells included) boiled for half an hour, ground in a meat chopper, and mixed with about 6 times their bulk of rolled oats. After about the third day a mixture of hard, finely broken corn, wheat, millet, and pin-head oats is also fed, and when the chicks are about 3 weeks old the rolled oat and egg mixture is gradually replaced by a moist mash made of a mixture of bran, corn meal, middlings or Red Dog flour, linseed meal, and fine beef scrap 2: 2: 1: 1: 1, wet up with a little water. The hard broken grains, it is stated, may be safely used all the time instead of the meal mixture, but the chicks do not grow so fast as when the mash, which should be rather dry to prevent looseness of the bowels, is fed.

Poultry experiments, J. DRYDEN (*Utah Sta. Bul. 92, pp. 115-197, figs. 25*).—*Chickens* (pp. 115-175).—Photographic records and the egg yield of a number of hens were kept to secure data which would show whether hens with long bodies and wedge-like forms, small heads, etc., are the best layers. The author states that this theory was not borne out by his experiments, some of the hens of a given type being poor layers and others good layers.

Records of the egg yield of hens showed wide variations in both the number and size of the eggs, and the author believes that laying qualities can be transmitted and that by proper selection a strain of fowls can be produced that will lay eggs of uniform color. As an illustration of the influence of good breeding, the record of 5 White Wyandotte pullets is given which averaged 189 eggs per year, an increase of 27 per cent over the average egg yield of their dams. As regards the color of eggs, great variation was noted with all breeds except Leghorns and Dorkings, which laid eggs uniformly white in color.

"In our tests it was very rare that we found 2 Wyandottes or 2 Plymouth Rocks laying eggs of the same color. The colors vary all the way from nearly white to the typical brown. The same hen, however, lays eggs of very little variation in color; occasionally she would lay an egg that was 'off-color.' Eggs from the same hen varied in size sometimes as well as in color."

The earlier work of the station (E. S. R., 12, p. 674), on the value of exercise for laying hens, was continued. Considering results extending over a number of years, the average egg yield per hen when the grain was scattered in the straw was 169, and when fed in boxes 161. With Leghorn hens good results have been obtained when all the feed was placed in a box, and there was apparently no advantage with this breed in making the hens scratch for their grain. When a Brown Leghorn, a White Plymouth Rock, and a White Wyandotte were kept in a small pen with board floor without straw or litter, the egg yield was respectively 52, 38, and 33 eggs per year. The fowls showed weakness in their legs at times, but the Leghorns seemed to bear the enforced idleness best. With Barred and White Plymouth Rocks the results were decidedly in favor of scattering the grain in straw litter.

In a comparison of different breeds for egg production for several years the average profit per hen was 51.5 cts. per year with Barred Plymouth Rocks, 88 cts. with White Wyandottes, and $1.12 with Rose Comb Brown Leghorns. Marked differences were observed in the size of the eggs laid by hens of different breeds and of the same breed, but, in general, the Leghorns showed less variation than Wyandottes or Plymouth Rocks. In the case of 41 hens of different breeds, for which complete records were kept for 2 years, it was found that the average egg yield was 178 per fowl the first year and 125 the second. "Whether there is a characteristic difference in the different breeds in this regard our experiments have not been continued long enough to form a basis for conclusion. The records show, however, that individualism must be taken into account, in a few cases more eggs being laid the second year than the first."

The relative value of fresh meat scraps, cut green bone, commercial meat meal, and milk albumin (a by-product of milk-sugar factories) was tested. The lot fed commercial meat meal average 133 eggs per fowl per year, as compared with 201.5 eggs in the case of a similar lot fed fresh meat scraps or cut green bones, and the lot fed milk albumin averaged 101 eggs, as compared with 143.5 in the case of a similar lot fed scraps. In a second test the average number of eggs per fowl per year on meat meal was 119, as compared with 154 on meat scraps and 189 on cut green bones. In the author's opinion the data presented are not sufficient to warrant the definite conclusion that the better egg yield with the fresh meat scrap was due to its higher percentage of fat and ash, but "they appear to indicate that in feeding for eggs the poultryman will be able to accomplish with cheap fat, or cheap foods rich in fat, what he has been vainly striving to accomplish with expensive protein."

As to the possibility of increasing the yellow color of egg yolk by feeding, it was found that when hens were fed dried alfalfa leaves in winter, the yolks of the eggs laid were normal in color, while those laid by similar lots fed no alfalfa were pale in color, and the same improvement in color was noted when hens had access to green grass, alfalfa, and clover. In another test, a mixture of white and yellow corn eaten in place of wheat did not produce yellow yolks, nor did skim milk fed in place of meat meal. "It was not noted that there was any difference in color of yolk from different breeds, nor did there appear to be any difference due to individuality. The color of shell is a question of individuality, but the proper color of yolk is a question of food."

Incubator experiments (pp. 175–191).—The results of weighings showed that eggs in incubators lost weight more rapidly than those under setting hens, and indicated that the ventilation was greater in the incubator. The air from incubators showed a much smaller amount of carbon dioxid than that found under setting hens. "From these tests it appeared that the theory that the chicks died in the shells because of insufficient ventilation or [an excess of] carbonic-acid gas was not well founded; rather, the results indicated that the cause was too much ventilation and too little carbonic-acid gas."

Tests of the effect of carbon dioxid with and without water on eggshells as a possible aid to the chicks in breaking the shell showed that when water was present carbon dioxid weakened or entirely dissolved the eggshells, but that dry carbon dioxid apparently had no influence. The thin membrane inside the shell was not affected in any case. "It is intended to continue these tests further to determine what amount of ventilation, if any, and of applied moisture, if any, are necessary for successful incubation."

Growing ducklings (pp. 191–194).—With a view to securing data relative to the cost of raising ducks, 5 newly hatched Pekin ducks were fed for 9 weeks a mixture of ground grains and skim milk in the form of a mash, with cut bones and a little green alfalfa. The grain consisted of bran, shorts, wheat, corn, rolled oats, and linseed meal, in varying proportions. At the close of the period the ducks had made a total gain of 27.3 lbs. Each pound of gain required 3.02 lbs. grain, a like amount of skim milk, and 0.16 lb. meat scrap, the cost being 3.93 cts.

At the close of the period 2 of the ducks were fed for 5 weeks longer and gained only 0.8 lb. The food required per pound of gain was 22.5 lbs. of grain, a like amount of skim milk, and a pound of cut bone, very much larger amounts than during the first period.

"It is the practice of the large producers to market the ducks at the age of about 10 weeks. The market demands young ducks. At this age they bring the best profit to the producer. If kept longer they begin to grow new feathers, and the food they eat is largely used in the making of feathers. Further growth is checked, and to feed them beyond this period is unprofitable."

Fattening turkeys (pp. 195–197).—The possibilities of profitably feeding turkeys in confinement and improving the quality of the flesh was tested with a lot of 6 nearly mature birds, kept in a small pen with an open front closed by a curtain. Whole wheat was scattered in straw litter in the morning, corn was fed at noon, and a grain mash at night. The turkeys were also given skim milk, sugar beets, and alfalfa leaves, with grit or gravel. One of the turkeys was sold at the end of 3 weeks, the others were fed for 4 weeks.

Considering the test as a whole, the 6 turkeys made a total gain of 16.4 lbs., of which 13.2 lbs. was made by 4 birds. When bled and plucked the turkeys lost 7 per cent in weight. The author calculated that there was a profit of $3.54 on an original investment of $8.50. "As to the quality of meat, those who ate it reported that they never ate better turkeys. There was no question about the quality of meat being greatly improved. The 2 smaller turkeys were not in as good condition as the others, but the meat was excellent."

"This experiment shows that young turkeys may be taken from the farm and fed in small pens at a profit; second, that the quality of the meat is greatly improved by such feeding."

Egg preservation, J. S. JEFFREY (*North Carolina Sta. Bul. 191, pp. 11-17*).—Different methods of preserving eggs were tested.

A 10 per cent solution of water glass gave very satisfactory results, the eggs keeping well from June until the following May. "Some of those used in December so closely resembled fresh eggs that it would take an expert to tell which were the fresh eggs and which were the packed ones after they were cooked." A 20 per cent solution of water glass did not give as satisfactory results. Though none of the eggs were spoiled, the whites in some cases were slightly coagulated and some of the eggs would not sink to the bottom of the solution.

A lime and salt solution gave as satisfactory results as water glass, none of the eggs being spoiled. A solution of lime and salt with British Egg Preserver (borax and sodium bicarbonate) also gave good results, "but it could not be seen that the addition of the preserver gave any returns for the money it cost and trouble of using." A solution of salicylic acid in water (1 oz. to a gallon) gave good results, none of the

eggs being spoiled, but it did not leave the eggs in as good condition as the water glass or the lime and salt solutions, since the acid weakened the shells.

Eggs were also coated with salicylic acid and cotton-seed oil with and without alcohol, with paraffin, collodium, and gum arabic, and then packed in cotton-seed hulls. Conclusions could not be drawn as to the value of these preservatives since the eggs were accidentally destroyed. However, the author is convinced that these preservatives and others of a similar character "are not as satisfactory as the liquid preparations, because of the extra labor in putting up and the evaporation that takes place, leaving the eggs shrunken in appearance when broken."

The report contains brief directions for testing eggs.

Experiments in the artificial rearing of oyster fry, J. NELSON (*New Jersey Stas. Rpt. 1904, pp. 415-446, pls. 9*).—A progress report is made of the investigations on the breeding of oysters. The conditions were unfavorable and general deductions were not drawn.

The construction of artificial inclosures called "claires," in which the oysters were kept and the character of the water controlled with reference to sediment, etc., are described. In one of these the water was filtered through several thicknesses of absorbent cotton quilted between sheets of galvanized wire netting of a quarter-inch mesh. Generally speaking, the oyster spawn during the past season was of poor quality. It was noted that sets of oyster spat were found in places where the water was very salt and in others where it was diluted with fresh water.

"So we can not conclude that a certain amount of fresh water is absolutely needed to induce a 'set.' It seems more likely that in those seasons characterized by a poor set, the result is due to a poor character of the spawn, owing to some previously acting influences on the mother oysters. This point needs careful investigation. . . . The experiences of previous seasons had led us to believe that the very climax of the spawning season occurs late in June, and that . . . southern seed would furnish an ample supply of spawn up to at least the latter part of August. Indeed, spawn is sometimes present in such oysters, and also in 'native' plants until quite late in the autumn.

"Oystermen are certain that there is a set of spat at the close of the spawning season of exceptional amount, known as the 'September set,' which may be due to a special increase in the spawning process early in September." It was found that late in June the oysters had already spawned to a greater or less extent.

"The eggs that remained in the half-filled oysters presented a poor appearance under the microscope. Many of them possessed ruptured shells, swollen nuclei, coarsely granular yolk, spherical shape, etc. Such an appearance leads me to believe that this spawn never is ejected, but is absorbed. Such absorption, or, at least, the disappearance of this spawn, was very slow, lasting at least to the middle of September, for a majority of the oysters.

"A certain proportion of the eggs in spawn of this character will be fertilized, and will undergo development, at first apparently quite normally, but finally they break down and disintegrate.

"It appears extremely probable that the character of the spawn, and therefore of the 'set' of seed, is determined by influences acting on the spawning oysters during the spring and early summer. It becomes, therefore, important to study how oysters are affected by surrounding conditions."

The histology of oysters was studied in detail, this phase of the work being illustrated by plates. (For earlier work see E. S. R., 16, p. 501.)

DAIRY FARMING—DAIRYING—AGROTECHNY.

Practical guide to dairying, R. T. ARCHER and P. J. CARROLL (*Jour. Dept. Agr. Victoria, 3 (1905), No. 4, pp. 279–329, pls. 12, figs. 8*).—This contains an introduction on the selection and preparation of land for a dairy farm and chapters on breeding, feeding, and management of cattle; common ailments of dairy cattle; dairy farm buildings; fodder for the dairy herd; dairy management; and milk testing.

Farm dairying, J. C. KENDALL (*North Carolina Sta. Bul. 192, pp. 19–48, figs. 9*).—This is a popular bulletin dealing with the various phases of dairying, with special reference to North Carolina conditions.

External conformation and productive capacity of cattle, H. ATTINGER (*Beiträge zur Kenntnis von Körperform und Leistung des Rindes. Leipsic: R. C. Schmidt & Co.; rev. in Vrtljschr. Bayer. Landw. Rat., 10 (1905), No. 1, p. 103*).—This volume deals especially with the question of the relation between external conformation and productive capacity in milch cows.

Report of the dairy husbandman, G. A. BILLINGS (*New Jersey Stas. Rpt. 1904, pp. 341–412*).—The first part of this report deals with soiling crops and is abstracted elsewhere (p. 353).

For 8 years the dairy herd has been fed soiling crops from May 1 to November 1 each year and silage for the remaining 6 months. On soiling crops the average production was 3,322 lbs. of milk and 167 lbs. of butter and on silage 2,997 lbs. of milk and 152.5 lbs. of butter. The cost of the roughage was also in favor of the soiling crops.

Dried beet pulp was compared with dried molasses beet pulp as regards influence on yield of milk and butter, effect on quality of milk, and relative cost of milk and butter. The test was made with 4 cows and lasted 30 days and indicated that the addition of beet molasses to beet pulp is no advantage in feeding for the production of milk. On the ordinary or unsweetened dried beet pulp the average daily yield of milk was 0.33 lb. and the yield of butter 0.02 lb. greater than on the dried molasses beet pulp. The relative cost of producing 100 lbs. of milk on the 2 rations was, respectively, 67.2 and 69.8 cts.

A similar comparison was made of dried molasses beet pulp and hominy meal. With rations otherwise alike 8 lbs. of dried molasses beet pulp produced 1.36 lbs. more milk and 0.09 lb. more butter per cow per day than 7 lbs. of hominy meal. The relative cost of producing 100 lbs. of milk on the 2 rations was, respectively, 68.9 and 78.1 cts. The hominy meal contained 8.41 per cent crude fat and the dried molasses beet pulp 0.42 per cent, yet the average fat content of the milk was 0.04 per cent higher on the pulp ration.

The usual monthly record of the dairy herd is given. The average yield for the year was 5,642.2 lbs. of milk or 280.58 lbs. of butter. The best cow produced 8,752.3 lbs. of milk and the poorest cow 3,443.9 lbs. The average cost of food per cow per year was $47.12. With milk at $1.00 per 100 lbs., 21 cows returned a net profit over cost of food of $22.39 per cow, while 11 cows were kept at a loss of $2.25 per cow. The average cost of producing 1 qt. of milk was 1.83 cts. for food and 1.03 cts. for labor and interest on the capital invested, or a total of 2.86 cts; the average for 8 years was 2.43 cts. The record of 1 Guernsey cow entered in the Advanced Register during the year was 8,603.4 lbs. of milk and 369.34 lbs. of fat.

The usual data are given on the fertilizing elements in the feeding stuffs purchased and the milk sold. The total gain to the farm in 8 years was 11,868 lbs. of nitrogen, 8,879 lbs. of phosphoric acid, and 2,836 lbs. of potash.

The hand separator was compared with the deep-setting system of creaming without ice. The average fat content of the separator skim milk for 8 days was 0.022 per cent as compared with 0.95 per cent with the gravity system.

Should dairy cows be confined in stalls? W. J. FRASER (*Illinois Sta. Circ. 93, pp. 25, figs. 24*).—This circular contains information obtained from 18 practical dairymen on the results of allowing cows the freedom of a closed shed or covered barnyard instead of confining them in stables. The greater part of the data is presented in tabular form and illustrations are given of many of the barns.

The very favorable results reported by the dairymen led the author to put the method into actual operation at the University of Illinois. Twenty-two cows were cared for in this way, with very satisfactory results. It was found that the cows kept much cleaner than when stabled, that the milking stable was in a more sanitary condition, and consequently that it was easier to produce clean milk. The cows were believed to be more vigorous and healthy than when kept in the ordinary stable. The saving of labor and also of manure are other strong points advanced in favor of this practice.

"The information at hand is not sufficient from which to draw definite conclusions for all sections of the country and all conditions. A tentative report is now published, as this system has been a marked success wherever we can find that it has been tried, and it seems probable that it could be put into practice by many dairymen of the State greatly to their advantage and to the general improvement of the milk supply." The station is desirous of communicating with all who have had experience in keeping cows in this manner and of receiving suggestions and criticisms concerning the method.

Suggestions for the improvement of dairy barns, H. A. HOPPER (*Illinois Sta. Circ. 95, pp. 20, figs. 15*).—The subjects discussed in this circular are the construction of floors, the interior arrangement of the barn, fastenings for cows, ventilation, and whitewashing.

Tests of materials for bedding cows, C. F. DOANE (*Maryland Sta. Bul. 104, pp. 9*).—Cut wheat straw, cut corn stover, sawdust, shavings, and rye straw were compared with uncut wheat straw as regards the quantity required to keep cows clean. Tests were also made of the absorptive power of each of the materials mentioned.

Cut wheat straw was not found as satisfactory as uncut wheat straw. At the rate used in the experiments, 2,300 lbs. of the cut straw as compared with 1,800 lbs. of the uncut straw would be required per cow yearly in order to keep the animals equally clean. About one-third more by weight of cut corn fodder was required to accomplish the same results as wheat straw. The corn fodder was considered better bedding material than the straw, and where wheat is grown purposely to secure straw for bedding purposes it is believed that corn fodder might well be substituted to a considerable extent. Sawdust was found the most satisfactory of the bedding materials used. Good results were also secured with shavings. These two materials are believed to be ideal bedding materials in sanitary dairying. Rye straw was not thought to be as good as wheat straw for cows.

From the results of laboratory tests as to the amount of water capable of being absorbed by each of the materials used, it was estimated that 2.8 lbs. of cut stover, 3.3 lbs. of wheat straw, 8.3 lbs. of sawdust, or 3 lbs. of shavings would be required to absorb the liquid manure produced by 1 cow in 16 hours. The yearly cost of bedding for cows stabled the entire day was estimated as follows: Cut stover $3.65, cut wheat straw $4.82, uncut wheat straw $4.15, sawdust $0.45, shavings $4.81.

Concentrated feeding stuffs and stage of lactation, A. OSTERMAYER (*Österr. Molk. Ztg., 12 (1905), No. 9, pp. 117-119*).—This is a report of an experiment with 17 cows, the results of which showed greater profit in feeding an additional supply of oil cake to cows in early than in late stages of lactation. In the first of the 3 periods of the experiment 9 of the cows were fed the additional feed with profit, while in the third period the number was reduced to 3.

Increasing the fat content of milk by feeding, P. DIFFLOTH (*Indus. Lait. Belge, 6 (1905), No. 35, pp. 276-279*).—Using the data obtained at the dairy tests at

the Chicago and St. Louis expositions and the results of some experiment station work in this country and of investigations in Belgium, the author concludes that the productive capacity of cows as regards yield of milk and butter may be increased by suitable feeding, though the percentage of fat in the milk remains practically unchanged.

On the influence of asparagin on the production of milk and its constituents, T. PFEIFFER, A. EINECKE, and W. SCHNEIDER (*Mitt. Landw. Inst. Breslau, 3 (1905), No. 2, pp. 179–225*).—In experiments with 6 goats lasting 2 years, the substitution, in quantities having equal fuel value, of a mixture of asparagin and cane sugar for a part of the proteids in a ration moderately rich in protein produced (1) no decrease in the yield of milk, but an increase in individual instances; (2) a lowering of the percentages of fat, proteids, and total solids in the milk; (3) a distinct reduction in the actual yield of fat; (4) unessential variations in the actual amount of proteids produced, and (5) an unfavorable influence on the increase in live weight of the animals.

Asparagin or the amids in general are, therefore, according to the authors, to be stricken from the list of nutrients. In rations very rich in food constituents the amids on the contrary are able, on account of their irritating or stimulating actions, as yet not satisfactorily explained, to exert a favorable influence on milk secretion, but always at the expense of other food constituents or body tissues.

Daily variations in the fat content of milk, M. SIEGFELD (*Molk. Ztg., 19 (1905), No. 38, pp. 975–978*).—The mixed milk of each of 14 dairy herds was tested daily for 1 year. Data are presented showing variations in fat content for short and long periods and causes of these variations are discussed. The fat content of the mixed milk of 1 herd milked 3 times daily was 2.91 per cent in the morning, 3.53 per cent at noon, and 3.18 per cent in the evening. In another instance the percentages were, respectively, 2.56, 3.65, and 3.10.

Variations in the yield and fat content of milk during one year, HARNOTH (*Molk. Ztg., 19 (1905), No. 28, pp. 712–714*).—Records of 20 dairy herds are summarized and used in this discussion of the causes and extent of variation in the yield and fat content of milk. The average fat content for the year was 3.24 per cent. Monthly variations ranged from 3.13 to 3,39 per cent.

On the origin of lactose, C. PORCHER (*Compt. Rend. Acad. Sci. [Paris], 141 (1905), No. 10, pp. 467–469*).—In studying the source of lactose in milk the author made hypodermic, intraperitoneal, and intramammary injections of glucose, using for this purpose cows, goats, and dogs in full lactation. Hyperglycemia under such conditions tended to produce lactosuria instead of glycosuria.

On the agricultural production of milk for infants, P. DIFFLOTH (*Indus. Lait. Belge, 6 (1905), No. 37, pp. 289–293*).—The suitability of various feeding stuffs for cows used in the production of milk for infants is discussed.

Principles and experiences in the preparation of milk for infants, BACKHAUS (*München. Med. Wchnschr., 52 (1905), No. 39, pp. 1883–1885*).—The author for years has advocated in infant feeding the so-called aseptic milking, the modification of the milk in suitable establishments rather than in homes, bottling, and sterilization, and in this article outlines the methods employed and comments on the good results obtained.

A discussion on infant milk depots, B. W. F. ANDERSON, N. STRAUS, ET AL. (*Brit. Med. Jour., 1905, No. 2333, pp. 643–647*).—This is a presentation of the work being done in Glasgow, New York City, and other places in furnishing a wholesome milk supply for feeding the children of the poor. The report on the Straus depots in New York is especially full.

The nutritive value of sterilized cow's milk, R. BRUNON (*Bul. Acad. Méd. [Paris], 3. ser., 53 (1905), No. 16, pp. 396–399*).—During 4½ years the infant milk depot in Rouen, known as the Goutte de Lait, distributed 223,000 liters of sterilized

milk, used in the feeding of about 2,000 infants, of whom 70 per cent suffered with malnutrition. The milk furnished was sterilized and modified. The composition, as shown by one analysis, was as follows: Fat 4.03, lactose 5.37, casein 2.85, and calcium phosphate 0.405 per cent.

There was no question as to the nutritive value of the milk in the great majority of cases. In numerous cases of enteritis it was believed to have had a curative effect. No case of Barlow's disease developed. Only a small number of infants failed to do well. Sterilization in an autoclave at 102° C. for 45 minutes does not, therefore, in the experience of the author, destroy the nutritive value of milk, and it is believed that the health of the infants consuming the milk is a better standard for judging than analytical data.

New methods of sterilizing milk and cream with reference to Danish milk, M. Riegel (*Molk. Ztg., 19 (1905), No. 30, pp. 763, 764*).—This is essentially a discussion of Budde's method of sterilizing milk with hydrogen peroxid and Dorn's experiments with ozone. The author has observed that in milk preserved by the Budde method the fat is colorless, the aroma is destroyed, and the proteids are to a certain extent oxidized.

Comparative experiments upon chemical preservatives in milk, H. C. Sherman, A. W. Hahn, and A. J. Mettler (*Jour. Amer. Chem. Soc., 27 (1905), No. 9, pp. 1060–1068*).—This is a preliminary report on the destruction of lactose and the development of acid in milk treated with sodium fluorid, sodium salicylate, and a mixture of boric acid and borax. Brief notes are also given on the determination of these preservatives and on the use of hydrogen peroxid as a milk preservative. A discussion of the effects of preservatives upon the wholesomeness of milk is being deferred until the completion of the experiments in progress. The results so far obtained are summarized as follows:

"Milk kept at 20 to 25° without preservative showed a rapid increase in acidity and decrease in percentage of milk-sugar during the first 3 to 6 days, after which the acid fermentation proceeded much more slowly, but neither the destruction of lactose nor the formation of acid had ceased entirely after 4 weeks.

"Hydrogen peroxid, sodium fluorid, sodium salicylate, and a mixture of equal parts boric acid and borax were each found to diminish distinctly the development of acidity in milk when added in the proportion of 1:1,000.

"When present in about this proportion any one of the preservatives can be determined quantitatively with a probable error of 1 to 6 per cent of the amount in the milk. In the case of hydrogen peroxid, however, the preservative disappears so rapidly that the amount found present gives little indication of the quantity originally added.

"In the presence of fluorid or salicylate the fermentation is changed qualitatively as shown by the ratio of acid formed to lactose destroyed. With these preservatives it was found that occasional exposure of the samples to air, especially when the quantity of preservative present was small, led to irregular results, the final acidity sometimes exceeding that in the control samples to which no preservative had been added.

"In the experiment with samples preserved by boric acid and borax or by hydrogen peroxid such irregularities did not appear. The boron preservative had no apparent influence upon the nature of the acid fermentation. The experiments with hydrogen peroxid are only preliminary."

On the keeping properties and legal status of milk treated with lime-sugar solution, Lührig (*Molk. Ztg., 19 (1905), No. 22, pp. 547, 548*).—The solution used contained 4.2 per cent of lime and 19.7 per cent of cane sugar and was added to milk in quantities varying from 0.5 to 5.0 per cent. The acidity of the milk was reduced, the reaction becoming strongly alkaline when large quantities of the solution were added, in which case bacterial growth stopped, coagulation did not occur, and the

milk was rendered unfit for use. The addition of lime-sugar solution to milk and milk products is, therefore, considered an adulteration.

The so-called "germicidal property" of milk, W. A. Stocking, Jr. (*Connecticut Storrs Sta. Bul. 37, pp. 20, dgms. 3*).—This is reprinted, with minor changes, from the last annual report of the station (E. S. R., 16, p. 1014).

The chemical composition of colostrum with special reference to the proteids, M. Nencki (*Opera Omnia. Brunswick: Vieweg, 1905, vol. 2, pp. 840–890; abs. in Biochem. Centbl., 4 (1905), No. 11–12, p. 348*).—From the proteids of colostrum coagulated by heat are produced by hydrolysis carbohydrates, alanin, amidovaleric acid, leucin, pyrrolin carbonic acid, serin, phenylalanin, tyrosin, aspartic acid, glutamic acid, cystin, tryptophane, and other amido acids. Arginin, histidin, lysin, and ammonia are also produced.

The colostrum examined contained the following organic constituents: Casein, globulin, albumin, fat, cholesterin, lecithin, probably small quantities of the higher fatty acids, glycerol phosphoric acids, lactose, and urea. Some of the quantitative determinations were as follows. Total solids 17.19, total nitrogen 1.52, total proteid nitrogen 1.43, total proteids 9.13, nitrogen in precipitate by acetic acid 0.47, nitrogen in precipitate by heat 0.79, albuminoid nitrogen 0.077, ether extract 2.40, cholesterin 0.04, lactose 2.9, and ash 0.67 per cent.

Milk examinations, J. Szilasi (*Chem. Ztg., 29 (1905), No. 44, pp. 607, 608*).—Of 664 samples of milk collected for the most part from large dealers in Budapest during the last 10 years, 292 were pronounced pure, 300 watered, 61 skimmed, and 11 watered and skimmed. The reaction for nitrates is taken as a proof of watering, either directly or from small quantities of wash water remaining in cans not properly cleaned.

Chemical investigations relating to dairy undertaken in 1904, F. T. Shutt (*Canada Dept. Agr., Dairy Comr. Branch Bul. 6, pp. 11*).—Examinations were made of samples of milk preserved by the hydrogen-peroxid method of Budde and forwarded by F. G. Korch, of Copenhagen, Denmark. Chemical tests showed the presence of hydrogen peroxid. Bacteriological examinations by W. T. Connell showed that the milk was sterile. From the samples examined the author concludes that it is impossible to draw a favorable conclusion regarding the palatability of the milk or its suitability for general use.

Tests were made of the patented butter-making process of James Estep, for which it is claimed that by mixing with cream a certain mixture of pepsin, milk sugar, alum, and saltpeter the yield of butter is increased, the time of churning is reduced, and disagreeable flavors are removed. The results of the tests failed to support these claims.

A milk powder produced by the evaporation of whey showed the following composition: Moisture 3.73, albumin and nitrogenous bodies 12.81, fat 3.91, milk sugar (by difference) 72.27, and ash 7.28 per cent. From this analysis it is considered clear that the preparation has a distinct nutritive value, though the author doubts if the process will prove economical or the food become popular.

A cheese 26 months old was found upon analysis to be normal in composition, indicating that age and cold storage do not affect genuine cheese so as to render it liable to be confounded with an adulterated article.

Trials were made of two outfits for determining the amount of water in butter. The Carroll tester, in which the butter is melted and the separated water measured, was found entirely untrustworthy. The Geldard tester, depending upon the loss of weight when the butter is submitted to such a temperature as will result in the evaporation of the water without causing a decomposition of the fat, was found to give results in close accordance with those obtained by accepted methods of analysis.

Butter investigation, H. Lührig (*Ber. Chem. Untersuch. Amt. Chemnitz, 1904, pp. 14–17; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 9 (1905), No. 12, p. 734*).—A butter showing a Reichert-Meissl number of 24.4, Polenske number of 2.1, and a

saponification number of 231.8 was pronounced adulterated with cocoanut oil, though it was shown that the cows producing the butter were fed large quantities of cocoanut cake.

Composition of Holland butter produced by dairies under government control, T. VAN SILLEVOLDT (*Über Zusammensetzung der niederländischen Butter, herstammend aus der Staatskontrolle unterstellten Molkereien. The Hague: Gen. Dir. Landw. Min. Waterst., Handel u. Gewerbe, 1905, No. 2, pp. 17; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 9 (1905), No. 12, pp. 734, 735*).—Of 3,945 samples of butter examined during January, February, and March, 1905, only 4 samples showed a lower Reichert-Meissl number than 24, while during the 3 months preceding 32 samples fell below that number.

Investigations on influences in Limburg affecting the composition of butter, D. KNUTTEL (*Untersuchung der Einflüsse, welche für die Zusammensetzung der Butter in Limburg massgebend sind. Weerdt: E. Smeets, 1904, pp. 11; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 9 (1905), No. 12, pp. 733, 734*).—Forty samples of butter produced under known conditions in this province of Holland were analyzed.

The refractometer number was usually low (42 to 45). The Reichert-Meissl number was generally 27, and rarely below 26. Both numbers were less favorable in the late fall, though no great variations were observed. The composition of butter is believed to be influenced by the care of the cows, the nature of the food, climate, and the condition of the soil.

Holland butter, A. JUCKENACK and R. PASTERNACK (*Ztschr. Untersuch. Nahr. u. Genussmtl., 10 (1905), No. 1-2, pp. 87-100*).—Analyses of 116 samples of Holland butter are reported. Of this number 69 were considered abnormal. Analyses are also reported of 30 samples of butter made by the authors from cream purchased from dairies in Berlin.

The data show a marked seasonal influence on the composition of the butter. The work is reported, however, mainly on account of the determination of the average molecular weight of the nonvolatile water-insoluble fatty acids, which was rarely below 260, though at certain seasons of the year somewhat higher. It is believed that this determination will prove of value in detecting adulteration.

Government butter control in Holland, A. J. SWAVING (*Ztschr. Untersuch. Nahr. u. Genussmtl., 10 (1905), No. 1-2, pp. 80-87, fig. 1*).—This is a discussion of the system employed in Holland.

The decomposition of fats, O. RAHN (*Centbl. Bakt. [etc.], 2. Abt., 15 (1905), No. 2-3, pp. 53-61*).—The author discusses the decomposition of fat in butter, in cheese, and in the soil.

Only a few bacteria are at present known to decompose fat. This process is much more commonly brought about by fungi. The decomposition of fat takes place only in the presence of organic nitrogen. As glycerin is first attacked decomposed fats show a high acid number. Fatty acids are all equally decomposed by bacteria, while fungi show a preference for the lower acids. In the oxidation of fatty acids no by-products are produced. Fat is not decomposed under anaerobic conditions.

Characteristics of camel's butter, J. VAMVAKAS (*Ann. Chim. Analyt., 10 (1905), No. 9, p. 350*).—To accompany the analyses of camel's milk by Barthe, previously noted (E. S. R., 16, p. 1121), an analysis of an authentic sample of the butter is reported as follows: Melting point of butter 38° C., melting point of fatty acids 47°, volatile fatty acids 8.6 per cent, fixed fatty acids 88.29 per cent, index of saponification 208, iodin number 55.10, and index of refraction 20.

On Oïdium lactis and the ripening of cream and cheese, J. ARTHAUD-BERTHET (*Compt. Rend. Acad. Sci. [Paris], 140 (1905), No. 22, pp. 1475-1477*).—*Oïdium lactis* is found almost always in milk, cream, butter, and cheese. A temperature of 65° C. for 5 minutes suffices to destroy this organism, as well as yeasts, fungi, and numerous casein ferments. The advantages of pasteurization are pointed out and mention is made of a new form of pasteurizing apparatus devised by the author, Mazé, and

Perrier, in which the desired temperature is kept constant by the use of a liquid having the corresponding boiling point.

On the action of rennet ferments on milk and casein, E. LAQUEUR (*Biochem. Centbl., 4 (1905), No. 11-12, pp. 333-347*).—This is a critical review of literature of this subject, with a list of 122 references.

The importance of direct microscopical preparations in studying the process of cheese ripening, A. RODELLA (*Centbl. Bakt.* [*etc.*], *2. Abt., 15 (1905), No. 4-6, pp. 143-153, pl. 1*).—This deals with the technique employed and the results obtained in the direct microscopical examination of cheese, but more fully with the question of the rôle of bacteria in the ripening process. Sections were cut with the microtome and stained with carbol-thionin after the method of Gorini. A simpler method, devised by the author, was to press a small cube of cheese between two slides, remove the fat from the material adhering to the glass by means of chloroform and alcohol, and stain. Illustrations are given showing the distribution of bacteria in ripe Emmenthal, Gorgonzola, and Grana cheese.

The 3 kinds of cheese mentioned were examined by both methods at different stages of ripening. The bacteria were found to be grouped in colonies, which were variable in size and irregularly distributed through the mass of cheese. The colonies were usually of one kind, though occasionally several forms were present. The spaces between colonies were occasionally, but not usually, entirely free from bacteria.

This method is believed to be of importance in studying the causes of cheese ripening.

Notes on the article by A. Peter entitled Technical-bacteriological investigations in Emmenthal cheese making, E. VON FREUDENREICH (*Centbl. Bakt.* [*etc.*], *2. Abt., 14 (1905), No. 18-20, pp. 616, 617*).—The author discusses the article referred to (E. S. R., 16, p. 1019), commenting especially upon the favorable results that may be secured by the use of artificial rennet and pure cultures.

Annual reports of the dairymen's associations of the Province of Ontario, 1904 (*Ann. Rpts. Dairymen's Assocs. Ontario, 1904, pp. 248, figs. 17*).—This contains about 50 articles, mainly of a popular nature, dealing with various phases of the dairy industry.

Some of the tests of individual cows being made under the supervision of the Ontario Department of Agriculture are reported by C. F. Whitley. The product of 20 cows in one herd amounted in 4 months to $302, while that of 20 cows in another herd during the same time amounted to $435.

In discussing the curing of cheese, J. A. Ruddick suggests certain points in favor of cool curing at 55 to 60° F. over cold curing at 40°, gives data showing a saving of 1.41 per cent in shrinkage by cool curing as opposed to curing in an ordinary curing room, and argues for the improvement of curing rooms, summarizing the advantages of the central cool-curing rooms as established by the government.

H. H. Dean reported that in experiments at the Ontario Agricultural College in comparing pepsin and rennet for coagulating milk in cheese making, the pepsin produced a little better quality of cheese, but a decrease in yield of ½ lb. per 1,000 lbs. of milk and ½ per cent greater loss in weight during curing. Owing to the difficulty in preparing and keeping pepsin for this purpose its use is not recommended over that of rennet, but further experiments will be conducted along this line.

A technical paper on The Bacterial Contamination of Milk and Its Control, by F. C. Harrison (E. S. R., 16, p. 506) is reprinted as an appendix.

Tests of new dairy apparatus at the Danzig Exposition in 1904, B. MARTINY (*Arb. Deut. Landw. Gesell., 1905, No. 110, pp. 79, figs. 36*).—Detailed reports are made upon the separators, filters, butter workers, and other forms of dairy apparatus tested.

Casein: Its preparation and technical uses, R. SCHERER (*Das Kasein. Seine Darstellung und technische Verwertung. Vienna and Leipsic: A. Hartleben, 1905, pp. 192, figs. 11*).

Progress in the manufacture of starch, H. HANOW (*Chem. Ztg., 29 (1905), No. 67, pp. 881–884*).—A review of the progress made in this industry in 1904.

Complete treatise on the manufacture of beer, G. MOREAU and L. LÉVY (*Traité complet de la fabrication des bières. Paris: Ch. Béranger, 1905, pp. 674, pls. 5, figs. 173; rev. in Bul. Inst. Pasteur, 3 (1905), No. 17, p. 697*).

Further inquiries into the systematic leaching of grape husks for the recovery of spirit usually allowed to go to waste in ordinary practice, A. J. PERKINS and W. R. JAMIESON (*Jour. Dept. Agr. So. Aust., 9 (1905), No. 1, pp. 24–38, figs. 2*).—Further investigations have shown that the husks carry away about 32 gal. of proof spirit per ton, or the equivalent of about 6 gal. of proof spirit per ton of grapes crushed. Of this amount about 80 per cent may be recovered by the systematic leaching of the pressed husks on the plan described by the authors here and in their previous report (E. S. R., 16, p. 267).

On the production of sweet cider, G. WARCOLLIER (*Compt. Rend. Acad. Sci. [Paris], 140 (1905), No. 26, pp. 1711–1713*).—In laboratory experiments good results were secured in keeping apple must under anaerobic conditions, whereby only part of the sugar was converted into alcohol before the fermentation ceased. Further experiments are to be made on a practical scale.

The national fruit and cider institute and its work, B. T. P. BARKER (*Jour. Bd. Agr. [London], 12 (1905), No. 6, pp. 321–334, figs. 4*).—In this account of the institute are given briefly some of the results so far obtained.

Twenty-eight varieties of apples and 4 varieties of pears obtained from 8 counties were analyzed and used separately in making cider. In general the cider made from a single variety was not of high quality. It is believed that the quality of a cider depends primarily on the varieties used, and that the principal characters of any variety affecting its value for this purpose are chemical composition, flavor, and rate of fermentation of juice.

In addition to securing data on the value of individual varieties for cider making, information has also been obtained on the subject of blending.

Pure cultures in vinegar making, W. HENNEBERG (*Centbl. Bakt. [etc.], 2. Abt., 14 (1905), No. 22–23, p. 681*).—In this preliminary communication the author reports the satisfactory use of pure cultures of bacteria in vinegar making. Vinegar containing 11½ per cent of acid and entirely clear has been produced in this way.

Citric acid from lemon waste direct, A. HEINGARTNER (*Mo. Consular Rpts. [U. S.], 1905, No. 297, p. 101*).—A method of extracting citric acid from lemon waste direct is reported to have been discovered by Giovanni Restuccia of Italy. Details are not given.

VETERINARY MEDICINE.

Some important foreign veterinary investigations, E. V. WILCOX (*U. S. Dept. Agr., Office Expt. Stas. Rpt. 1904, pp. 545–573*).—This article is a digest of results obtained by foreign investigators in the study of tuberculosis, rabies, tetanus, anthrax, Texas fever, rinderpest, and milk fever.

Report of veterinary director general, J. G. RUTHERFORD (*Rpt. Min. Agr. Canada, 1904, pp. 49–186, figs. 15*).—The usual details and special reports are presented concerning the health of animals in various parts of the Dominion of Canada.

Hog cholera appears to be on the decrease. Attention was given to the eradication of tuberculosis and glanders. In a study of the Pictou cattle disease, results were obtained which indicate that the disease is due to eating ragwort. All attempts to transmit the disease by contagion gave negative results. Further experiments will be conducted along this line. A vigorous campaign is being carried on for the eradication of cattle mange and maladie du coit.

Brief notes are given on mange in horses, sheep scab, anthrax, blackleg, actinobacillosis, actinomycosis, swamp fever, meat inspection, quarantine, and dipping

plants. Special reports are presented by C. H. Higgins and various inspectors in different parts of the Dominion of Canada regarding cattle dips, tuberculin, verminous bronchitis in hogs, poultry diseases, etc.

The actual conceptions of experimental pathology, CHARRIN (*Rev. Sci. [Paris], 5. ser., 3 (1905), No. 10, pp. 289–296*).—In this article the author presents definitions of many terms and conceptions used in the literature relating to general pathology.

Immunization as a means of controlling contagious diseases, J. B. TIFFANY (*Mo. Bd. Agr. Mo. Bul., 4 (1905), No. 9, pp. 46–50*).—A brief discussion is presented of the field of immunization as at present understood with particular reference to anthrax, blackleg, tetanus, and hog cholera.

Anaerobic bacteria in the intestines of cattle, J. NEUBAUER (*Arch. Wiss. u. Prakt. Tierheilk., 31 (1905), No. 1–2, pp. 153–176*).—The literature relating to this subject is discussed in a critical manner in connection with a short bibliography.

The results of the author's experiments and study may be briefly stated as follows: Anaerobic bacteria in the large and small intestines of cattle are rare. They occur more frequently, however, in the large than in the small intestines. No bacilli or spores of tetanus or malignant edema were found in the intestines. The vegetative forms or spores of anaerobic bacteria taken up in the food are usually destroyed in the stomach or duodenum.

The pathogenic action of parasites in the intestines, J. GUIART (*Arch. Par., 9 (1905), No. 2, pp. 175–186*).—According to the author's investigations parasites may cause harmful effects in 3 ways: By irritating the end organs of the intestinal nerves, by secreting the toxins which destroy the red corpuscles and hemoglobin, and by producing ulcerations of the intestinal mucous surfaces thus giving opportunity for infection with pathogenic bacteria.

An infectious pneumonia of rabbits and its control by means of an antiserum, H. J. SÜDMERSEN (*Centbl. Bakt. [etc.], 1. Abt., Orig., 38 (1905), No. 3, pp. 343, 344*).—From cases of pneumonia in rabbits the author isolated a bacillus which evidently belongs to the coli group and which develops a very active toxin in cultures of bouillon. The organism may be destroyed by subjection to a temperature of 60° C. for 10 minutes. It was found that cultures thus destroyed exercised a decided vaccinating action when injected into rabbits. After repeated injections with dead cultures the blood of rabbits contained pronounced agglutinating and bactericidal properties sufficient to immunize the animal.

Furonculine, G. MITROWITSCH (*Berlin. Tierärztl. Wchnschr., 1905, No. 5, pp. 77–80*).—Furonculine is a name given to a form of beer yeast used in the treatment of animal diseases on account of its supposed antiseptic properties. It is recommended that it be administered by way of the mouth.

The author describes the powder form in which the material is ordinarily sold, and reports upon culture experiments made with this material. A number of bacilli and streptococci were obtained from this substance and the material proved to be pathogenic for mice and rabbits after administration by the intraperitoneal or subcutaneous methods. The author states that in his practice a number of cases of animal diseases have occurred in which he tried furonculine without any satisfactory results.

The remedy appeared to have no beneficial effect in the treatment of rabbits artificially inoculated with streptococci, and among 26 horses treated for contagious coryza one died of pyemia, while the majority of the rest had to be treated by surgical operation.

Investigations concerning lysoform, B. PROMNITZ (*Fortschr. Vet. Hyg., 2 (1905), No. 11, pp. 281–295*).—The appearance and chemical composition of lysoform are described in considerable detail, together with notes on its bactericidal properties toward various pathogenic organisms, including anthrax spores and the organisms of malignant edema, blackleg, hog cholera, and fowl cholera.

In order to gain information regarding the toxic properties of lysoform the author conducted experiments on rabbits, dogs, cats, horses, cattle, sheep, and chickens. In these investigations the subcutaneous, intravenous, and intraperitoneal methods were avoided. Lysoform was given by way of the mouth. As a result of the author's experiments it is concluded that lysoform is the least poisonous of the ordinary disinfectants. It appears to satisfy the ordinary veterinary requirements for an antiseptic substance, and is more effective as a deodorizer than the majority of similar disinfectants. Lysoform appears to be particularly adapted for use in veterinary obstetric practice and in the treatment of weak animals.

Crude oil as a disinfectant, F. C. QUEREAU (*Demeter, 3 (1905), No. 4, pp. 13–16, fig. 1*).—A method is described by which crude oil may be used in burning the carcasses of animals dead of anthrax and simultaneously disinfecting the ground immediately around the carcass.

The biology of tubercle bacilli of low virulence, J. BARTEL and R. STEIN (*Centbl. Bakt.* [*etc.*], *1. Abt., Orig., 38 (1905), Nos. 2, pp. 154–163; 3, pp. 264–271; 4, pp. 292–302*).—The authors briefly review the literature relating to this subject, and cite some of the more important references.

During the experiments reported in the paper various races of tubercle bacilli of different origin were utilized and inoculation experiments were made with various laboratory animals. Detailed notes are given on the technique of the authors' experiments. As a result of the authors' investigations it appears that in general the multiplication of tubercle bacilli post-mortem in tissues specifically altered by the bacilli probably takes place in the absence of other micro-organisms and under favorable temperature conditions, although this is not a matter of certainty.

It was possible to observe various morphological alterations in the tubercle bacilli, such as segmentation, granular disintegration, branching, and other changes of form. Dead tubercle bacilli which were low in virulence when encapsulated in organs specifically affected by the bacilli are not able to cause specific alterations or general infection in inoculated animals.

Immunization of cattle against tuberculosis and serum experiments with this disease, LIBBERTZ and RUPPEL (*Deut. Med. Wchnschr., 31 (1905), Nos. 4, pp. 139–142; 5, pp. 182–184*).—A test was made of a method of immunization recommended by Friedmann in using tubercle bacilli obtained from turtles. During these experiments the authors treated 3 cattle with tubercle bacilli from turtles and subsequently examined the serum of the treated animals.

As a result of the test the authors conclude that Friedmann's cultures are not without danger for warm-blooded animals. It appears that they produce serious intoxication and organic changes which may cause death without the development of true tuberculosis. Intravenous injections of Friedmann's cultures are not capable of protecting warm-blooded animals from later infection with tuberculosis. The injections of these cultures do not produce immune bodies in warm-blooded animals.

Immunization against tuberculosis by means of tubercle bacilli from turtles, F. F. FRIEDMANN (*Deut. Med. Wchnschr., 31 (1905), No. 5, pp. 184–186*).—This article is of a controversial nature and was written in reply to a criticism by Libbertz and Ruppel.

According to the author's experiments, guinea pigs may be successfully immunized against tuberculosis by previous treatment with tubercle bacilli from turtles. The control animals died within 3 weeks of generalized tuberculosis, while immunized animals were found to be quite free from the disease when killed and examined 70 days after inoculation. It is denied that the cultures of tubercle bacilli from turtles exercise any pronounced harmful action upon cattle. Cattle treated with such cultures acquire a rather pronounced immunity, which can be further intensified by inoculation with bovine tubercle bacilli.

A case of abortion and puerperal collapse due to tuberculosis, G. Ceramicola (*Gior. R. Soc. ed. Accad. Vet. Ital., 54 (1905), No. 10, pp. 217-224*).—The case observed by the author occurred in a cow and was described in detail with particular reference to the pathological anatomy and distribution of the lesions. It appeared to be a case of primary uterine tuberculosis and led to the involvement of the uterus to such an extent that abortion took place.

Reaction to tuberculin, H. Vallée (*Rev. Gén. Méd. Vét., 5 (1905), No. 54, pp. 305-310*).—This article is of a controversial nature and in it the author seeks to defend his position against the criticism of Arloing.

The author has conducted a number of experiments for the purpose of determining the length of time which ordinarily elapses after tuberculin injection before reaction occurs for the first time and at subsequent tests. According to these experiments the temperature reaction takes place much more promptly after the second or third injection than after the first. The author recommends, therefore, that after the first tuberculin injection the temperature readings be begun within 12 hours and continued for 6 to 9 hours. If the animal has been previously tested with tuberculin, however, especially if the injection has been recently given, it is recommended that the temperatures be taken within an hour or two after injection.

Fraud in connection with tuberculin test, E. Thierry (*Jour. Agr. Prat., n. ser., 9 (1905), No. 2, pp. 44, 45*).—This is a brief discussion of results recently obtained by Nocard and especially by Vallée. On account of the fact that tuberculous animals react very quickly to a second tuberculin test it is recommended that large doses of tuberculin be given in suspicious cases and that the temperatures be taken within 2 or 3 hours after inoculation.

Experience with a method for demonstrating anthrax, A. Marxer (*Ztschr. Fleisch u. Milchhyg., 15 (1905), No. 5, pp. 129-136*).—The author finds as a result of numerous experiments that the best method for securing spores in anthrax bacilli, and for preserving and shipping material containing such bacilli, is by the use of rods of plaster of Paris. This material may be formed into rods by small wires as a basis and may be of convenient length for enclosing in test tubes. Experiments with this method indicate that sporulation takes place very rapidly upon the plaster of Paris rods.

Pyrosoma diseases of cattle, J. W. Schütz (*Arch. Wiss. u. Prakt. Tierheilk., 31 (1905), No. 3, pp. 317-329*).—An account is given of various diseases of cattle due to forms of pyrosoma. Particular attention is devoted in the article to Texas fever, hemoglobinuria of cattle in Germany, African coast fever, and Trans-Caucasian pyroplasmosis. Hemoglobinuria in Germany appears to be identical with Texas fever.

Eradication of African coast fever (*Rhodesian Agr. Jour., 2 (1905), No. 4, pp. 127-129*).—It seems to be established that cattle which have recovered from the disease do not permanently remain a source of infection. In order, therefore, to free an area from African coast fever it is recommended that no susceptible cattle be introduced into the area until 12 months after the last case known to have occurred on the ground in question. Calves from immune cows should be isolated for a period of 12 months before being allowed with susceptible cattle.

The Texas fever cattle tick situation, H. A. Morgan (*Louisiana Stas. Bul. 82, 2. ser., pp. 15*).—Previously noted from another source (E. S. R., 17, p. 189).

Preventive vaccine for heartwater, D. Hutcheon (*Agr. Jour. Cape Good Hope, 26 (1905), No. 5, pp. 647, 648*).—The vaccine method of Dr. Purvis for the prevention of heartwater was tested on 40 sheep, with 10 control sheep. Of the inoculated sheep 27.5 per cent became sick, while of the controls 60 per cent were affected.

Pathogenesis and etiology of chronic hematuria in cattle, E. Liénaux (*Ann. Méd. Vét., 54 (1905), No. 4, pp. 185-198, figs. 3*).—Chronic hematuria in cattle may be due to various causes which operate as irritants upon the kidneys. Cases may be due to infestation with parasitic worms, to neomorph formations in the kidneys, and

to other causes, but all such cases are readily distinguishable from hematuria as the result of Texas fever. The disease most frequently affects cattle in a badly nourished condition, but sometimes attacks fat cattle.

Broncho-pneumonia of cattle; its association with Bacillus bovisepticus, P. G. WOOLLEY and W. SORREL ([*Philippine*] *Bur. Govt. Labs.* [*Pub.*], *1904, No. 20, pp. 21-33*).—This disease chiefly affects young animals and the symptoms vary considerably. Detailed clinical notes are given on 9 such cases in which *Bacillus bovisepticus* was found. In the cases under discussion the organism in question was not the primary pathogenic agent. Where it occurs as a primary infection the disease probably runs a more acute course. It appears that *B. bovisepticus* is quite commonly found in the respiratory tract of cattle in the Philippines.

Cattle complaint, DESMOND (*Jour. Dept. Agr. So. Aust., 8* (*1905*), *No. 8, pp. 435-438, figs. 2*).—Brief notes are presented on a disease of cattle which was not at first understood but which is apparently due to poisoning from eating rabbits destroyed with phosphorus. The symptoms and post-mortem lesions resemble those of phosphorus poisoning.

Infectious granular vaginitis and metritis of cattle, M. G. DE BRUIN (*Tijdschr. Veeartsenijk., 32* (*1905*), *No. 4, pp. 159-179, fig. 1*).—A historical statement is presented regarding the development of knowledge concerning this disease and the literature of the subject is critically reviewed. The characteristic symptoms of the disease are described with reference to making a differential diagnosis between it and similar diseases. The micro-organism found in cases of this disease usually appears as a diplococcus or streptococcus. Notes are given on the results obtained by the author and other investigators in applying antiseptic treatment. Considerable success may be expected from the application of creolin, lysol, bacillol, lysoform, nitrate of silver, ichthargan, and other antiseptics in 1 to 2½ per cent solutions.

Mammitis in cows, A. LANFRANCHI (*Clin. Vet.* [*Milan*], *28* (*1905*), *No. 10, pp. 49-57*).—A study of mammitis in cows led the author to the conclusion that in certain cases this disease may be due to *Micrococcus tetragenus septicus* or *M. tetragenus albus.* The symptoms and pathological anatomy of the disease vary somewhat according to the extent of infection and the micro-organism concerned in the case.

Specific arthritis of lambs (*Jour. Bd. Agr.* [*London*], *11* (*1905*), *No. 11, pp. 678-680*).—This disease is due to infection through the navel cord soon after birth. The best method of prevention consists in isolation of diseased lambs and a thorough application of antiseptic methods about the sheep quarters.

Navel ill or specific arthritis of lambs (*Bd. Agr. and Fisheries* [*London*], *Leaflet 130, pp. 3*).—A brief account of the etiology, symptoms, treatment, and means of prevention of this disease. Isolation of diseased lambs and disinfection of the premises are recommended.

Results of further experiment with nodule disease of the intestines of sheep. "Bare-lot" method of raising lambs, W. H. DALRYMPLE (*Louisiana Stas. Bul. 83, 2. ser., pp. 16, figs. 4*).—Lambs were allowed to run with the ewes in bare lots from which all vegetation had been removed. The ewes were fed by the soiling method. The lambs were kept with the ewes till they were ready to be fed for market. Water was supplied in a wooden trough.

In the experiment 9 ewes and 6 lambs were placed in one bare lot. Only 3 of the lambs became infested, and these so slightly that the lambs did not loose flesh or condition. The greatest number of *Œsophagostoma columbianum* found in any lamb was 3. All of the 9 ewes were infested with the worms at the beginning of the test. It is concluded, therefore, that it is possible by the bare-lot method to raise the lambs of ewes affected with nodule disease of the intestines without serious danger of infestation. The method is so simple that it may be used successfully by the average sheep man. It may be well, however, to use some effective vermifuge in connection with the bare-lot method.

Liver rot or fluke, A. A. BROWN (*Jour. Dept. Agr. Victoria, 3 (1905), No. 1, pp. 41-47, pls. 8*).—The appearance and life history of *Distomum hepaticum* and *D. lanceolatum* are described. Notes are given on the symptoms of liver rot, the pathological lesions, and methods of treatment. In order to keep down the development of snails, in which the early stages of the fluke worm are found, the use of lime and salt on wet grass lands is recommended. Tonics may be of some assistance in improving the condition of infested sheep, but little hope can be entertained of satisfactory results from medicinal treatment of this disease.

Fluke or slak in the liver of sheep, D. HUTCHEON (*Agr. Jour. Cape Good Hope, 26 (1905), No. 1, pp. 33-48, pl. 1, figs. 17*).—The nature of this disease is discussed and notes are given on the life history of the fluke worm in its different hosts. Although there is no known effective treatment for liver fluke a change to uninfested pastures and attention to the nutrition and general health of the animals may have a favorable influence in a considerable percentage of cases. A brief account is given of the symptoms and post-mortem appearances of the disease.

Lungworm in sheep (*Agr. Jour. Cape Good Hope, 26 (1905), No. 5, pp. 666-669*).—The symptoms and post-mortem appearances of this disease are briefly described. A sheep raiser obtained excellent results from the use of McDougall's dip diluted at the rate of 1 to 60 and in doses of 3 tablespoonfuls. Isolation of affected animals is recommended, together with a supply of pure drinking water. Formulas are also presented for the preparation of a number of remedies to be used in the stomach and as intratracheal injections.

Contagious abortion in sheep and goats, E. THIERRY (*Jour. Agr. Prat., n. ser., 9 (1905), No. 10, pp. 304, 305*).—The symptoms of this disease are briefly described and notes are given on the usual means by which it becomes distributed and also on the means of controlling it.

The characterization of the hog cholera group of bacilli, H. SMIDT (*Centbl. Bakt. [etc.], 1. Abt., Orig., 38 (1905), No. 1, pp. 24-30*).—A study was made of the bacilli of paratyphoid, mouse typhus, and hog cholera bacilli.

As a result of the author's investigations it appears to be impossible in individual cases to distinguish between these organisms either in respect to their morphology, cultural characters, agglutinating power, or pathogenic action. It was not possible to determine to what extent heredity in different races of bacilli modified the results obtained. The author is not prepared to state definitely the connection between hog cholera and paratyphoid of man, but believes that the subject is worthy of more study.

The problem of swine plague, SCHMIDT and R. OSTERTAG (*Berlin. Tierärztl. Wchnschr., 1905, No. 13, pp. 231-236*).—These articles are of a controversial nature and relate to the governmental measures which should be taken for the control of swine plague. It appears that in order that such regulations should be effective they must be established on a uniform basis throughout the German Empire.

Serum therapy and serum vaccination against swine erysipelas according to the method of Leclainche, A. DE MESTRAL (*Jour. Soc. Agr. Suisse Romande, 46 (1905), No. 2, pp. 59-63*).—The method proposed by Leclainche, when applied to healthy animals, is said to be absolutely harmless. It is not certain, however, whether pure serum may be injected with safety. The method of Leclainche is considered very effective in the control of swine erysipelas.

Vaccination for swine erysipelas and consequent complication with swine plague, GLAGE (*Fortschr. Vet. Hyg., 2 (1905), No. 12, pp. 305-319; 3 (1905), No. 1, pp. 3-11*).—According to the author's experience vaccination for swine erysipelas in animals which are affected with swine plague may be followed with serious consequences. It appears necessary, therefore, to make a careful diagnosis of the disease in order to be sure that swine plague is not present before applying the vaccination treatment.

An improved medium for cultivating Trypanosoma brucei, W. J. MACNEAL (*Rpt. Mich. Acad. Sci., 6 (1904), pp. 173–178*).—Up to the present time 114 successful culture trials have been made with this organism. Numerous changes had been made in the nutrient media before one was obtained in which the organism could be successfully cultivated. It appears that *T. brucei* requires a blood agar medium in the ratio of 2:1. Meat extractives must be present in considerable quantity. Common salt is not harmful when present in a not greater proportion than 5 gm. per liter. A detailed account is given of the method of preparing the nutrient medium.

The trypanosome problem, H. ZIEMANN (*Centbl. Bakt. [etc.], 1. Abt., Orig., 38 (1905), Nos. 3, pp. 307–314; 4, pp. 429–447*).—Descriptive and biological notes are given on various trypanosomes which affect domesticated and laboratory animals. The author discusses also the pathogenic action of various trypanosomes for sheep, goats, cattle, and horses.

Dourine, F. S. W. BALDREY (*Jour. Compar. Path. and Ther., 18 (1905), No. 1, pp. 1–22, figs. 9*).—The nomenclature, history, etiology, and symptoms of this disease are briefly outlined, with notes on the systematic position of the blood parasite. The incubation period after artificial inoculation is said to be from 7 to 10 days, and after natural infection from 12 to 20 days. Brief directions are given regarding suitable methods of studying the blood parasite in the laboratory. The author discusses also the preventive measures which are necessary in controlling the disease.

The virulence of a pasteurella in a horse affected with anasarca, COQUOT (*Bul. Soc. Cent. Méd. Vét., 82 (1905), No. 6, pp. 126–129*).—The symptoms and pathological anatomy of a case of anasarca in a horse are described in considerable detail. A pasteurella was isolated from this case which proved to be pathogenic for guinea pigs, producing lesions similar to those of hemorrhagic septicemia.

Botryomycosis in horses, P. CHAUSSÉE (*Rev. Gén. Méd. Vét., 5 (1905), No. 56, pp. 425–435, figs. 4*).—Notes are given on the clinical symptoms and pathological anatomy of this disease. According to the author's investigations it appears that botryomyces is made up of masses of botryococci which are eliminated during the process of suppuration. The tumors which are characteristic of this disease are diffuse and resemble in many respects those of actinomycosis, although more fibrous.

Subcutaneous botryomycosis in the horse, BIDAULT (*Rev. Gén. Méd. Vét., 5 (1905), No. 50, pp. 68–71*).—The lesions which occurred during the progress of this disease are described in considerable detail. A bacteriological study was made of material obtained from cases of the disease. Cultures were made on bouillon, gelatine, potatoes, carrots, etc. The cultures, as a rule, exhibit a white color and contain organisms resembling staphylococcus.

Transmission of glanders by a reacting horse apparently healthy, and reinfection of ceased reactors, A. CONTE (*Rev. Gén. Méd. Vét., 5 (1905), No. 52, pp. 199–203*).—A brief report is made on a case which demonstrates the possibility of the transmission of glanders by means of horses which show no clinical evidence of the disease but which merely react to mallein. It was also found, in making observations on 2 horses which thus became infected, that the disease may recur after an apparent recovery and after the animals have failed to react to mallein.

The sanitary control of glanders, V. GALTIER (*Jour. Méd. Vét. et Zootech., 56 (1905), Mar., pp. 129–138*).—In controlling glanders it is considered necessary that all cases or suspected cases of glanders be immediately reported, and that the diseased animals be destroyed and proper measures taken for quarantining exposed animals and protecting healthy animals from infection with the disease.

Biliary fever in the horse, A. EDINGTON (*Jour. Compar. Path. and Ther., 18 (1905), No. 1, pp. 35–40*).—This disease was studied in Cape Colony in cases of spontaneous origin and after artificial inoculation. The disease can be readily transmitted by the latter method. Animals which come from the coast region appear to be somewhat refractory. In a series of 50 horses upon which inoculation experi-

ments were made, 16 proved insusceptible, 27 developed fever and were subsequently insusceptible, while 2 showed no fever even after the second inoculation. The author believes that one attack renders the animal immune.

The so-called maxillary disease of horses and mules in Kamerun, H. ZIEMANN (*Arch. Wiss. u. Prakt. Tierheilk.*, *31* (*1905*), *No. 3*, *pp. 300–311, figs. 3*).—This disease is described in great detail. The temperature of affected animals appeared not to be greatly affected. In most cases the result was fatal after the disease had run a course of from 4 to 12 months. The most pronounced lesion was in the maxillary bones and soft tissues of the face. The etiology of the disease was not definitely determined. From unsatisfactory inoculation experiments it appeared that if the disease was of a bacterial nature the incubation period was of about 50 days.

Tetanus and antitetanic serum, W. H. DALRYMPLE (*Vet. Rec.*, *17* (*1905*), *No. 867*, *pp. 513–516*).—A record is given of 9 cases of tetanus in horses treated by the author, with recovery in 7 cases, and a similar recovery of 15 out of 28 cases which occurred in the practice of a colleague of the author. It is argued that since the difficulty of obtaining perfect asepsis in deep wounds is very great, the desirability of using antitetanic serum is sufficiently apparent.

The virulence of the blood in rabid animals, A. MARIE (*Compt. Rend. Soc. Biol.* [*Paris*], *58* (*1905*), *No. 12*, *pp. 544, 545*).—Mice inoculated hypodermically with the defibrinated blood of rabid guinea pigs and a rabbit inoculated in the brain with the blood serum of another rabbit which had died of rabies developed rabies in a virulent form. These positive results from inoculation are supposed to indicate the presence of virus in the blood.

Is rabies hereditary? D. KONRÁDI (*Centbl. Bakt.* [*etc.*], *1. Abt., Orig.*, *38* (*1905*), *No. 1*, *pp. 60–66*).—Attention is called briefly to results thus far obtained in a study of the hereditary transmission of various infectious diseases. This question was tested by the author with regard to rabies, the experimental animals being rabbits and guinea pigs. It appears from these experiments that rabies virus may be transmitted from the mother to the fetus, but that the virus becomes somewhat attenuated during this transmission. It is recommended that in such experiments both rabbits and guinea pigs be used, and that observations be extended over a period of about 1½ years.

RURAL ENGINEERING.

Report of irrigation and drainage investigations, 1904, E. MEAD (*U. S. Dept. Agr., Office Expt. Stas. Rpt. 1904*, *pp. 425–472, pls. 5, figs. 5*).—A leading feature of the irrigation work from the beginning has been the measurement of the quantities of water used in irrigation. This has served to bring to the attention of water users the possibility of extending their irrigated area by economy in the use of water.

One canal in California diverts sufficient water to cover the land irrigated to a depth of more than 13 ft., while the water diverted by another would cover the land irrigated to a depth of less than 2 ft. The first season's measurements on the Sunnyside Canal in Washington showed sufficient water to cover the land to a depth of 10 ft., while the measurements in 1904 showed a reduction to 6 ft., and there is thought to be still room for great improvement.

In 1904 these measurements were supplemented by experiments on the water requirements of crops, the application of water at different stages in the growth of the crops, to determine the influence on the yield and quality of the product, and means of checking the loss of water from the fields. Taking the quantity of water evaporated under surface flooding as a basis, applying water in shallow furrows made a saving of 13 per cent and in deep furrows a saving of 25 per cent.

As to the adaptability of different methods of irrigation, checking was found advantageous for light sandy soils which are approximately level. With this method an irrigator can handle a large volume of water, reducing the cost of applying water to a minimum. It requires, however, much preliminary preparation in making

levees and in leveling. Flooding was found best adapted to irrigation of grains and grasses. It requires little preliminary preparation, but large amounts of labor in applying the water to the fields. Furrow irrigation is used for orchards and cultivated crops. The losses of water by evaporation are smaller, and small streams can be used to better advantage than under the other methods.

The data collected regarding cost of preparing land for irrigation show that the removing of sagebrush, leveling and smoothing the land, and the construction of laterals varies from \$3.50 to \$35 per acre.

A large part of the arid region can not be supplied with water from streams, and during 1904 the possibilities of supplying this section by means of pumps was investigated. The average cost of windmills per acre irrigated was found to be \$42, and the annual cost of maintenance, \$2.35 per acre. Computing interest on the investment at 7 per cent and depreciation at 10 per cent, the annual cost for windmill irrigation amounts to an average of \$9.49 per acre. This is a heavy charge, and when considerable areas are to be irrigated some other kind of power will be found cheaper.

Information was collected from a large number of localities as to the cost of pumping plants and of their operation. The plants examined showed the following average fuel cost per acre-foot of water raised 1 ft. for the pumps of different sizes: All sizes, 3 cents; less than 1 cu. ft. per second, 9.4 cents; 1 and less than 5 cu. ft. per second, 4.9 cents; 5 and less than 10, 2.5 cents; 10 or more, 2.3 cents. This brings out the great economy in fuel cost of using large plants. The saving in cost of attendance is even greater than in fuel. Laboratory tests of typical pumps showed the great importance of having the pump proportioned to the work to be done. Each pump works most efficiently at a particular speed and with a fixed lift, and these matters should be taken into consideration when the pump is purchased.

Measurements of the water used in rice irrigation, carried on for 4 years, showed a tendency to use less water. It was found that when water is maintained at too great a depth on the rice fields the soil is not sufficiently warmed to produce the best results. During low water in the streams along the Gulf Coast, salt water sometimes sets in from the Gulf and it was feared that the use of this water might, in addition to injuring the crop to which it was applied, permanently injure the land, but so far no such permanent injury has taken place. The rains of winter and the irrigation with fresh water have washed out the salt, leaving the land in good condition.

The drainage work summarized in this report includes the drainage of the lands injured by seepage water and alkali in the arid region, the drainage of large areas of bottom land through the Middle West, the protection of river-bottom lands by levees and the drainage of lands within the levees, the drainage of farm lands, and the protection of hillsides from erosion by the use of underground drains.

The most serious defects in levees for protecting the bottom lands are found to be insufficient preparation of the land on which the levees are to rest, thus allowing water to seep under the levees; and insufficient care in maintaining the levees, so that when floods come weak places are found.

A list of the publications issued during the year 1904 is given.

Disposal of household wastes at summer resorts, encampments, and farm houses. Pure water supply and other sanitary conditions, R. FLETCHER (*N. H. Sanit. Bul., 1905, July, Sup., pp. 23, figs. 8*).—This paper, prepared for the New Hampshire State Board of Health, treats this subject with reference to a pure water supply and other sanitary conditions.

It deals with intolerable means of disposal; methods and appliances for disposal of wastes, including fecal matter, kitchen and chamber slops, and other liquid sewage and garbage; the construction of wells and their protection from contamination. The septic tank method of sewage disposal receives special attention. Farmers' Bulletin 43 of this Department is one of the principal sources from which the paper is compiled.

Better roads for Missouri (*Mo. Bd. Agr. Mo. Bul., 5 (1905,) No. 2, pp. 30, figs. 10*).—A fourth revised edition of this bulletin, dealing mainly with road dragging by the King method (E. S. R., 15, p. 415).

Industrial and agricultural development in Europe and America, A. CHATTERTON (*Madras: Rev. Dept., 1905, pp. 36*).—This report to the Madras Government contains the information bearing on various lines of agriculture, obtained during an extended trip through Europe and the United States.

Much statistical matter is given on the extent of irrigation, the cost and value of water obtained by pumping for irrigation, the use of electric power and of gasoline and steam for pumping, the size and location of wells, the use of centrifugal pumps, the use of the windmill, and the development of power for general farm purposes.

Hydraulic engines at the U. S. Naval coaling station, Bradford, R. I. (*Engin. News, 54 (1905), No. 5, pp. 127, 128, figs. 2*).—This is an illustrated description of a pair of unusually large hydraulic rams recently built, which show a very high efficiency according to the following results of tests made by engineers of the Navy Department:

	No. 1.	No. 2.
Total water delivered to engine, gallons per minute	582	578
Water delivered to standpipe, gallons per minute	232	228
Power head in engines, feet	36.75	37.25
Pumping head, in feet, at engines	84.0	84.0
Strokes per minute	130	130
Efficiency, per cent (Rankine formula)	85.2	81.9

AGRICULTURAL EDUCATION.

Progress in agricultural education, 1904, A. C. TRUE (*U. S. Dept. Agr., Office Expt. Stas. Rpt. 1904, pp. 575–616, pls. 5, figs. 6*).—A review is given in this article of the leading features of progress in agricultural education, including the general educational work of this Department, the educational work of this Office in relation to both American and foreign institutions, that of the Association of American Agricultural Colleges and Experiment Stations, and of the different agricultural colleges, secondary schools, and primary schools throughout the country.

The article devotes considerable attention to the development of courses of study, especially courses in rural engineering and rural economics and sociology, including an outline for a proposed course in rural sociology by K. L. Butterfield. A report on The Teaching of Agriculture in the Rural Common Schools, presented by the standing committee on methods of teaching agriculture at the last convention of the Association of American Agricultural Colleges and Experiment Stations, is also included.

Exhibits at the Louisiana Purchase Exposition, W. H. EVANS and W. H. BEAL (*U. S. Dept. Agr., Office Expt. Stas. Rpt. 1904, pp. 687–714, pls. 8*).—Included in this article are brief descriptions of the exhibit of this Office in the Government Building, and that of the colleges of agriculture and mechanic arts and experiment stations in the Palace of Education at the Louisiana Purchase Exposition.

Annual report of farmers' institutes, 1904, J. HAMILTON (*U. S. Dept. Agr., Office Expt. Stas. Rpt. 1904, pp. 617–675*).—This report includes a brief review of the work of the farmers' institute specialist for 1904; an account of the annual meeting of the American Association of Farmers' Institute Workers at St. Louis; a discussion of the progress and needs of the institutes, with suggestions regarding normal schools for institute workers and further aid to the institutes by this Department, and detailed reports on farmers' institutes in the different States and Territories.

Report of the extension work of the college, A. E. STENE (*Bul. R. I. Col. Agr. and Mech. Arts, 1 (1905), No. 2, pp. 21, pls. 3, dgm. 1*).—This report contains a discussion of the aims of college extension in agriculture and an outline of work of this

nature at the Rhode Island College, including demonstration work and cooperative experiments, the service of traveling lecturers, and the nature study and school garden work. The report also contains an article on Some Special Phases of the Extension Work, by F. W. Card; one on The Poultry Library, a discussion of literature bearing on poultry culture, by Cooper Curtice, and Notes on Correspondence, by H. J. Wheeler.

Agriculture at Purdue University, W. E. STONE (*Indiana Sta. Bul. 107, pp. 12*).—A description of the facilities for teaching agriculture at Purdue University is given, together with syllabi of the four-year course, the two-year course and several special courses; brief notes regarding farmers' institutes and reading circles, and a brief account of the agricultural investigations conducted by the experiment station.

County schools of agriculture in Wisconsin, K. C. DAVIS (*U. S. Dept. Agr., Office Expt. Stas. Rpt. 1904, pp. 677–686, pls. 4*).—The author describes the equipment of the county schools of agriculture located at Menomonie and Wausau, Wis., and discusses the character and methods of instruction, the attitude of students, and the popular and correlative work of the schools.

Elements of agriculture, J. H. SHEPPERD and J. C. MCDOWELL (*St. Paul, Minn.: Webb Pub. Co. [1905], pp. 254, figs. 79*).—This text-book of elementary agriculture was prepared especially for the common schools of North Dakota in which agriculture is now a required subject of instruction.

The arrangement of topics in the text-book is somewhat unusual, but this seemed to be necessary in order that the course of study might follow the seasons, the work on farm crops coming in the fall, that on domestic animals in the winter, and that on soils and the beautifying of home and school grounds in the spring. In addition to the work mentioned above there are chapters on weeds, injurious insects, birds, fruit culture, the care of farm machinery, roads, corn-growing contest, and legal weights. Numerous exercises for the illumination of the different subjects are outlined.

Course of study for the common and graded schools of North Dakota (*Bismarck, N. Dak.: Dept. Pub. Instr., 1904, pp. 176, figs. 17*).—Among the subjects outlined in this course of study are nature study and agriculture. The nature study work extends over the first 6 years of the common school course and has a decided agricultural trend, especially in the fifth and sixth years. The work in elementary agriculture is intended for the seventh year and includes studies of farm crops, weeds, plant diseases, injurious and beneficial insects, live stock, dairying, the improvement of home and school grounds, the garden, birds, forestry, roads, and soils.

Program of studies for the common schools of New Hampshire (*Concord, N. H.: Dept. Pub. Instr., 1905, pp. 157*).—This program of studies was prepared under the direction of the State superintendent of public instruction, and contains outlines and detailed instructions for presenting the various subjects of instruction. Among these subjects are nature study and agriculture.

The nature study program extends over 4 years, and includes a discussion of methods and detailed suggestions for conducting the work by years and months. Elementary agriculture is to be taught in the grammar school (fifth to eighth years, inclusive), and is outlined by years and school terms. The first year is devoted to soils, their composition, formation, cultivation, exhaustion, improvement, etc.; the second year to plant production, including propagation, cultivation, enemies, diseases, etc., of the principal fruits, forest trees, farm crops, garden vegetables, and ornamentals used in decorating home grounds.

The third year farm animals and poultry are taken up; and the fourth year farm manufactures and domestic economy. Farm manufacturers include milk, sugar, dried and canned fruits and vegetables, soap, honey, etc.; and domestic economy the care and handling of milk in the home, sewing, canning and preserving fruits, washing delicate-colored goods, cooking, home sanitation, and other related subjects.

Nature-study lessons for primary grades, LIDA B. MCMURRAY, with an introduction by C. A. MCMURRAY (*New York: The Macmillan Co., 1905, pp. 191*).—This is a teachers' manual, consisting of a series of nature-study lessons which were worked out by the author in the class room and in outdoor excursions with children. The book is divided into two parts—(1) animal life, containing lessons on pets, domestic animals and fowls and common birds and insects, and (2) plant life, with lessons on flowers, trees, buds, leaves, and fruit. The lessons consist of stories intended to arouse an interest in plant and animal life on the part of the children, and suggestive questions for the teacher.

The author holds that "a teacher in nature study must know how to live happily and companionably with children among the birds, flowers, insects, and trees," and "how to enjoy an excursion with children." Furthermore, "one must learn to concentrate the children's thoughts along given lines, for a mere chasing after chance birds and butterflies will not answer. Having awakened the attention and interest of children in certain lines, it is necessary to lead on to more definite observations, and, sooner or later, to get from the children a clear statement of facts."

MISCELLANEOUS.

Annual report of the Office of Experiment Stations, 1904 (*U. S. Dept. Agr., Office Expt. Stas. Rpt. 1904, pp. 724, pls. 42, figs. 11*).—This contains the usual report on the work and expenditures of the agricultural experiment stations in the United States; annual reports of the experiment stations in Alaska, Hawaii, and Porto Rico; reviews of irrigation and nutrition investigations, and several other articles abstracted elsewhere in this issue.

Included in the report on the work and expenditures of the stations are statistical summaries; brief reports of nutrition and irrigation investigations; a summarized account of the meeting of the Association of American Agricultural Colleges and Experiment Stations; a review of the work of this Office; a report on the governing board, station staff, general outlook, lines of work, income, and publications of each experiment station; a list of station publications received by this Office during 1904; federal legislation, regulations, and rulings affecting agricultural colleges and experiment stations, etc.

Seventeenth Annual Report of Louisiana Stations, 1904 (*Louisiana Stas. Rpt. 1904, pp. 16*).—This contains statements on the condition of crops at the Louisiana stations, outlines of work conducted during the year, organization lists, and a financial statement for the fiscal year ended June 30, 1904.

The work at the substations, L. R. TAFT and C. D. SMITH (*Michigan Sta. Bul. 226, pp. 149–164, figs. 6*).—This is a review of the reports of the South Haven and Upper Peninsula substations for 1903 and 1904, published as Special Bulletins 27, 28, 30, and 31 of the station (E. S. R., 16, pp. 250, 260, 261; 17, pp. 22, 35, 37).

Annual Report of New Jersey Stations, 1904 (*New Jersey Stas. Rpt. 1904, pp. XIX+652*).—This includes the organization lists of the stations; a financial statement of the State station for the year ended October 31, 1904, and of the college station for the fiscal year ended June 30, 1904; a report of the director reviewing the different lines of station work; and reports of the chemists, soil chemist and bacteriologist, horticulturist, dairy husbandman, biologist, botanist, and entomologist, abstracted elsewhere. Included in the report of the chemists are reprints of Bulletins 175 of the station on concentrated feeding stuffs (E. S. R., 16, p. 394), and 183 on agricultural lime (E. S. R., 17, p. 18).

Experiment Station Work, XXX (*U. S. Dept. Agr., Farmers' Bul. 227, pp. 32, figs. 2*).—This number contains articles on the following subjects: Top-dressing grass land, extension of the corn-growing area, culture of peanuts for forage, winterkilling of fruit trees, cranberry culture, lime-sulphur-salt wash, destroying prairie dogs, clean milk, and construction and ventilation of poultry houses.

NOTES.

Florida University and Station.—P. H. Rolfs, at present in charge of the Subtropical Laboratory of this Department at Miami, and formerly connected with the university and station, has been elected director of the station. He will also succeed F. M. Rolfs, resigned, as horticulturist in the university and station. He will enter upon his duties some time in January.

Kansas College and Station.—The contracts have been let for the new Horticultural Hall, appropriation for which was made by the last legislature. The basement and first floor will be used by the horticultural department and the second floor by the botanical department. The building will cost something over $35,000, and new greenhouses costing $10,000 will be constructed later. The contract calls for the completion of the building by September 1, 1906.

Maine University and Station.—G. E. Tower, who was erroneously mentioned in a previous issue as professor of chemistry, is in charge of the department of forestry in the university. The station is just completing the erection of an incubator house. The building is one story, with basement, and is 31 ft. square. The high, well-lighted basement will be used for an incubator room, and the upper story and attic as a tenement for the poultryman.

Maryland Station.—C. W. Nash, a graduate of the Iowa State College in the class of 1905, has succeeded E. P. Walls, resigned, as assistant agronomist.

Massachusetts College and Station.—The large college barn erected in 1893 was totally destroyed by fire on the night of November 16, together with the greater part of its contents. The latter included about 300 tons of hay, a large amount of silage, a carload of grain feed, 600 bu. of potatoes, large quantities of other root crops, and several thousand dollars worth of farm implements and machinery, among which was the apparatus used in the dairy school. This was entirely destroyed. Considerable live stock, including about 20 head of young cattle, 3 cows, 4 bulls, a prize ram, and nearly 60 head of swine, was also lost. The origin of the fire, which started in the hay, is unknown, but there are said to be good grounds for believing it was incendiary. The building was lighted by electricity, which was the only light used about the building, but there were no electric wires in the part where the fire apparently started.

The original cost of the barn and its equipment was about $45,000, and the value of the property destroyed is estimated at more than $15,000. The rooms for the dairy school had been fitted up in recent years, and the loss of machinery and apparatus will seriously handicap that department. Arrangements have been made to fit up rooms in the basement of a dormitory building for the dairy school, which will open in January. A part of the live stock has been sold at auction owing to lack of accommodations for it. The State had of late followed the plan of insuring its own property, so that a considerable part of the insurance formerly carried had been allowed to lapse. From the unexpired policies $17,229 will be allowed by the insurance companies on the barn and its contents. The legislature will be asked for an appropriation to rebuild the barn, probably using a more permanent style of construction, such as concrete or cement throughout for the stables.

Rutgers College.—Dr. Austin Scott has resigned the presidency of the college, owing to the condition of his health, but will retain the chair of history and political science.

Cornell University and Station.—A course of lectures on agricultural journalism will be delivered at the college during the winter, probably at the time the short courses are in session. R. C. Lawry has been appointed assistant in poultry husbandry. The dairy department has leased the Sage creamery, situated about six miles north of Ithaca. This was done to secure a continuous supply of milk for instruction and experimental work in the winter. In the summer the place will be run as a skimming station.

Oklahoma College and Station.—The contract has been let for the new agricultural building, work upon which will be begun at once. The building will be 166 ft. long by 76 ft. wide, and consist of a basement of full height and entirely above ground, with two stories above and an attic. The basement, or first story, will be of white limestone and the rest of red pressed brick. The general style will be colonial. Mill construction will be followed, with the main partitions of brick and extending from the basement to the roof. The building will be heated from a central heating plant by indirect radiation, the flues being built into the walls. Provision will be made for the work in animal husbandry, agronomy, farm mechanics, and agricultural physics, of both the college and the station, and the agricultural chemistry work of the station. There will be administrative offices for both the college and the station officers, and in the basement will be located a large stock-judging room and rooms for agricultural machinery. The cost of the building will be about $64,000, exclusive of equipment.

Tennessee Station.—By an agreement between the station and a local poultry publishing company it has been possible to establish a poultry department in the station. The station will furnish the necessary land and feed for the poultry, and the local company will erect the buildings and give the services of an expert poultryman. J. H. Sledd, editor and manager of *The Industrious Hen*, will be in charge of the department and will also lecture on poultry in the short course at the university.

Adams Bill in Congress.—Hon. H. C. Adams reintroduced his bill for the increase of the appropriation to the experiment stations on the opening day of Congress, and it was referred to the Committee on Agriculture. As is generally known, the bill provides for an increase of $5,000 the year that it becomes a law, and an additional increase of $2,000 each year for five years, making the ultimate appropriation under the bill $15,000 in addition to the Hatch Fund.

Smith Agricultural School.—Reference has previously been made to this school, the fund for which was bequeathed by Oliver Smith, of Hatfield, Mass., sixty years ago. The original amount of the bequest was $30,000, which has increased until it now amounts to over $300,000. The fund will become available December 22 of this year, and in order to prepare for the establishment of the school the trustees have purchased a tract of 93 acres of land near Northampton, Mass., at a cost of $19,450. The provisions of the will are sufficiently liberal to allow the trustees to exercise wide discretion in planning the school and mapping out its work. It is understood that training in mechanic arts, as well as in agriculture, will be included.

The Royal Agricultural College.—The curriculum of the Royal Agricultural College, at Cirencester, has recently been extended in two important particulars, according to a note in *Mark Lane Express*. A two-year course of lectures and demonstrations in poultry and poultry keeping has been provided. The lectures will cover the whole field of scientific poultry farming, and the students as they become qualified will have charge of the fowls, incubators, etc., under supervision. There will be an examination for certificates at the end of the course. The other departure is the establishment of "postgraduate dairy classes." Students who have taken the college diploma will have the opportunity of attending the vacation dairy classes without payment of any fee, i. e., during three weeks in the spring vacation and four weeks in the summer vacation. Students attending these classes will be expected to perform the manual operations of butter and cheese making, under supervision, and to qualify by examination for the special certificate of the college in dairying.

Agricultural Education in Roumania.—The institutions giving instruction in agriculture in Roumania, according to an article in *Mitteilungen der Deutschen Landwirtschafts-Gesellschaft*, for October 28, 1905, are mostly included under 4 heads: (1) Seven elementary agricultural schools offering 2-year courses, (2) 6 secondary agricultural schools offering 3-year courses, (3) 2 model State farms, and (4) the Central Agricultural School, near Bukharest, which stands at the head of the system. The present attendance at the Central Agricultural School is 166. The course of study includes instruction in animal industry, sericulture, and apiculture, and extends over 4 years, 1½ years of which are spent on the model State farms, located respectively at Laza and Studina. There are also special schools for instruction in dairying, horticulture, mulberry growing, phylloxera extermination, and domestic science, the latter connected with the secondary school at Armasesti.

Experiment Farms in Natal.—The principal experiment farm in Natal is the Central Experiment Farm, established in 1902, at Cedara, 8½ miles northwest of Pietermaritzburg. This farm contains 3,614 acres, upon which 1,493 experiment plats have been in operation during the past year. There have also been 1,174 variety tests of field crops, and 140 acres devoted to experimental orchards. A dairy herd is being developed, and it is proposed to establish schools of agriculture on the farm for both young men and young women.

At Winkle Spruit a 500-acre farm was acquired in 1904, and has been devoted to special problems relating to coast agriculture and the cultivation and preparation of semitropical products, especially sugar cane and cotton. A farm of 59 acres at the Weenen Irrigation Settlement, and another at Stanger, on the North Coast, have been started this year.

International Institute of Agriculture.—In an article in the current number of the *Fortnightly Review*, noted through *Nature*, the Marchese Raffaele Cappelli sketches the growth of the ideas which led to the recent international conference on agriculture, held at Rome last spring. He enumerates also the advantages likely to accrue from the International Institute of Agriculture created on that occasion. "At the close of the conference referred to, a protocol was signed by the representatives of all the governments of the world—with the exception of some minor ones—favoring the establishment of the International Institute, and asking the respective governments to adhere to the same. In the opinion of the writer of the article, the institute must aim at regularizing, promoting, and generalizing its internationalism. It must provide for the rapid and general diffusion of knowledge of technical improvements in the economics of production. The institute must further undertake the task of coordinating the efforts of many cooperatives scattered throughout the world, so that they may act in harmonious agreement. But most important of all will be the services which the international corporation will be able to render in the field of the economics of distribution."

Association of Farmers' Institute Workers.—The American Association of Farmers' Institute Workers met at Washington, November 9–11. The meeting was attended by about a hundred delegates and visitors, and was regarded as a success from both a business and social standpoint. The sessions were presided over by Prof. E. A. Burnett, vice-president, in the absence of President J. C. Hardy. The association was welcomed by the Secretary of Agriculture, and papers on consolidated public schools and on movable agricultural schools were read by Assistant Secretary W. M. Hays and Prof. John Hamilton, of this Department. There were also papers on institute organization and methods, cooperation with other educational agencies and with the National Department of Agriculture, and upon boys' and girls' institutes. There was a mild protest against the consumption of so much time by reports from the several States and Provinces, and it was decided to limit this feature in future to one session.

The officers elected for the ensuing year are: President, G. C. Creelman, of Guelph, Ontario; vice-president, W. W. Miller, of Ohio; secretary-treasurer, John Hamilton,

Department of Agriculture; executive committee, the president and secretary-treasurer (ex officio), J. G. Lee of Louisiana, F. H. Hall of Illinois, and W. L. Amoss of Maryland.

Children's Gardens in New York City.—The children's farm school, inaugurated in 1902 by Mrs. Henry Parsons on the site of the proposed DeWitt Clinton Park, has now been incorporated as a permanent feature in the completed park. A definite area has been set apart for gardens, and adjacent to this, in the basement of a brick pergola, are school rooms, some of which are furnished for domestic science work, which is a feature of instruction required of girls who raise vegetables in the gardens. During the past season 2,500 children took part in the garden work and raised about 90,000 vegetables of different sorts.

Personal Mention.—Dr. Alonzo D. Melvin, assistant chief of the Bureau of Animal Industry, has been appointed chief of the Bureau, vice Dr. D. E. Salmon, resigned.

Among the honors conferred on the occasion of King Edward's birthday was that of commander of the Order of St. Michael and St. George upon Dr. William Saunders, director of the Central Experimental Farm, at Ottawa, Canada.

Director L. H. Bailey, of Cornell, will deliver one of the lectures in the series on Educational Problems, provided by the department of education of the City of New York.

Charles Robert Wynn-Carrington has been appointed president of the board of agriculture in the new British cabinet.

The death is announced of Prof. Th. Freiherr von der Goltz, director of the Agricultural Academy at Poppelsdorf and professor of political economy in the University of Bonn. He was a well-known writer upon agricultural topics, especially in the field of farm management, agricultural taxation, and the history of agriculture.

Miscellaneous.—A regulation recently issued by this Department directs that packages containing parasites of the gypsy and brown-tail moths, or parasitized specimens of these moths, when addressed to A. H. Kirkland, the superintendent for suppressing the gypsy and brown-tail moths, Boston, Mass., may be shipped from any European country into the United States, entry to be made through the ports of Boston or New York.

The Proceedings of the Eighth Annual Session of the Texas Farmers' Congress, a volume of nearly 300 pages, have been received. This congress was held at the Texas Agricultural and Mechanical College, July 25–27 last, and was attended by about 2,500 farmers. Meetings of 13 State agricultural and horticultural associations were held during the congress, and the minutes of each of these, with the more important papers, are included in the proceedings.

The Ohio State University has begun the publication of a series of agricultural college extension bulletins. Vol. 1, No. 1, of this series which was issued in October, 1905, contains an article on The Life of a Moth, by F. M. Webster, and one on Planting on Rural School Grounds, by A. B. Graham.

The Department of Agriculture and Technical Instruction for Ireland has established a seed-testing station at its laboratories in Dublin, which, in addition to making purity and germination tests for farmers, offers to identify plants and plant diseases free of charge.

Fermes et Châteaux is a new French publication, the first number of which was issued in September. It is similar in plan to *Country Life in America* and the *Country Calendar*, and is intended to occupy the same place in French agriculture that these publications do in American agriculture.

O

EXPERIMENT STATION RECORD.

Vol. XVII. January, 1906. No. 5.

The International Live Stock Exposition at Chicago has become the leading live stock event of the year. As such it is of interest not only from the showman's point of view, but in its bearings upon the improvement of the live stock of the country and as a great educational factor. The exposition of 1905, the sixth to be held, surpassed all previous ones both in the number of entries in the various classes and in the general excellence of the animals shown. The attendance also broke all former records and taxed the capacity of the new amphitheater to the utmost.

This new building, which was only barely completed in time for the exposition, added greatly to the attractiveness of the exposition and to the comfort of the judges, the spectators, and the animals. The pavilion is fireproof, being built of iron, brick, and concrete. It is 600 feet long by 310 feet wide, 60 feet high in the walls, and is covered with a roof quite largely of glass. It is heated by steam, so as to be comfortable at all times. The roof is supported by iron trusses and hence there are no posts in the building to obstruct the view.

In the center of the amphitheater is a tan-bark arena, occupying a space 236 feet long by 100 feet wide. It was sufficient for showing three or even four classes of stock at a time without confusion, and furnished a splendid ring for the display of horses in harness and in saddle, and six-horse draft teams. The maneuvering of five of these six-horse teams at a time in this great arena, with the display of some excellent fancy driving, was one of the spectacular features of the show. A wide passageway surrounds the arena, and from this rise the boxes and tiers of seats, estimated to accommodate from eight to ten thousand people. These afforded a splendid view of the animals in the arena and the work of the judges.

In spite of the size of the building, it could not begin to accommodate the crowds, especially at night, and it is understood that it is to be enlarged before another year. The turnstiles showed an attendance of from thirty to forty thousand people a day, and the total estimated for the week exceeds six hundred thousand admissions.

The catalogue of the exposition contained ten hundred and fifty-five entries of cattle, eight hundred and fifty-seven of sheep, two

hundred and fifteen of hogs (barrows), and six hundred and seventy-nine of horses. This was aside from the entries for prizes offered by the breeding associations and other specials, and does not include the carload lots shown in the yards, which nearly doubled the number of cattle. The number of entries in some of the classes was exceptionally large and the competition very sharp. So even were the individuals in some classes that the finest discrimination of the judges was called for, slight differences determining the prize winners.

The cattle were stabled in wings adjoining the arena, and the horses, sheep, and swine in nearby buildings. The accommodations for the stock were comfortable, and reduced the element of danger from exposure to a minimum. The excellent provision made for the conduct of this exposition and the comfort of the visitors, together with the apparent smoothness which characterized the events of the week, reflects great credit upon the management and the officials in charge of the various departments.

The importance of this great show as an educational event is coming to be more appreciated every year. It brings together the finest specimens of horses, cattle, sheep, and certain classes of swine, representing many types and breeds, to compete for prizes offered by the exposition and the breeders' associations. Such an aggregation is not to be seen anywhere else in the country, perhaps in the world. Naturally a large number of representative breeders and stockmen of the country attend the show to compare notes with their colleagues and competitors, and to keep track of developments in their lines, as well as for business purposes. But what is quite as important, the show now attracts thousands of farmers and stockmen from all over the country, who go there to learn and to have their ideals developed. This perhaps constitutes its greatest value and influence. There is no question that it has stimulated interest in better stock, and already raised the standard of many farmers and stockmen. The result is felt in a larger demand for thoroughbred animals for breeding purposes, and in closer and more intelligent discrimination in buying grades and crosses.

A man must first know and be able to appreciate the good points of an animal, and to weigh their relative value in determining excellence, before he can be in position to improve the stock which he keeps or breeds. Such a display of animals as is presented for his inspection in the show ring, and judged by experts before his eyes, is an incomparable opportunity for studying types and degrees of excellence as determined by the judges. Add to this the chance to inspect the animals leisurely at close range in the stables, to learn their breeding and records, and to meet with some of the leading breeders and importers of stock, and the advantages of this show to the practical stockman

will be fully apparent. To the man of fine discrimination, the exhibition in the immense arena is a genuine treat and an inspiring spectacle from start to finish.

The farmers and stockmen were in attendance this year in full force, from Canada and from Texas, throughout the Middle and Central West, and many from the far West. They followed the work of the judges with close interest and were evidently there to see and to learn. Their presence in such numbers and their attitude was an illustration of the interest the show has aroused and of its educational possibilities.

But the educational advantages of this great animal show are not confined to the actual stockmen and breeders of the country by any means. They are equally apparent in the case of the embryo experts—the students of the agricultural colleges. For them no such opportunity presents itself elsewhere. At the college they see a few specimens of the principal breeds of their section, necessarily very limited in number and sometimes also in quality. They make a few trips perhaps to some breeding farms and fairs where they have opportunity to examine and compare the animals. But what is this in comparison with the opportunity to see a score or more of the choicest specimens of a class in the ring at once, to have such a succession of breeds and types presented, to go through the stables under the guidance of an instructor and have the points of excellence of animals by the hundreds explained to them?

It is interesting to follow a party of these students. They are interested, anxious to keep close to the instructor, to get their hands on the animal, and to hear about its record and special merits. They have not come to the show merely for a lark. The attendants in charge of the stock know the professors and bring their prize animals out for a better view; and the boys have a lesson in type, conformation, and qualities that is worth weeks at the college, and will be often referred to in the class room. It is a splendid experience.

That this is appreciated was evidenced by the large bodies of students in attendance upon this year's show. Seventeen States and the Province of Ontario sent delegations in varying numbers. There were about a hundred each from Illinois, Iowa and Nebraska, large numbers from the colleges nearer by, like Wisconsin, Michigan, Indiana and Ohio, thirty from Colorado, ten from Texas, several from Kansas, Missouri and Louisiana, and eighteen from Ontario. These bodies of students were a notable element in the crowd. They made their presence evident, and their banners and emblems called attention to their respective colleges.

The opening day was given up to the competitive student judging. It will be recalled that there are two trophies in this competition, offered by the exposition company—one for horses, and the other for

cattle, sheep, and swine. Teams of five students each from the Ohio, Iowa, Michigan, Kansas, Missouri, Texas, and Ontario agricultural colleges took part in this competition, which was in charge of Prof. W. J. Black, the president of the new Manitoba Agricultural College. The utmost fairness characterized the contest. A somewhat different method was followed this year than in past years, the boys appearing singly before the judges after they had completed their work, and giving the reasons for the order in which they had placed the animals, instead of presenting papers to be marked subsequently. While this was something of an ordeal for the boys it enabled the result to be known within a day or two.

The horse-judging trophy, held by Iowa, was won this year by the Ohio team; and the one for cattle, sheep and swine, held by Ohio, went to the Ontario team. The Ohio boys led in work with cattle as well as horses, Texas on swine, and Ontario on sheep. The latter, however, scored the largest combined number of points in judging cattle, sheep and swine, with Iowa second. The corn-judging team from Iowa won the Cook bronze trophy, held by the Kansas Agricultural College, Nebraska ranking second, and Kansas third.

The spirit of good-natured rivalry which this competition engenders is a healthy one and is something of a stimulus to both students and instructors in their work. Considerable college spirit is developed, and the opportunity to measure swords with another institution is helpful to the boys and those responsible for their instruction. The experience of taking part in such a contest is a valuable one, helping to develop confidence, self-reliance, and decision.

Properly managed, the students' judging contest becomes an attractive and valuable feature of this show. Incidentally it attracts considerable attention to the colleges and to the practical nature of their work.

The agricultural colleges and experiment stations were a notable feature of the show, aside from the student representation. The official catalogue showed no less than two hundred and seventy-five entries by them in ninety-five different classes. While some animals were of course entered in more than a single class, this summary indicates the wide range covered by their exhibits. The entries were largely in the fat stock, sheep and swine classes, although there were several in the breeding classes and among the horses. Iowa, Michigan, Nebraska, and Cornell University also showed in the dressed carcass classes for cattle, Wisconsin in those for sheep, and Iowa, Cornell and Ohio in those for swine. Seventy-three of the entries mentioned above were in the college and station specials, seventy being in those provided through the generosity of Clay, Robinson & Co.

The grand championship of the fat stock show was won by the Iowa State College, with an Angus steer selected by Prof. C. F.

Curtiss about a year ago from a carload lot at the stockyards, and fed at the college. The reserve champion was also from the college, a quite remarkable fact. This is the fourth year that the grand championship has fallen upon a college or station animal. In 1902 it went to Iowa, in 1903 to Nebraska, and in 1904 to Minnesota. The showing made by the colleges in the fat stock classes has demonstrated their high ability to pick out prize animals from market lots and to feed and finish them to perfection.

The champion steer among the Shorthorns was from Purdue University, and the University of Nebraska won a prize on a yearling steer. Ohio State University took a large number of prizes on its swine, including the grand championship in several classes. Numerous awards were also made to the Iowa College on its pigs, and to the University of Wisconsin on its sheep and on finished carcasses, in addition to those in the college and station specials.

The showing made by the colleges in the open classes was very gratifying in view of the limited means of these institutions for acquiring and breeding live stock. Their success has again given rise to complaint against allowing them to participate, on the ground that they are backed by public funds. It hardly seems probable that such a protest voices the feeling of any considerable number of exhibitors, or that it can represent the more liberal and broad-minded element among them. It is understood to carry no antagonism toward the colleges, but to be one of principle against the competition of private exhibitors with public institutions. As such, however, the objection does not seem to be well taken or to represent the highest interests of the live-stock industry. As one of the leading agricultural papers has remarked, the object of the exposition, conducted at such great expense, is to educate by the exhibition of the highest class of animals, and rises far above the mere division of prize money among individual exhibitors.

As a matter of fact, the grand champions for the past four years have been purchased in the open market at market prices, or at auction, and any advantage which the colleges and stations may have had has been in the line of ability rather than of funds. In feeding and fitting these animals no secret practices have been followed. The conditions are a matter of careful record and the results are therefore a contribution to the practice of feeding. The protest is a compliment to the institutions, for it is an acknowledgment of their abilities and their facilities for teaching animal husbandry. "If the college men can beat the practical breeders in breeding, selecting, and feeding animals, it is a fine thing for the public to know." They have so long been held in disregard, and so recently in connection with this International Exposition, that if they are now showing unmistakably that they are

coming into their own, the fact should call for congratulation rather than discrimination.

The increasing prominence of the agricultural colleges and experiment stations in connection with this show is one of the striking illustrations of the change in attitude toward these institutions. Their success in open competition with the world's masters has had great influence in popularizing agricultural education. Everywhere the college and station men were greeted and referred to with respect. Farmers in the audience were pointing them out to one another, and in the judging ring they were much in evidence. These things have demonstrated the practical character of the colleges and the high degree of confidence now reposed in their specialists.

Of the list of judges at the show, nine were men connected with the agricultural colleges and experiment stations, and they judged in nearly one hundred and fifty classes of horses, cattle, sheep, and swine, being in many classes the only judges. Their work was repeatedly commended for the soundness of judgment displayed, and the reasons for their decisions were uniformly intelligible and freely given. As formerly, Prof. C. F. Curtiss, who is one of the directors of the exposition, was an active member of the executive committee and one of the conspicuous figures of the exposition.

This is indeed a great change. It is worth a great deal to have attained, and those who have brought it about have reason to be proud and deserve much credit. As measured by other attempts to popularize this form of education, the effort must commend itself as entirely legitimate.

For a long time the agricultural college instructors, following the course of other educational institutions, sat in their class rooms waiting for students and teaching the few who chose to come. Later they went after the farmer, met him on his own ground by any means they could devise, and by sheer force of argument demonstrated their practical nature and usefulness to him, and gradually changed their title from one of derision to respect and confidence. The man who scoffs at the college and station expert now is likely to be pitied in return; and in bringing about this change of feeling, especially as related to the important branch of animal husbandry, the International Live Stock Exposition has been an important factor.

CONVENTION OF ASSOCIATION OF OFFICIAL AGRICULTURAL CHEMISTS, 1905.

H. W. Lawson,
Office of Experiment Stations.

The twenty-second annual convention of the Association of Official Agricultural Chemists was held at the George Washington University, Washington, D. C., November 16–18, 1905, C. L. Penny, of Delaware, presiding. The attendance was unusually large, as was also the number of papers and reports presented.

In his opening address, President Penny stated that while in the main the association's work had shown gratifying improvement in the uniformity of analytical results for phosphoric acid and potash, the results with nitrogen were less satisfactory. Much of the variation with the Kjeldahl method was believed to be due to the manner of digestion, which subject was discussed in some detail. The speaker urged that the technological questions of analysis should not be left as finished work. He emphasized the importance of permanent reference samples, and suggested as one of the most urgent questions for consideration the correct valuation of basic slag. The institution by the association of vegetation tests for studying the availability of plant food was characterized as an important forward step.

During the course of the meetings, Honorable James Wilson, Secretary of Agriculture, and Prof. William M. Hays, Assistant Secretary of Agriculture, made brief addresses expressing interest in the work of the association, and commenting especially upon the progress made in the suppression of food adulteration.

A resolution offered by R. J. Davidson, that at future meetings all reports and papers be presented by title or abstract, precipitated considerable discussion, which brought out the feeling that some regulations concerning the presentation of reports and papers and the participation in discussions were desired. The matter was referred to the executive committee.

The following officers were elected for the coming year: *President*, C. G. Hopkins, Urbana, Ill.; *Vice-President*, J. P. Street, New Brunswick, N. J.; *Secretary*, H. W. Wiley, Washington, D. C.; *Additional members of executive committee*, H. Snyder, St. Anthony Park, Minn.;

and M. B. Hardin, Clemson College, S. C. The referees and associate referees will be announced later.

Some of the more important features of the convention are summarized below.

SUGAR.

The referee, L. S. Munson, reported that the work done during the year was largely a continuation of the lines of investigation reported upon at the last meeting. The results, as a whole, were considered extremely gratifying, especially as regards methods for the determination of various reducing sugars in mixtures of dextrose and levulose in the presence of sucrose, methods for molasses analysis, and the unification of methods for reducing sugars.

The referee recommended that the work on sugars be continued until uniform methods are obtained for the various reducing sugars, and that copper-sugar factors be determined for the various concentrations of the different reducing sugars and for various mixtures and proportions of sucrose and reducing sugars, which was approved. He also recommended that the methods selected by the International Committee for Unifying Methods of Sugar Analysis be made official; that the method for the determination of copper in the cuprous oxid precipitate requiring reduction in hydrogen, and also the electrolytic methods C and D, on page 38 of Bureau of Chemistry Bulletin 46, be dropped as official methods; and that Low's thiosulphate method, as given in the report of the referee, be substituted for the volumetric permanganate method of the association. Action on these recommendations was deferred for one year.

The report on special analytical methods, by C. A. Browne, jr., associate referee, embraced a study of a method for the analysis of simple mixtures of reducing sugars, further trials of a method for the determination of dextrose, levulose, and sucrose in mixtures, and a study of the influence of temperature upon the polarization of raw cane sugars. The recommendations that the work upon the separation of sugars be submitted to collaborative tests, and that the work upon the identification and determination of the various organic solids-not-sugar, upon which some progress was made during the year, be continued, were approved by the association.

The associate referee on molasses methods, H. E. Sawyer, presented a verbal report giving some general results obtained with his method of examining dark molasses, in which the normal weight is made up to 500 cc. Recommendations regarding changes in the official methods were deferred until the next meeting. The recommendations that a further study be made of the choice of a constant or variable factor for employment in the Clerget equation and that a table of logarithmic factors be prepared for use with the new modification of the Soxhlet

solution in computing the percentage of reducing sugars were approved by the association.

P. H. Walker read a paper entitled A Uniform Method for the Determination of Reducing Sugars, in which a modified method for the determination of both dextrose and invert sugar was described. This was designed to avoid confusion in work on reducing sugars arising from using Allihn's tables for dextrose and Meissl's tables for invert sugar.

TANNIN.

The report of the referee, H. C. Reed, contained the results of extended collaborative investigations, and was presented only in abstract. The following subjects were recommended for collaborative research during the coming year: (1) Soluble solids filtration, (2) analysis of liquors and the effect of the acidity of the liquors upon the analysis, (3) estimation of acid in tan liquors, (4) the influence of acidity and alkalinity upon the chroming of hide powders and upon the subsequent analysis, (5) extraction, (6) the Parker-Payne method of tannin analysis, and (7) estimation of nitrogen in leather and tan liquors. Methods adopted provisionally included the chroming of hide powder by the addition of the entire amount of chrome alum at one time, limiting the moisture content of wet chromed hide powder used for analysis between 70 and 75 per cent, the analysis of liquors as detailed in the report of the referee, and use of the form of apparatus known as the combined evaporator and drier. Action was deferred until the next meeting upon a method for tannin analysis which was proposed for an official method.

A paper on the Extraction of Tanning Material for Analysis was presented by F. P. Veitch.

A communication was received from a committee representing the American Leather Chemists' Association in which it was suggested in substance that the two associations appoint the same referees, or that the Association of Official Agricultural Chemists abandon work on tannin. The communication was referred to the referee for report at the next meeting.

INSECTICIDES, FUNGICIDES, AND DISINFECTANTS.

The report on this subject was submitted by the referee, B. H. Smith. The work followed suggestions of the previous referee, and included comparative analyses by several chemists of samples of Paris green, London purple, tobacco extract, soda lye, sulphur dip, formaldehyde, chlorid of lime, and a phenolic disinfectant. An examination of 28 samples of commercial formaldehyde from various sources showed an average strength of approximately 37 per cent of formaldehyde. The

two modifications of the Avery-Beans method of determining total arsenic in Paris green, recommended for adoption last year, were made official, as was also the thiosulphate method of determining copper.

In a supplementary paper the referee reported the results of some investigations showing the rapidity with which bleaching powder loses chlorin upon standing, largely due to the chemical changes taking place within the product itself.

The results of a study of the lime-sulphur-salt-soda wash, carried out along the same lines as recent investigations on the lime-sulphur-salt wash (E. S. R., 17, p. 55), were presented in a paper by J. K. Haywood. The two washes were found to decompose in the same manner, except that the rate of decomposition of the lime-sulphur-salt-soda wash was much slower. By substituting soda for lime, the author has prepared, in laboratory experiments, an insecticide which does not require boiling in its preparation and which corresponds, so far as chemical changes are concerned, to the lime-sulphur wash and which he recommends for practical trial. The proposed formula is as follows: Water 20 gal., powdered sulphur 7¾ lbs., and caustic soda (98 per cent) 4 lbs. The salt was not found to enter into the changes taking place in this material.

FOODS AND FEEDING STUFFS.

Neither the referee, J. O. La Bach, nor the associate referee, J. K. Haywood, presented reports upon this subject.

C. A. Browne, jr., recommended that a committee be appointed by the association for the purpose of establishing standards for the composition of various unmixed feeds, such as wheat bran, rice bran, cotton-seed meal, etc. By vote of the association this matter was referred to the committee on food standards. Doctor Browne also recommended that the method adopted by the Fifth International Congress of Applied Chemistry for the analysis of molasses feeds be adopted by the association as an official method. Action on this recommendation was deferred until next year.

FOOD ADULTERATION.

Brief remarks were made by the referee, W. D. Bigelow, on the work as a whole. Reports of 12 associate referees which were presented are noted below. No reports were offered on the subjects of wine, beer, vinegar, baking powder and baking chemicals, infants' and invalids' foods, vegetables, condiments other than spices, and cocoa and cocoa products, for which the association has associate referees. The appointment of an additional associate referee on the determination of water was authorized.

During a recess of the convention an informal meeting of food chemists was held at which A. McGill demonstrated certain simple tests

for the detection of food adulterations, and McGill, W. D. Bigelow, L. M. Tolman, R. E. Doolittle and others discussed with decided want of agreement the advisability of placing such tests in the hands of dealers and others not trained in chemistry.

Colors.—W. D. Bigelow stated that the associate referee on colors, W. G. Berry, had completed an exhaustive compilation of literature on the subject of coloring matter, which is now being printed.

Saccharine products.—The report on saccharine products, by J. Hortvet, presented the results of comparative analyses of maple sugar and sirup by a number of analysts. The methods employed were published in Circular 23 of the Bureau of Chemistry and were adopted as provisional.

C. H. Jones called attention to the work which has been carried on at the Vermont Station, stating that a satisfactory method for the detection of cane sugar in maple products had been devised. (See E. S. R., 17, p. 219.)

Fruit products.—In the report of E. M. Bailey it was stated that the work of the associate referee on fruit products had been confined to an effort to devise a practical method for the determination of water in dried fruits. Comparative results in drying prunes, peaches, apricots, and apples with and without sand were reported. Drying with sand gave slightly higher and presumably more accurate results. Drying for 30 hours at 100° C. and cooling in a desiccator for at least one hour before weighing was recommended.

The determination of moisture was further discussed by William Frear, who called attention to Benedict's method of drying at normal temperatures, and by H. W. Wiley, who spoke of the method recently described by L. Maquenne (see p. 437) and of drying in a partial vacuum as carried out in the Bureau of Chemistry. The referee on food adulteration was requested to assign the methods of determining moisture mentioned for testing during the coming year.

Distilled liquors.—The report on this subject, presented by C. A. Crampton, dealt mainly with the determination of fusel oil. The method of A. Trillat and that of Riche and Bardy for the detection of methyl alcohol in distilled liquors, and the method of Leach and Lythgoe for the estimation of ethyl and methyl alcohol in mixtures, were recommended for adoption as provisional methods, which was done. A method of determining aldehydes was offered as a substitute for the one given on page 97 of Bulletin 65 of the Bureau of Chemistry, and methods of determining ethereal salts and furfurol were offered as substitutes for those given on page 98 of the same bulletin. These methods were adopted as provisional, as was also Allen and Marquard's method for fusel oil.

H. E. Sawyer described some methods employed by him in examining distilled liquors, and stated that aniline dyestuffs were coming into

use in coloring liquors. H. W. Wiley spoke on the color and adulteration of whisky in the United States and abroad. A paper on artificial coloring matter in whisky, by P. H. Walker and J. H. Schreiber, gave the results of tests of a number of methods employed in the examination of a large number of samples of whisky for artificial coloring matter.

Vinegar.—No report was presented on this subject. The detection of malic acid, however, was discussed by L. M. Tolman and L. L. Van Slyke, and upon motion of the former it was agreed to eliminate from the printed method the statement that the presence of malic acid distinguishes cider vinegar and also the tests with silver nitrate and barium chlorid.

In a paper on the determination of solids in cider and vinegar, by J. A. La Clerc and L. M. Tolman, it was stated as quite possible to obtain a correct estimation of solids in cider and vinegar by exposing them in a flat-bottomed evaporating dish in a live steam bath for two hours. Another paper by the same authors showed that cider prepared by pressing pomace which had been allowed to lie in large heaps for ten days or more varied considerably in composition from that prepared from pressing the juice from freshly ground apples. It was considered that the addition of second-pressing to first-pressing cider can be readily detected by the presence of considerable quantities of pentosans and galactans in the second-pressing cider.

Flavoring extracts.—E. Chase reported that no satisfactory work had been done upon flavoring extracts during the year. An outline for future work along this line was presented and approved. Leach's test for coumarin, the colorimetric ferrous-sulphate method for determining vanillin, Winton's modification of the Hess and Prescott method for the determination of vanillin, coumarin, and acetamid, and Leach and Lythgoe's refractometric method for the detection of methyl alcohol were adopted as provisional methods.

Spices.—A. L. Winton reported that the work during the year had been confined to the analysis of prepared mustard, with the view of developing suitable analytical methods and gaining an idea of the range in composition of commercial products. A compilation of methods of analysis for prepared mustard was presented and numerous analyses were reported. The methods were adopted as provisional.

Meat and fish.—In the report on meat and fish, by M. E. Jaffa, determinations of some nitrogenous constituents in raw meat were reported.

Fats and oils.—L. M. Tolman reported that cooperative work on the titer test during the year had brought this subject to such a stage that a method including the use of a standard thermometer, which was described, was recommended for adoption as provisional, which was done. A further study, however, of the method of drying fatty acids

was recommended. The methods classified under the name of the cold test were collected and studied. This test was defined as the congealing or solidifying point of an oil. The associate referee was inclined to believe that the test used by Armour & Co. was the best of the methods given and, if improved by the addition of time element, would prove satisfactory. Unknown mixtures of lard and beef tallow were sent out for cooperative work on the Belfield test, and the reports of nine chemists were considered as indicating that where a satisfactory method was used, there was no difficulty in detecting additions of beef tallow to lard. Further work was considered necessary before a satisfactory method could be devised. The correction for temperature with the refractometer, recommended in 1903 (Bureau of Chemistry Bul. 81, p. 64), was adopted as official, as was also the Hanus method.

Dairy products. —This report, by A. E. Leach, dealt with the examination of milk by means of the Zeiss immersion refractometer. A minimum standard of 39° was adopted, below which it was considered safe to allege that the sample was fraudulently watered, especially if in addition to this the solids-not-fat were below 7.3 per cent. Analytical data, obtained by the associate referee, by R. B. Fitz Randolph of New Jersey, and by J. Hanley of Liverpool, England, were included in the report. The refractometric method of Leach and Lythgoe for the detection of water in milk was adopted as a provisional method.

Cereal products.—No formal report was presented on the subject of cereal products, but the associate referee, A. McGill, called attention to certain physical tests used in the examination of flour, and recommended further work.

Cocoa and cocoa products.—A paper on cacao starch was read by B. J. Howard. The author's studies were occasioned by statements that it was possible to change cacao starch by heating in the process of roasting into aggregates resembling other starches. He failed to produce starchy masses resembling wheat and potato starch, and believed that with the microscope, and more especially with the micropolariscope, the question of foreign starches in cacao products can be established, care being exercised to make sufficient micro-chemical tests to establish beyond a doubt that the masses under consideration are starch and not fat globules.

Tea and coffee.—No cooperative work had been done during the year, but H. C. Lythgoe reported that the methods submitted at the last convention had been used with marked success in the laboratory of food and drug inspection of the Massachusetts State Board of Health for the approximate quantitative determination of the ingredients of samples of adulterated coffee.

Preservatives.—W. D. Bigelow stated that analyses were made of a number of products which had been canned with and without the addition of preservatives, the results of which showed that in no case where

preservatives had not been used was any reaction obtained that could be interpreted as indicating the presence of chemical preservatives. Methods for the detection of formaldehyde, benzoic acid, salicylic acid, saccharin, boric acid and borates, fluorids, and in some instances methods of quantitative determination, were presented in the report and adopted provisionally by the association.

DAIRY PRODUCTS.

A report on this subject by the referee, G. E. Patrick, gave the results of studies on the effects of preservatives on the determination of albumin and casein in milk and of tests for renovated butter.

The referee for next year was instructed to continue the study of the effect of preservatives on the determination of the proteids of milk, and to study methods for determining sugars in condensed milks and dried milks or milk powders, and also methods of detecting adulteration of butter with small quantities of foreign fats.

A paper on milk analyses by calculation, by G. A. Olson, was also presented. The author uses the following formula: $P = .368T + .33A - .383F$, in which P = proteids, T = total solids, A = ash, and F = fat. By using Richmond's or Babcock's formula for total solids and assuming that all milk contains a definite amount of ash, namely 0.75 per cent, a complete analysis can, therefore, be computed from determinations of specific gravity and fat content, sugar being obtained by difference. Comparative data obtained by gravimetric analysis and by calculation were reported.

SOILS.

The referee, C. G. Hopkins, explained why the work recommended last year had not been carried out. He presented the results of a pot culture experiment on the comparative value of steamed bone meal and finely ground raw rock phosphate. As a general average, wheat made slightly better gains with the rock phosphate than with the steamed bone meal.

A modified method for the determination of total phosphorus in soils was presented in a paper by J. H. Pettit and A. Ystgard, and comparative determinations by the method described and the alkali carbonate method were reported.

In a paper on the proper strength of acid to be used for determining available plant food in soils, by A. M. Peter and S. D. Averitt, were presented the results of determinations with $\frac{1}{10}$, $\frac{1}{20}$, and $\frac{1}{40}$ normal nitric acid, along with those obtained by the authors with $\frac{1}{5}$ nitric acid and $\frac{1}{200}$ hydrochloric acid the previous year. Preference was expressed for the $\frac{1}{5}$ normal nitric acid.

B. L. Hartwell and J. W. Kellogg reported determinations of the phosphoric acid removed by crops, by dilute nitric acid, and by

ammonium hydroxid from a limed and unlimed soil receiving various phosphates. The results with flat turnips indicated that this crop may serve a useful purpose in testing the relative assimilability of different phosphates. Ammonium hydroxid of $\frac{1}{5}$, $\frac{1}{25}$, and $\frac{1}{100}$ normal strength and nitric acid of $\frac{1}{100}$ and $\frac{1}{25}$ normal strength failed to extract from the soil amounts of phosphorus corresponding to crop results. It was considered doubtful if any solvent will extract from all soils amounts of phosphorus bearing relations to those removed by a given crop.

F. P. Veitch presented in abstract a paper on The Effect of Fertilizers on the Reaction of Soils. The reaction and acidity of some of the limed and unlimed plats, which had received different fertilizer treatment in the rotation experiments of the Ohio Experiment Station, were determined by the lime-water method and by the sodium-chlorid method and it was found that those unlimed plats which had received large applications of sodium nitrate, either alone or in conjunction with phosphates and potash salts, were less acid than those plats receiving no nitrate. Acid phosphate alone slightly reduced acidity, but with other materials produced no change. Potassium chlorid did not change the acidity of the soil. The results obtained on this soil are not considered to be of general application to soils of different constitution.

The same author also presented a paper on Plant Growth as Influenced by Soil Acidity. The results of experiments with red clover, cowpeas, alfalfa, tomato, lettuce, wild marsh grasses, corn, and timothy were considered as indicating the desirability of rendering the soil faintly alkaline with calcium carbonate rather than stopping with smaller applications, and it was suggested that possibly with very sensitive plants, such as alfalfa, it may be necessary to incorporate the lime to a greater depth than can be done by the ordinary harrow or cultivator.

INORGANIC PLANT CONSTITUENTS.

Samples of corn meal, ground oats, cotton-seed meal, and white mustard were sent out by the referee, R. W. Thatcher, for collaborative work on the determination of sulphur by the nitric-acid, sodium-peroxid, Barlow-Tollens, and chromyl-chlorid methods. The results were considered as proving conclusively that the nitric-acid method does not yield all the sulphur present in plant tissues. The peroxid method was considered the most accurate and feasible method. The combustion method of Barlow-Tollens proved satisfactory to the two chemists who used it. The chromyl-chlorid method gave unsatisfactory results. It was recommended that the provisional nitric-acid method be dropped and the peroxid method be adopted provisionally, which was done. The referee for next year was requested to investigate the Barlow-Tollens method as a means of distinguishing between organic sulphur and sulphur of the ash.

POTASH.

The report of the referee, G. S. Fraps, dealt with the determination of water in kainit and mixed fertilizers and the volumetric method for potash. In the determination of potash the modified method which provides for the use of an acid solvent was found to be more satisfactory than the official method. Experiments were made to ascertain how much potash would be removed from insoluble silicates by the modified method, from which the conclusion was drawn that this method does not open the way for the potash-bearing silicates for fillers, as the amount of potash that could be so added is insignificant. While believing that the modified method is accurate, the referee hesitated to give it his unqualified indorsement, inasmuch as the laws of 27 States require potash to be soluble in water. The referee recommended that the volumetric method be further studied with particular reference to its use in soil analysis, which was approved by the association. The referee for next year was also instructed to study, in the determination of potash in mixed fertilizers, incineration at low temperature and solution in dilute acid.

The discussion showed a considerable difference of opinion as to the availability of organic potash and the advisability of using an acid solvent in determining potash in mixed fertilizers. It was suggested that the different forms of potash be determined and stated.

A paper on the use of acetic and oxalic acids for extracting the charred material in preparing ash, by B. L. Hartwell and J. W. Kellogg, was read by title. The amount of crude ash was generally greater when oxalic acid was used.

DETERMINATION OF NITROGEN.

A letter from the referee, F. W. Robinson, stated that there were no results ready to report on this subject.

By vote of the association the referee for next year was instructed to study the addition of ½ to ¾ gm. of copper sulphate after digestion with sulphuric acid and potassium sulphate in the determination of nitrogen by the official Gunning method.

R. J. Davidson proposed a change in the method of standardizing the hydrochloric acid used in the determination of total nitrogen.

SEPARATION OF NITROGENOUS BODIES.

The report on milk and cheese proteids was submitted by the referee, R. Harcourt. The method elaborated by Van Slyke and Hart for the separation of nitrogenous bodies in cheese was subjected to collaborative tests. Eight chemists reported results which formed the main part of the report. The referee recommended that the work be continued, special attention being given to the problem of making a com-

plete extraction of water-soluble nitrogenous bodies and to their complete separation in filtering; that in making the extract the amount of water be increased from 500 to 1,000 cc.; and that after the fat and insoluble nitrogenous bodies have been removed by absorbent cotton the filtrate be passed through asbestos. The recommendations were approved.

J. S. Chamberlain, associate referee on vegetable proteids, reported that no cooperative work had been planned and carried out. The method of H. T. Brown for the separation of the nitrogenous bodies in barley and malt was recommended, and was adopted as provisional by the association.

A paper entitled Notes on the Determination of Albuminoid Nitrogen in Cereals, by J. A. La Clerc and W. C. Lounsbury, was read by title.

W. D. Bigelow, associate referee on meat proteids, presented a verbal report on work done by him and F. C. Cook on the separation of albumoses and peptones from the lower amido bodies by the use of the tannin and salt reagents.

PHOSPHORIC ACID.

The referee, E. W. Magruder, made a verbal report on this subject, speaking of the determination of the neutrality of the citrate solution and suggesting that the determination of iron and alumina in phosphates be further studied.

By vote of the association the referee for the coming year was instructed to study and make a report at the next meeting on the official examination of basic slag phosphates, on the determination of iron oxid and alumina in rock phosphates, and on the neutrality of the ammonium citrate solution as actually used by analysts.

A modified method of determining phosphoric acid was submitted by A. B. Foster, and some results obtained were reported.

MEDICINAL PLANTS AND DRUGS.

The referee, L. F. Kebler, recommended that the association adopt the method prescribed by the eighth revision of the United States Pharmacopœia for the assay of opium as a provisional method that the work on the analysis of opium be continued and extended to ipecac and golden seal; and that associate referees be appointed to take up different features of the work.

SPECIAL COMMITTEES.

Food standards.—A report of progress was submitted by the chairman of the committee, W. Frear. It was stated that standards for a number of products were decided upon during the year and that tentative standards were also drawn up and distributed to those interested.

Fertilizer legislation.—The chairman of the committee, H. W. Wiley, reported that considerable progress was made during the year in the duties assigned to the committee, and that the committee had agreed upon the principles which it was believed should underlie interstate traffic, but was not ready to recommend legislation. The committee was continued with instructions to consult various organizations interested in the matter and to report at the next meeting.

In this connection a paper, by R. E. Rose, was submitted in which the following question was discussed: What Variations from Maximum Guaranteed Analysis and Fertilizers shall be Considered Adulterations or Deficiencies?

Testing chemical reagents.—The committee on testing chemical reagents, L. F. Kebler, chairman, considered that the amount of information at present available to the committee was insufficient to recommend any action relative to the adoption of standards for the chemicals so far investigated. Upon the recommendation of the committee the work was ordered to be continued and extended to include 10 additional chemicals which in the opinion of the committee may be considered most important. The chairman exhibited a number of samples of impure chemicals.

Unification of terms for reporting analytical results.—R. J. Davidson, chairman of the committee, reported that a statement had been prepared on this subject by the committee and published and distributed in pamphlet form by the Bureau of Chemistry, but that the committee was not yet ready to make a final report. The committee was continued.

Unification of soil methods.—L. L. Van Slyke, chairman of the committee, reported that the only feasible plan for accomplishing the desired results, in the opinion of the committee, was in the line of the traditions established by the association, namely, studying all proposed methods by referees supplemented by individual work in laboratories, the methods examined to stand or fall by the results reached. The committee requested that it be discharged from further action, which was done.

Definition of "plant food."—H. W. Wiley, chairman of the committee, reported that during the year extensive correspondence had been carried on with a similar committee representing the botanists of the United States. No agreement was obtained between the two committees. The committee of the association was of the opinion that "plant food is a term which should be applied to bodies entering the organism of the plant from without and taking part in its metabolic activity, whether these bodies be organic or inorganic in character." The committee recommended that further conference be had with the botanists, and if no common ground for a definition be found that the committee prepare a definition of plant food to be reported at the next meeting.

RECENT WORK IN AGRICULTURAL SCIENCE.

AGRICULTURAL CHEMISTRY.

The practice of agricultural chemists, M. Passon (*Die Praxis des Agrikultur chemikers. Stuttgart: Ferdinand Enke, 1905, pp. VIII + 295, pls. 5*).—This book describes the various materials which the agricultural chemist is likely to be called upon to examine, and gives in some detail the analytical methods suited to such examination.

The subjects treated are fertilizers, including various forms of nitrogenous, phosphatic, and potash fertilizers, mixed fertilizers, calcareous manures, fraudulent fertilizers, barnyard manure, composts, and night soil; the soil, including investigation of various soil types, the valuation of soils on the basis of chemical analysis, soil tests with fertilizers, and the examination of the products obtained in such tests; feeding stuffs, including various by-products of oil making, milling, and other industries; and briefer sections relating to milk, butter, margarin, water, and seed.

On the determination of magnesium and phosphoric acid as magnesium pyrophosphate, K. K. Järvinen (*Ztschr. Analyt. Chem., 44 (1905), No. 6–7, pp. 333–342; abs. in Jour. Chem. Soc. [London], 88 (1905), No. 514, II, p. 555*).—In the method proposed the solution, which should not contain a great excess of ammonium salts, is exactly neutralized, using lacmoid as indicator. A slightly ammoniacal solution of diammonium phosphate is then added drop by drop.

When time has been given for the greater part of the precipitate to separate 1 per cent ammonia is added and then 10 per cent ammonia in quantity equal to one-third of the volume of the whole. After standing 2 hours the precipitate is collected on a filter, dried, ignited over a Bunsen flame, and weighed. Ammonium oxalate in moderate quantity has no effect on the precipitation.

An alkalimetric method of determining phosphoric acid in the presence of other acids and its application in the examination of phosphatic materials, V. Boulez (*5. Internat. Kong. Angew. Chem., 1903, Ber. 3, pp. 746, 747*).—The method is based upon the difference in behavior of phosphoric acid and other acids toward methyl orange and phenolphthalein as indicators.

Further notes on simple methods of determining potash, F. Klinkerfues (*Chem. Ztg., 29 (1905), No. 81, pp. 1085, 1086*).—Referring to his previous note on this subject (E. S. R., 16, p. 843), the author calls attention to the fact that it is not necessary to evaporate to complete dryness after the addition of formic acid, and that by taking advantage of this fact the operation is greatly shortened. He also describes an adaptation of his method for potash to the determination of nitrogen in potash-free ammonium salts.

The new Paul Wolff apparatus for the determination of lime in high percentage marls, P. Sommer (*Deut. Landw. Presse, 32 (1905), No. 82, p. 692, fig. 1*).—The apparatus described is adapted to marls containing over 50 per cent of calcium carbonate. Two gm. of the marl is decomposed by boiling with 50 cc. of normal hydrochloric acid, for which a special pipette is provided. The excess of acid is titrated (using phenolphthalein as indicator) with ½ normal sodium hydroxid

solution, which is run into the flask from a burette so graduated that its readings indicate directly the percentage of calcium carbonate.

On the question of the separation of iron and aluminum from manganese, calcium, and magnesium in the analysis of plant ashes, P. KASCHINSKY (*Jour. Landw., 53 (1905), pp. 179–185*).—A series of comparative tests of König's method (precipitation of iron phosphate in presence of ammonium acetate) and Tollens's method (precipitation in presence of acetic acid) is reported. From the results the author concludes that neither of these methods gives accurate results, due to the fact that considerable amounts of calcium phosphate are precipitated with the iron phosphate.

Determination of the loss on ignition in soil analysis, H. MEHRING (*Jour. Landw., 53 (1905), No. 3, pp. 229–237*).—It is claimed that incineration with ammonium carbonate gives a greater weight than that which can be ascribed to the restoration of carbon dioxid which would be lost by ignition without the use of carbonate.

The loss on ignition is a very indefinite factor, and is made up of three main elements, carbon dioxid driven off, chemically combined water eliminated, and organic matter destroyed. The use of ammonium carbonate in ignition increases rather than decreases the error of the determination. It is claimed that the determination of humus by combustion with copper oxid or chromic acid is more reliable and useful than incineration.

On the difficulty of detecting small variations in the nitrogen content of soils by means of the Kjeldahl method, R. THIELE (*Mitt. Landw. Inst. Breslau, 3 (1905), No. 2, pp. 157–178, figs. 4*).—This article reviews very thoroughly the literature relating to the sampling of soils and discusses the difficulty of securing representative samples showing with accuracy the small differences occurring in the plant-food constituents, particularly nitrogen, in soils.

A series of determinations of nitrogen (5 for each sample) by the Gunning-Atterberg method in 24 samples of soil, composites of samples from 10 different places at regular intervals on 200 square meter plats, are reported, and the results are platted in comparison with the curve for rainfall for the period during which samples were taken. Examinations were also made of 10 samples of soil made up from portions of 10 spadefuls of soil taken around the 10 selected points.

The results indicate that it is not possible to get a strictly representative sample of a large area by present methods of sampling, but that it is possible to detect by chemical analysis much smaller variations in nitrogen content than are likely to be of significance in experimental work.

Determination of nitric acid in the presence of organic substances, B. PFYL (*Ztschr. Untersuch. Nahr. u. Genussmtl., 10 (1905), No. 1–2, pp. 101–104, fig. 1; abs. in Analyst, 30 (1905), No. 355, pp. 345, 346, fig. 1*).—The method described is based upon the reduction of the nitric acid to nitric oxid by means of ferrous chlorid and hydrochloric acid, the nitric oxid being washed by passing it through sodium hydroxid solution and absorbed by one-tenth normal potassium permanganate solution. The excess permanganate solution used is titrated with tenth normal ferrous chlorid solution. A special form of apparatus for use in the reduction is described.

Methods of examination of potable waters and the interpretation of the results, F. DIENERT (*Ann. Inst. Pasteur, 19 (1905), No. 9, pp. 541–563, figs. 4*).—Various methods of examining potable waters are discussed in this article, especial attention being given to a method based on electric conductivity, which is described in detail, and which it is claimed is well adapted to a study of variations in underground waters. This method with quantitative determinations of *Bacillus coli communis* is believed to furnish an adequate basis for judging of the sanitary quality of waters.

The estimation of cellulose and lignin in feeding stuffs and foods, J. KÖNIG (*5. Internat. Kong. Angew. Chem., 5 (1903), Ber. 3, pp. 1052–1060*).—The author

describes his method of determining crude fiber in food or feeding stuffs by means of a mixture of glycerin and sulphuric acid (E. S. R., 9, p. 1021). The amount of lignin in the crude fiber can be determined by treatment with hydrogen peroxid to which ammonia has been added. This reagent dissolves the lignin, leaving the pure cellulose behind.

The cleavage products of starch, A. Rössing (*Chem. Ztg., 29 (1905), No. 66, pp. 867–873*).—This article has to do with the cleavage products obtained by hydrolysis of starch with hydrochloric acid, their estimation in starch sugars and sirups, and their effect upon the use of the latter in the confectionery industry.

According to the author, the hydrolysis of starch with hydrochloric acid under suitable conditions gave a modification of the ordinary glucose, which may be detected by its lower reducing power under the influence of barium hydroxid. The lower reducing power is due largely to the formation of lactic and other organic acids and serves for the determination of normal glucose and dextrin.

In addition to abnormal glucose, unfermentable bodies, dextrin, and reversion products were also obtained which have a strong reducing power and are hygroscopic. The author believes that the use of starch sirup obtained in this way in confectionery should not be permitted.

The analysis of wheat flour for commercial purposes, H. Snyder (*5. Internat. Kong. Angew. Chem., 1903, Ber. 3, pp. 702–710, pls. 2*).—Different factors which should be studied in the commercial analysis of flour are recorded and analytical methods described. The author believes that it is possible to judge of the quality of flour and that satisfactory and definite standards can be formulated.

The estimation of moisture in bread, A. Pagniello (*Bol. Chim. Farm., 43 (1904), pp. 309–313; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 9 (1905), No. 11, p. 693*).—The amount of water in crust and crumb of bread was determined by heating samples weighing 50 to 100 gm. for 7 hours in a drying oven at 105 to 110° C. and calculating the amount of water in the original loaf.

On the absolute desiccation of vegetable materials, L. Maquenne (*Compt. Rend. Acad. Sci. [Paris], 141 (1905), No. 16, pp. 609–612*).—Starches and flours placed in tubes through which a current of dry air was forced to pass at the rate of about 1 liter per hour, and dried in a thermostat at 120° C. for 1 hour or 100° for 2 hours, showed about 1 per cent more moisture than samples dried in the ordinary way.

The harmfulness of artificial colors in foods, G. Schacherl (*5. Internat. Kong. Angew. Chem., 1903, Ber. 3, pp. 1041–1048*).—A summary and discussion of data regarding artificial coloring matters and their use in food products.

A simple method for determining boric acid quantitatively, O. von Spindler (*Chem. Ztg., 29 (1905), No. 43, pp. 582–584*).—The author describes a modification of the method of estimating boric acid which depends on the fact that it is volatilized with methyl alcohol and may be distilled with this reagent.

On fat determination in milk, T. S. Thomsen (*Mælkeritid., 18 (1905), No. 18, pp. 359–365*).—The author explains the lower results obtained by the extraction method of milk analysis as compared with the Gottlieb method (in the author's analyses, amounting to 0.38 to 0.06 per cent for buttermilk, and 0.26 to 0.03 per cent for skim milk), by an incomplete extraction of the fat in the milk solids, because the casein protects some of the fat from the action of the ether. When the casein of the milk was peptonized previous to the drying of the milk, identical results were obtained by the two methods, both in the case of buttermilk, half-skimmed milk, and skim milk high or low in fat. The peptonization did not, on the other hand, affect the results obtained by the Gottlieb method.

The peptonization of the milk was conducted in the following manner: To 3 drops of strong hydrochloric acid placed in the dish to be used for the determination of the solids in the milk were added 10 cc. of milk, and finally about 0.1 gm. of strong

pepsin dissolved in about 1 cc. of water. The whole was then stirred with a platinum wire and left for about 2 hours at 40° C., and then at room temperature until the following day, when as much of a mixture of 9 volumes of granular kaolin and 1 volume barium carbonate was added as was necessary to absorb completely the contents of the dish. The material was then placed in a drying oven for 4 to 5 hours at about 98° C., and the desiccated mass finally extracted with anhydrous ether. The pepsin used was found free from ether-soluble substances.

The author concludes that the Gottlieb method gives correct results, and should be used to the exclusion of the extraction methods in the analysis of milk low in fat.—F. W. WOLL.

Contribution to the detection of watered milk, O. BIALON (*Milchw. Zentbl., 1 (1905), No. 8, pp. 363-366*).—The specific gravity of milk serum is shown to vary irregularly with the method of coagulation employed.

In one instance the specific gravity of the serum obtained by spontaneous coagulation was 1.0284, by acetic acid 1.0266, and by rennet 1.0291. The variations are explained as due to the different amounts of phosphates, lime, and proteids left in solution. Complete analyses showed furthermore that the properties of the serum obtained by the same method are not constant. Instead of using determinations of total solids and specific gravity of the serum, the author would make use of the specific gravity of the fat-free milk determined by the formula:

$$\sigma = \frac{100s - f}{100 - \frac{f}{0.933}}$$

in which s represents the specific gravity of the milk, f the percentage of fat, and 0.933 the average specific gravity of milk fat. For pure milk σ or the specific gravity of the fat-free milk was found to be about 1.0323.

On the basis of a large number of determinations, the author concludes that a specific gravity of 1.0323 or above calculated by this formula shows that the milk is unadulterated, while a lower figure shows that water has been added. The method is, of course, not applicable to curdled milk.

Refractometric examination of milk, M. HENSEVAL and G. MULLIE (*Rev. Gén. Lait, 4 (1905), No. 23, pp. 529-538*).—Ripper's method of preparing the serum is preferred. This consists in adding 1 cc. of 20 per cent acetic acid to 50 cc. of milk, heating on a water bath to 65 to 70° C. for 5 minutes, cooling to 15° and filtering. The determination of the index of refraction may be made at room temperature and calculated to 15° by adding or subtracting 0.000117 for each degree that the room temperature is respectively above or below 15°.

The index of refraction of normal serum varies from 1.3429 to 1.3445. The principal refractive substances in the serum are lactose, salts, and albumin. The addition of 10 per cent of water to milk causes a decrease of about 0.00102 in the index of refraction. A lower index than 1.3425 may be accepted as an indication of watering. An abnormally high index would warrant a suspicion that soluble substances had been added.

The authors did not find that the index of refraction of the milk of diseased cows was always low, not even when a positive tuberculin reaction was obtained. Such, however, was often the case in mammary tuberculosis, but in those instances the milk could generally be recognized by its abnormal appearance. The milk of the healthy quarters showed a normal index. The lowering of the index was found due to a diminution of the lactose.

Cryoscopy of milk for detecting the addition of water, C. BARTHEL (*Rev. Gén. Lait, 4 (1905), No. 22, pp. 505-512*).—Numerous determinations are reported which go to show that the freezing point of milk is not appreciably affected by the individuality or breed of cows, the quarter of the udder from which the milk is obtained, the fat content of the milk, estrum, etc., but that it is very constant between

—0.55 and —0.57° C. The addition of water, however, makes a marked difference, and for the estimation of this cryoscopic examination is believed to be a valuable supplement to the usual determinations of specific gravity, fat content, and total solids.

Review of the literature of milk chemistry, R. W. RAUDNITZ (*Separate from Monatsschr. Kinderheilk., 3 (1905), No. 12; abs. in Milchw. Zentbl., 1 (1905), No. 8, p. 384*).

The commercial utilization of milk waste and more recent products of milk in dry form, J. A. JUST (*5. Internat. Kong. Angew. Chem., 1903, Ber. 3, pp. 870–891*).—The food value of milk, buttermilk, casein products, milk powders, and other commercial products is spoken of, as well as the use of milk by-products for feeding farm animals and for different commercial purposes, the article as a whole being a summary and discussion of the importance of milk by-products.

The quantitative analysis of lard, D. WESSON and N. J. LANE (*Jour. Soc. Chem. Indus., 24 (1905), No. 13, pp. 714–717*).—On the basis of experience different methods of determining the quality of commercial lard are discussed.

The authors conclude that "there is no method for the determination of tallow, its constants being very similar to lard, and it can only be detected qualitatively by the microscope. The phytosterol test is probably one of the best methods for detecting vegetable oil in lard, but is not mentioned in this paper, because it was not in use when the writers were doing the work described. . . . [The Wesson test for free fatty acids, the titer tests, the determination of the saponification value or the iodin value, the Hübl or Wijs method for liquid acids and their iodin value, and Wesson's cooling test] will give results which are within 2 to 3 per cent of the truth, and sufficiently close for commercial purposes. While the lard having the extraordinary iodin value of 115 on the liquid acids . . . may occasionally occur, it is too infrequent to be taken into consideration."

The chemical nature of the sugar product obtained by overheating, F. STOLLE (*5. Internat. Kong. Angew. Chem., 1903, Ber. 3, pp. 359–370*).—On the basis of investigations, the author concludes that in the manufacture of sugar the greater part of the colored matter which is commonly regarded as caramel is formed by the action of lime on nonsugar products, and that only a little caramel is formed. He considers caramel a true carbohydrate, and believes that it is formed from a sugar by the cleavage of two molecules of water at a temperature between 170 and 180°.

Experiments with caramel as a cleavage product of caramelan, F. STOLLE (*5. Internat. Kong. Angew. Chem., 1903, Ber. 3, pp. 370–377, fig. 1*).—The investigations summarized were undertaken with a view to studying the chemical composition of caramelan.

The quantity of sugar permissible in imported preserved pineapples, H. W. WILEY (*5. Internat. Kong. Angew. Chem., 1903, Ber. 3, pp. 105, 106*).—On the basis of data regarding sugar content of pineapples, the author recommends that pineapples imported into the United States contain not over 14 per cent sugar (estimated as reducing sugar), or more than an average of 13 per cent in a whole cargo. If more than this amount be present the goods should be regarded as pineapples to which sugar has been added and classified for duty accordingly.

The occurrence and estimation of organic acids of wines, A. PARTHEIL (*5. Internat. Kong. Angew. Chem., 1903, Ber. 3, pp. 1019–1022*).—According to the author's investigations, the usual method of estimating the total lactic acid in wine neglects the fact that lactic acid is volatile with water vapor. A method which he considers more satisfactory is proposed. This depends upon the fact that the barium salts of tartaric, citric, and succinic acids are difficultly soluble in 80 per cent alcohol and that in the filtrate from these salts the lactic and acetic acid can be distilled with water vapor and estimated without difficulty by means of the carbon-dioxid reaction.

Household chemistry, H. T. Vulté and G. A. Goodell (*Easton, Pa.: Chemical Publishing Co., 1904, pp. 88*).—In this volume, which is designed as a guide and introduction to the study of household science, some directions for laboratory manipulations are given, and air and water, fuel, food constituents, milk testing, antiseptics and preservatives, and related questions are taken up. The appendix among other matters contains a summary of data on the removal of stains from fabrics.

Chemistry of the household, Margaret E. Dodd (*Chicago: American School of Household Economics, 1905, pts. 1, pp. 1–55, figs. 15; 2, pp. 55–88, figs. 5; 3, pp. 89–122, figs. 12*).—A series of lessons on chemistry with special reference to the household designed for instruction by correspondence. Some of the subjects taken up are water, atmosphere, combustion, food and cookery, chemistry of cleaning and laundry work, and plant growth.

METEOROLOGY—WATER.

Climate [of Idaho] (*The State of Idaho. Boise: Bur. Immig., Labor, and Statis., 1905, pp. 154–157*).—A brief general description of the climate of Idaho, including tabular data for temperature and precipitation for different sections of the State during 1903. The annual mean temperature for 1903 was 45.1°, the highest temperature 110°, the lowest −37°. The total precipitation was 16.6 in., the total snowfall 57 in. The total precipitation for the different sections of the State varied from 10.93 in. in the southern section to 19.36 in. in the central section and 24.74 in. in the northern section.

An account of some features of the climate of Reno, Nevada, S. B. Doten (*Nevada Sta. Bul. 59, pp. 21, pls. 4*).—Meteorological observations on temperature, rainfall, snowfall, frost, and cloudiness which have been made at the Nevada State University since 1888 are summarized and discussed in their bearing on the climatic characteristics of the region.

Work of the station of agricultural climatology of Juvisy during 1904, C. Flammarion (*Bul. Mens. Off. Renseig. Agr. [Paris], 4 (1905), Nos. 7, pp. 780–793, figs. 7; 8, pp. 928–952, figs. 3*).—This report is of the same character as those of previous years (E. S. R., 16, p. 855). It contains tabular and diagrammatic records of the temperature of the air during each day and month of 1904, and of the annual and seasonal temperatures from 1885 to 1904; observations on barometric pressure, humidity, cloudiness, rainfall, direction of the wind, hours of sunshine, and solar radiation; a study of the diurnal and annual course of temperature for the climate of Paris, and of the diurnal variations of the temperature of the air.

The results of a study of the relation of the sun to vegetation and the action of different rays on vegetation and on silkworms are also reported, as well as the influence of the moon and of electricity on vegetation.

Meteorological observations, J. E. Ostrander and C. H. Chadwick (*Massachusetts Sta. Met. Buls. 201, 202, pp. 4 each*).—Summaries of observations at Amherst, Mass., on pressure, temperature, humidity, precipitation, wind, sunshine, cloudiness, and casual phenomena during September and October, 1905. The data are briefly discussed in a general note on the weather of each month.

Meteorological summary for 1903–4, E. Burke (*Montana Sta. Rpt. 1904, pp. 237, 238*).—Monthly and annual summaries of observations on temperature, precipitation, cloudiness, prevailing winds, etc., for the year ended October 31, 1904. The mean temperature for that period was 41.2°, the highest temperature 89° August 14, the lowest −23° November 17. The total rainfall was 16.34 in., total snowfall 95 in., number of clear days 103, days on which 0.01 in. or more of precipitation occurred 89.

Meteorological summary for 1903, C. A. Patton (*Ohio Sta. Bul. 152, pp. 195–208*).—This summary includes notes on the weather and tabulated daily and monthly

records of observations at the station at Wooster, Ohio, on temperature, precipitation, cloudiness, direction of the wind, etc., and for comparison, similar data for previous years and for other parts of the State. The following is a summary of results:

Summary of meteorological observations in Ohio.

	For the experiment station.		For the State.	
	1903.	1888–1903.	1903.	1888–1903.
Temperature (° F.):				
Mean	49.1	49.2	50.5	50.8
Highest	(July 4 and 9) 94.0	(Aug. 8, 1891) 99.0	(July 25) 104.0	(July 4, 1897) 113.0
Lowest	(Feb. 19) −9.0	(Feb. 10, 1899) −21.0	(Feb. 19) −20.0	(Feb. 10, 1894) −39.0
Mean daily range	21.6	20.1		
Greatest daily range	(Nov. 18) 48.0	(Oct. 6, 1897) 55.0	(Sept. 25) 60.0	(Sept. 25, 1897) 67.0
Clear days	148.0	131.0		
Cloudy days	159.0	124.0		
Days rain fell	121.0	128.0	111.0	120.0
Rainfall (in.):				
Greatest monthly	(Aug.) 6.58	(July, 1896) 8.05		
Least monthly	(May) 1.59	(Sept., 1897) .29		
Mean yearly			39.87	37.26
Prevailing direction of wind	SW.	SW.	SW.	SW.

Annual precipitation in Oklahoma and Indian Territory, C. M. STRONG (*Oklahoma Sta. Rpt. 1905, pp. 60, 61*).—The total annual precipitation as observed at 25 places in Oklahoma is given for 1904 and 15 preceding years. A similar summary is given of observations at 11 places in Indian Territory. The average annual rainfall for Oklahoma varied from 38.93 in. at Lincoln to 16.34 in. at Beaver; for Indian Territory from 42.40 in. at South McAlester to 26.99 in. at Chickasha.

Meteorological observations on Ben Nevis, LORD MCLAREN ET AL. (*Rpt. Brit. Assoc. Adv. Sci., 1904, pp. 55–60*).—A brief account is given of a continuation of observations during 1903 at the low-level observatory at Fort William and the high-level observatory on Ben Nevis. (See also E. S. R., 15, p. 125.) The principal results arrived at are thus summarized:

"(1) When the difference of the mean temperatures of the day is only 12°, or less, the calculated sea-level pressure for the top of the mountain is markedly greater than at Fort William, and the accompanying meteorological conditions are anticyclonic, the weather being clear, dry, and practically rainless; (2) when the difference of temperature is 18°, or greater, the meteorological conditions are cyclonic, and the accompanying weather dull, humid, and rainy.

"The large result here arrived at empirically is in accordance with the principle laid down by Dalton, viz., that air charged with vapor or vaporized air is specifically lighter than when without the vapor; or, in other words, the more vapor any given quantity of atmospheric air has in it the less is its specific gravity.

"Another important result is that the cases of small differences of temperature between the two observatories are chiefly occasioned by an increase of temperature at the top of the mountain, and large differences of temperature by a decrease of temperature at the top.

"The intimate relation thus disclosed between the varying temperatures and sea-level pressures of a high-level and a low-level station is of prime importance in forecasting the weather, inasmuch as it reveals, in a way not hitherto attempted, the varying conditions of the hydrometric states of the atmosphere, particularly at high levels, upon which changes of weather so largely depend. The setting in of a process of saturation of the atmosphere at great heights may thus be made known, even when no cloud has yet been formed to indicate any such saturation. The important bearing of these results on such practical problems in meteorology as the forecasting of the monsoons of India is evident."

The rainfall and sunshine of Guernsey for the year 1904, A. COLLENETTE (*Guernsey Soc. Nat. Sci. Rpt. and Trans. 1904, pp. 391–399*).—Observations on rainfall at 9 stations are summarized and compared with the averages for 62 years. The total for the year was 37.72 in. as compared with an average of 36.62 in. for the past 62 years. A monthly summary of observations on sunshine during 1904 compared with similar data for the preceding 11 years is also given. The total sunshine for 1904 was 1,925.75 hours as compared with an average of 1,927.11 hours for the past 11 years.

Rainfall in the agricultural districts, G. G. BOND (*Queensland Agr. Jour., 16 (1905), No. 1, p. 152*).—A table is given which shows the total rainfall for each month from June, 1904, to June, 1905, inclusive, in 41 agricultural districts of Queensland.

Hourly observations of atmospheric phenomena at the Manila central observatory, 1903 (*Ann. Rpt. Philippine Weather Bur., 1903, pt. 1, p. 158, pls. 2*).—Detailed observations are recorded on pressure, temperature, precipitation, evaporation, humidity, direction and force of wind. There are also general notes on the weather conditions of the year.

The heaviest rainfalls in the world (*Jour. Mét. Russe, 1905, No. 1; abs. in Nature [Paris], 33 (1905), No. 1677, Sup., p. 25; Rev. Sci. [Paris], 5. ser., 4 (1905), No. 13, p. 408*).—It is stated that the heaviest recorded rainfall in the world occurs in Cherra Poonjee in the Indian Province of Assam. The mean annual rainfall of this region from 1895 to 1903 was 11.223 meters; that of the region of Bombay was 6.83 meters. The rainfall of Debundscha in Kamerun was 10.454 meters, principally during the summer. The highest recorded rainfall during any given year at Cherra Poonjee was 14.789 meters in 1851, at Debundscha 14.133 meters in 1902. At the latter place 456 mm. of water fell during a single day, June 16, 1902. These heavy rainfalls are explained as due to the proximity of warm seas and high mountains.

Weather conditions and statistics (*Ann. Rpt. Dept. Agr. Northwest Ter., 1904, pp. 7–22*).—This is a summary of observations during the year by the voluntary meteorological service of the Northwest Territories on temperature and precipitation, with notes on the general weather conditions during each month and the relation of crop yields and temperature and precipitation.

Forecasting the weather and storms, W. L. MOORE (*Nat. Geogr. Mag., 16 (1905), No. 6, pp. 255–305, pls. 5, charts 20*).—It is stated that this article is to constitute the first chapter of a treatise to be entitled *The New Meteorology*. After a brief historical note the preparation and use of the daily weather map is explained and illustrated.

A new method of determining the direction and velocity of storm movement devised by E. H. Bowie, which is claimed to be "a marked advance over anything heretofore accomplished in this direction," is fully described. The method is based upon a study of the pressure gradients about the base of the storm, in connection with the general drift of the upper air, thus making it possible "to obtain a resultant that approaches with close precision to the line of least resistance at the moment of the taking of the observations on which the weather chart is founded. In the majority of cases his system locates the place to which the storm center will move during the coming 24 hours with considerable accuracy."

Some aspects of modern weather forecasting, W. N. SHAW (*Abs. in Nature [London], 72 (1905), No. 1867, pp. 354, 355*).—In this address, delivered before the Royal Institution of Great Britain, the close relation existing between weather conditions and barometric distribution and changes is pointed out and some of the difficulties in the way of quantitative association of rainfall or temperature changes with barometric variations are discussed.

Islands for weather forecasting purposes, W. E. COOKE (*Nature [London], 72

(*1905*), *No. 1867*, *pp. 343*, *344*).—A discussion of the importance and value of Lockyer's suggestion regarding this subject (E. S. R., 17, p. 161) as applied to the meteorology of Western Australia.

Water and agriculture, L. Thiry (*Rev. Gén. Agron.*, *14* (*1905*), *Nos. 4*, *pp. 161–164; 5*, *pp. 198–206; 6*, *pp. 258–265*; *7–8*, *pp. 296–307*).—This is a general article treating of the rôle played by water in the life of plants and means of preventing injuries by drought, concluding with the statement that the future of Belgian agriculture depends in large part on the judicious use of water in irrigation.

Natural vegetation and the purity of waters, L. A. Fabre (*Compt. Rend. Acad. Sci.* [*Paris*], *141* (*1905*), *No. 13*, *pp. 537–539; abs. in Rev. Sci.* [*Paris*], *5. ser.*, *4* (*1905*), *No. 15*, *p. 466*).—It is stated that the purification of natural waters appears to be essentially a biological process.

The oxygen of the air is slowly carried down into the soil with the percolating waters and destroys by eremacausis the organic matter of the soil, at the same time increasing the vitality and multiplication of the aerobic organisms, which increase the fertility of the soil. The opposite effect, however, is produced on the pathogenic anaerobes. The latter, which are useless to plants, are eliminated or transformed after having lost their virulence into auxiliaries of the aerobes. Certain pathogenic races of organisms show a tendency to return to saprophytic types, which appear to be the original form of all micro-organisms in uncultivated soils.

Geology and underground water conditions of the Jornada del Muerto, New Mexico, C. R. Keyes (*U. S. Geol. Survey, Water-Supply and Irrig. Paper No. 123*, *pp. 42*, *pls. 9*, *figs. 11*).—This bulletin deals with the general character of the New Mexican plateau region, and surface relief, formations, structure, and underground waters of the Jornada del Muerto. "It presents new and valuable information regarding the geologic structure of this large desert area, and shows that the conditions are favorable for the extensive occurrence of underground waters which, to some extent, are available for irrigation and domestic supplies. The region is one of fine climate and fertile soil, and the development of its underground waters will afford the means for sustaining settlers at a number of localities."

Water for domestic purposes in North Dakota, E. F. Ladd (*North Dakota Sta. Bul. 66*, *pp. 559–571*).—This bulletin discusses the standard of purity for potable waters, explains the significance of the results of analysis, and reports quantitative determinations of total, volatile, and nonvolatile solids, and chlorids, and qualitative tests for carbonates, sulphates, lime, magnesia, and soda in 160 samples of water from different parts of North Dakota. Few of the waters from deep artesian wells contained as little as 500 parts per million of solids, which has been recommended as the maximum limit for waters suitable for drinking purposes.

The city of Paris and the water question, L. Grandeau (*Ann. Sci. Agron.*, *2. ser.*, *10* (*1905*), *I*, *No. 3*, *pp. 342–401*, *figs. 2*).—This article first appeared as a series of letters to the *Temps*, of Paris, December, 1904, to May, 1905. It discusses mainly three conditions affecting the health of Paris as dependent upon the water supply, (1) the sewage contamination of the Seine, (2) the unsanitary condition of the sewer beds and farms due to their inability to properly dispose of the sewage brought to them, and (3) the lack of means of purifying the water supply derived from brooks and streams.

Sewage disposal by spreading it on the land, including sewage irrigation, is considered inadequate and unsatisfactory, and various other methods of disposal—the bacteriological process (using septic tanks and contact beds) and the Candy process (using sprinklers and "carboferrite" filters)—are discussed as possible substitutes or supplements. Accounts are also given of studies by Calmette on the biological purification of sewage. The causes and prevention of the contamination of the Seine are considered.

The means of correcting present conditions proposed are (1) extension of the area of the sewage farms, (2) substitution of bacteriological treatment for sewage irrigation, and (3) a combination of the two. The last seems to offer many advantages. An account of the Berlin sewage farm and its successful operation is given.

SOILS—FERTILIZERS.

The availability of potash and phosphoric acid in soil, G. S. FRAPS (*North Carolina Sta. Rpt. 1904, pp. 26–47*).—This article discusses and reviews investigations relating to the "influences which act to release the plant food locked up in the soil," grouping and defining these influences under three "factors of availability," viz, (1) chemical availability, (2) physical availability, and (3) weathering availability. These should take into account "the amount of plant food which is present in forms of combination that can be taken up by the plant; the physical condition of the soil; the amount of plant food converted into assimilable forms during the period of growth of the plant; the feeding power of the plants."

A study of the changes caused by weathering and by varying conditions of moisture, organic matter, and calcium compounds in 3 typical North Carolina soils is reported. The results show that "nitric acid of 1/50 normal strength dissolved from 40 to 80 per cent as much potash as 1/5 normal nitric acid from samples (differently treated) of one soil, and from 50 to 90 per cent from another. The amount of phosphoric acid soluble in 1/5 normal nitric acid may increase or decrease in a moist soil after standing 4 months, but increases if calcium sulphate is present. An increase in the amount of potash soluble in 1/5 normal nitric acid took place in a soil kept moist 4 months, with or without the presence of calcium sulphate.

"The presence of calcium carbonate had a tendency to decrease the amount of potash dissolved. There was a difference in the behavior of the three soils, one showing a tendency to decrease in soluble potash, while the other two increased. In the same samples the quantity of potash soluble in 1/50 normal acid had decreased. The effect of moist calcium carbonate was to reduce the solubility of phosphoric acid in 1/5 normal acid as compared with dry calcium carbonate. In one soil calcium carbonate increased decidedly the amount of phosphoric acid soluble in 1/5 normal acid, and in two soils it decreased the amount. It caused a decrease in the amount of soluble potash in every case. Calcium sulphate increased the amount of phosphoric acid soluble in 1/5 normal acid, particularly in one of the soils. It caused a decrease in the solubility of potash in two cases and a decided increase in one.

"There is no contradiction in the fact here brought out that calcium salts decrease the amount of potash dissolved by 1/5 normal or 1/50 normal nitric acid, and the fact that calcium salts cause more potash to go into solution in an aqueous extract of the soil—'liberates potash.'

"The decay of organic matter (starch or sawdust) in a soil caused a decrease in the amount of phosphoric acid dissolved, but a great increase in the amount of potash, from 20 to 99 per cent with 1/5 normal acid, and from 11 to 20 per cent with 1/50 normal acid. . . .

"There was a variation in the power of soils to convert organic matter into humus and retain it. In three soils, the amount of humus gained from starch at the end of 6½ months was 0.0, 0.06, 0.18; and from sawdust 0.03, 0.14, 0.30 per cent of the ignited soil. A relatively small amount of organic matter added to soils was converted into humus. The maximum obtained in this work was 3 per cent of the starch and 4.1 per cent of the sawdust, though from 75 to 95 per cent of the starch and from 30 to 37 per cent of the sawdust disappeared during the 4 months."

On the source, amount, and importance of carbon dioxid in soil, J. STOKLASA and A. ERNEST (*Centbl. Bakt.* [*etc.*], *2. Abt., 14 (1905), No. 22–23, pp. 723–736; abs. in Chem. Ztg., 29 (1905), No. 68, Repert. No. 17, p. 249; Jour. Chem. Soc.* [*Lon-*

don], *88* (*1905*), *No. 515, II, p. 607*).—It is stated that the principal sources of carbon dioxid in the soil are micro-organisms and the roots of the higher plants.

The results of studies by means of special apparatus of the rate of production of carbon dioxid by micro-organisms and the roots of plants are reported and from them it is estimated that the organisms in 1 hectare of soil to a depth of 40 cm. produce 75 kg. of carbon dioxid per day during the 200 days a year on which the temperature reaches a mean of 15° C. Assuming that a hectare of soil bears 2,000,000 plants of a cereal, the production of carbon dioxid by their roots would, according to the results reported, be 60 kg. per hectare daily. Of the plants experimented with, red clover, beets, and oats produced the largest amounts of carbon dioxid.

It is claimed that the large amounts of carbon dioxid derived from these sources convert a notable amount of soil material into soluble forms. It is held that the solvent action of roots, especially young roots, is due to this carbon dioxid and not to organic acids, which, as Czapeck and Kohn and Kossowich have shown (E. S. R., 16, pp. 344, 1048), are not secreted by plants.

Contributions to our knowledge of the aeration of soils, F. H. KING (*Science, n. ser., 22* (*1905*), *No. 564, pp. 495–499*).—A review of Bulletin 25 of the Bureau of Soils (E. S. R., 16, p. 752), claiming that a weakness of the conclusions drawn lies in the fact that they are based upon "the mathematical treatment of a very limited series of laboratory experiments, which, however, have been executed with great care," but have not been checked by field observations and experiments. It is maintained "that rates of transpiration, as measured in the laboratory trials, are quite inapplicable for use in giving a measure of the rate of flow of air through soils under field conditions."

The influence of packing of the soil on the growth of oats, C. VON SEELHORST and KRZYMOWSKI (*Jour. Landw., 53* (*1905*), *No. 3, pp. 269–278*).—The observations recorded indicate that rolling hinders the growth of plants by interfering with transformation of nitrogen in the soil and with root breathing. The influence of rolling on the lodging of cereals is discussed.

Bare fallow, C. VON SEELHORST (*Deut. Landw. Presse, 32* (*1905*), *Nos. 71, pp. 601, 602; 72, pp. 608–610; 73, pp. 615, 616*).—A review of evidence showing, as Pfeiffer claims (E. S. R., 16, p. 858), that bare fallowing is soil robbery and is as a rule bad practice on ordinary soils (not containing an excess of organic matter).

Investigations on evaporation from cultivated soils and from uncultivated stubble soil, C. VON SEELHORST (*Jour. Landw., 53* (*1905*), *No. 3, pp. 264–268*).—Observations on large vegetation cylinders are reported which indicate that in case of heavy rainfalls more water evaporates from hoed soil than from unhoed, but that with small rainfalls the reverse is true.

Investigations on the percolation of rain water in sandy and loamy soils, C. VON SEELHORST (*Jour. Landw., 53* (*1905*), *No. 3, pp. 260–263*).—Observations on vegetation cylinders of 1¼ cubic meter content showed no great difference in the amount of evaporation on sand and medium loam soil whether fallow or stubble.

Some agricultural and geobotanical observations, S. KRAVKOV (*Zeml. Ghaz., 1904, Nos. 46, 47; abs. in Zhur. Opuitn. Agron.* (*Russ. Jour. Expt. Landw.*), *6* (*1905*), *No. 1, pp. 24–26*).—One of the observations relates to the water-soluble salts in the soil. The concentration of the soil solutions was found to vary greatly according to the weather, the properties of the soil, the relief of the locality, and other conditions. It was noted that a field apparently uniformly cultivated and with a uniform cover of living plants and plant remains showed very different amounts of substances soluble in water at points close to one another. Such fluctuations the author ascribes to differences in thickness of the plant cover, to the influence of animals, etc. During the winter the soil solution remained almost unaltered; in the spring there was in the drained soil a washing out or accumulation of dissolved substances according to the character of the weather until a sufficient plant covering grew up, when

the concentration was maintained at a certain level; in the less active, undrained soil the conditions of concentration were reversed.—P. FIREMAN.

Distribution of the population of Sweden as determined by the geological character of the soil, C. RABOT (*Géographie, 11 (1905), No. 5, pp. 359–367, figs. 6*).

The sugar-cane soils of Jamaica, III, H. H. COUSINS (*Bul. Dept. Agr. [Jamaica], 3 (1905), No. 7, pp. 137–146*).—This is a third communication on this subject (E. S. R., 15, p. 459) and reports mechanical and chemical analyses of 12 samples of soil with brief discussions of the fertilizer requirements of the different samples. The most striking characteristic common to all the soils was the deficiency of calcium carbonate. "In some cases it was not possible to detect any carbonates at all."

Geological notes on cacao soils, E. H. CUNNINGHAM-CRAIG (*Trinidad Bot. Dept., Bul. Misc. Inform., 1905, No. 47, pp. 196–200*).—The 8 principal rocks that have been observed as forming cacao-bearing soils are noted, the soils themselves are described, and suggestions are given regarding the kinds of fertilizers which should be used on the soils of different origin in the culture of cacao.

Investigations in regard to the phosphoric acid in cultivated land in Java, T. MARR (*Meded. Proefstat. Oost-Java, 4. ser., No. 4, pp. 65–87, figs. 2*).—Many Java soils present the peculiarity of producing good crops and failing to respond to applications of phosphates, although containing less total phosphoric acid than is generally considered necessary for a productive soil (0.1 per cent). The assimilable phosphoric acid was determined in some of these soils by Schloesing's method of digestion in dilute (0.01 to 0.1 per cent) nitric acid (E. S. R., 11, p. 131), and Dyer's method of digestion in citric acid (E. S. R., 5, p. 1013), using, however, 2 per cent acid. The first method showed much less available phosphoric acid (0.0017 to 0.0234 per cent) than is considered by de Sigmond (E. S. R., 12, p. 907) necessary for a productive soil, viz, 0.075 per cent. With Dyer's method, however, the available phosphoric acid was, as a rule, higher (with one exception 0.018 to 0.071 per cent) and well over the limit set by Dyer for a productive soil, viz, 0.01 per cent. There was little or no relation between the total phosphoric acid and that found by either of the above methods.

Investigations on the potash content of moor soils, P. VAGELER (*Vrtljschr. Bayer. Landw. Rat., 10 (1905), No. 2 (Ergänzungsh.), Sup. 1, pp. 125–133*). The averages of 143 analyses of cultivated Bavarian moor soils are reported showing a variation in potash content of from 0.0544 per cent to 0.089 per cent. The average amount of potash in virgin upland moor soil was 0.033 per cent. In spite of the fact that most of these soils are well supplied with potash, they are much benefited by liberal applications of potash fertilizers. The potash is apparently in very unavailable form.

The soil of the Pontine marshes, A. ORTH (*5. Internat. Kong. Angew. Chem., 1903, Ber. 3, pp. 741–745*).—Analyses of several samples of soil are reported and the character of the soils of the Roman Campagna is discussed.

On the difficulty of ascertaining the productiveness of tropical soils, A. COUTURIER (*Bul. Assoc. Chim. Sucr. et Distill., 22 (1905), pp. 1302–1304; abs. in Chem. Centbl., 1905, II, No. 11, pp. 849, 850*).—The author points out that the climatic agencies which have resulted in the formation of tropical and subtropical soils bring about a very different series of physical and chemical changes from those which take place in the soils of temperate zones. Tropical soils therefore can not be judged on the same basis as soils of temperate zones. For this reason there is great need of careful study of tropical soils.

Soil analysis and the value of the results in the fertilizing of vineyards, A. HUBERT (*Monit. Sci., 4. ser., 19 (1905), II, pp. 582–588; abs. in Chem. Centbl., 1905, II, No. 9, p. 695*).—Descriptions are given of the methods used, which were in the main the official methods of the committee of French agricultural experiment stations. Directions for fertilizing based upon analyses of various vineyard soils are

given and the value of chemical analyses in determining the fertilizer requirements of soils pointed out.

A new method of mechanical soil analysis, A. SABANIN (*5. Internat. Kong. Angew. Chem., 1903, Ber. 3, pp. 896–898*).—A method involving the use of small amounts of soil (3.75 to 4 gm.) and based upon boiling in a small Erlenmeyer flask, passing through sieves, and allowing to settle in cylinders, is briefly described.

The bacteriological examination of cultivated soils, T. REMY (*5. Internat. Kong. Angew. Chem., 1903, Ber. 3, pp. 784–794*).—Comparative studies of the behavior of different soil organisms under varying conditions are reported.

Soil inoculation (*Jour. Bd. Agr. [London], 11 (1905), No. 11, pp. 669–673*).—In a previous publication (E. S. R., 16, p. 541) an account was given of experiments with the improved Nitragin for the inoculation of leguminous crops. In the present report a description is given of the methods of application and a comparison is drawn between this improved inoculating material and that distributed by this Department.

As formerly, the Nitragin is prepared for special crops, cultures being now available for beans, clovers of various kinds, alfalfa, vetches, etc. The cultures are distributed in glass tubes and must be protected from heat and too much light. The contents of the tubes are to be turned out into water, or better still, fresh milk, and nutrient substances, said to be peptone and grape sugar, are dissolved in the solution before adding the culture. The seeds to be inoculated are wet with the solution and sown at once, care being taken to prevent their drying. Nitragin differs from the material prepared by this Department in that it must be prevented from drying, while the inoculating material of this Department is sent out in a dry condition and may be allowed to dry on the seed. The other methods of handling are quite similar for the two substances.

Contribution to the knowledge of nitrogen bacteria, F. LÖHNIS (*Centbl. Bakt. [etc.], 2. Abt., 14 (1905), Nos. 18–20, pp. 582–604; 22–23, pp. 713–723; abs. in Jour. Chem. Soc. [London], 88 (1905), No. 515, II, pp. 601, 602*).—This is a review of the investigations by the author during several years past, as well as of similar studies by other investigators on nitrogen-fixing bacteria, bacteria which assimilate nitrates, and urea bacteria.

The principal organisms in these 3 classes are described, and it is shown that the various nitrogen-fixing bacteria (*Bacterium pneumoniæ, B. lactis viscosum, B. radiobacter, B. radicicola, B. prodigiosum,* and *B. turcosum*) also assimilated nitrates, but to different extents. *B. agreste* did not fix nitrogen but assimilated nitrates vigorously, while *B. fluorescens* decomposed nitrates chiefly by denitrification. In cultures inoculated with soil urea was rapidly converted into ammonium carbonate, probably by the action of *Urobacillus pasteurii*, but attempts to isolate this micro-organism were unsuccessful.

The characteristics and behavior in cultures of *Bacillus freudenreichii* are described. This organism showed but small capacity for transforming urea into ammoniacal compounds.

On the value of some new nitrogenous fertilizers, H. G. SÖDERBAUM (*Meddel. K. Landtbr. Akad. Exptlfält. [Stockholm], No. 85, pp. 27*).—The author discusses a number of new methods of utilizing the nitrogen of the air for agricultural purposes, and gives an account of pot and field experiments with 2 new fertilizers at the experiment station at Albano, Sweden, viz., with calcium cyanamid and calcium nitrate.

The former fertilizer produced an increase in the yield of white mustard of 52.9 per cent of that of an equivalent amount of nitrogen in nitrate of soda. In experiments with oats in vessels buried in the ground, the yield obtained with calcium cyanamid was to that obtained with nitrate of soda as 76:100. The increase in the straw was, however, relatively larger than in grain.

Pot experiments with oats showed that calcium cyanamid produced yields of grain from 86.1 to 102.7 per cent of those obtained with similar amounts of nitric nitrogen, the total increase in the yields of grain and straw ranging from 86.1 to 98.3 per cent. Ammonium sulphate in the same series of trials produced an increase of 95.9 to 101.7 per cent in the total crop, and of 98.9 to 102.7 per cent in the yield of grain, the yields obtained with equivalent amounts of nitrate of soda being placed at 100. Similar results were obtained in field experiments with oats.

When applications of calcium cyanamid containing 150 kg. of nitrogen per hectare (134 lbs. per acre) were made directly before sowing, a decided poisonous effect was produced in the case of mustard, while similar applications added 11 days before sowing oats produced no symptons of poisoning whatever. Pure calcium nitrate produced approximately the same increase in the yield of oats as equivalent amounts of nitrate of soda when grown in pots or in plat experiments.

The effect of the presence of nitrites in calcium nitrate was studied in a series of experiments with oats, nitrate containing different quantities of nitrite, viz, from 1 to 20 per cent, being applied. It was found that such impure nitrate produced fully as good, if not better, results than nitrates free from nitrites, the increase in yields of total crop on the former fertilization ranging from 113 to 120 per cent of those obtained on the latter fertilization, and in yield of grain from 108 to 113 per cent. A bibliography of the subject is given at the end of the report.—F. W. WOLL.

Preservation and action of the nitrogen of urine, E. BÖHME (*Illus. Landw. Ztg., 24 (1904), Nos. 87, pp. 1001, 1002, figs. 3; 88, p. 1011, figs. 7; 89, pp. 1023–1025, figs. 5; abs. in Centbl. Agr. Chem., 34 (1905), No. 5, pp. 300–305; Jour. Chem. Soc. [London], 88 (1905), No. 513, II, p. 477*).—In the experiments reported gypsum, used at the rate of 10 per cent, reduced the loss of nitrogen to 7 per cent in 250 days, untreated urine losing 56 per cent of its nitrogen in that time. Sulphuric acid (1 per cent) reduced the loss to 5.5 per cent, while 2 per cent of sulphuric acid retained all of the nitrogen.

Addition of lime and gypsum increased the action of the urine when used as a fertilizer. Urine treated with these substances and with sulphuric acid gave better results when applied before seeding than as a top-dressing. The nitrogen of the urine was almost equal in effect to that of sodium nitrate.

Ammoniacal nitrogen as a plant food, GERLACH and VOGEL (*Centbl. Bakt. [etc.], 2. Abt., 14 (1905), No. 3–4, pp. 124–128, figs. 2; abs. in Chem. Centbl., 1905, I, No. 24, p. 1609*).—Parallel experiments were carried out in sterilized soil in pots of special construction to test the comparative effect of ammoniacal nitrogen (ammonium sulphate) and nitric nitrogen (sodium nitrate) on the corn plant.

Notwithstanding the fact that no nitrous or nitric organisms were present and no nitrites or nitrates were formed in the soils to which ammonium sulphate was added, the yields of dry matter and the nitrogen content of both the above ground and below ground parts of the plants were markedly increased. The yields of dry matter and nitrogen content per pot were, respectively, 55.42 and 0.189 gm. without application of nitrogen; 80.88 and 0.445 gm. with sodium nitrate; and 72.54 and 0.387 gm. with ammonium sulphate. These results indicate that the maize plant can take up and use the nitrogen of ammonium sulphate without nitrification.

Ammonium salts or nitrate of soda, CLAUSEN (*Deut. Landw. Presse, 32 (1905), No. 72, pp. 611, 612*).—An account is here given of experiments during 1904 with oats on a moderately loamy sandy soil to determine the relative effect of ammonium salts and nitrate of soda on dry and moist soils, one series of plats receiving only the natural rainfall, another being kept moist by irrigation until 3 leaves had appeared, and a third kept moist until the time of harvest.

The nitrate of soda gave the best results on the unirrigated soil, but was less effective than the ammonium salts in the other 2 cases. The lower efficiency of the nitrate, however, was apparently not due to washing of nitrates into the drainage,

since the plat receiving the larger amount of water gave a larger yield with nitrate of soda than that receiving the smaller amount.

Nitrate by-product, AUMANN (*Abs. in Centbl. Agr. Chem., 33 (1904), No. 12, p. 852*).—A product obtained by the evaporation of water from the holds of ships carrying nitrate of soda is found on the market under the name of nitrate by-product. It consists largely of common salt, but contains small amounts of potash and 3 to 4 per cent of nitrogen corresponding to 18.2 to 24.3 per cent of nitrate of soda. Attention is called to a spurious article, consisting almost entirely of salt, which is being sold under the same name.

Calcium nitrate in agriculture, E. S. BELLENOUX (*Compt. Rend. Acad. Sci. [Paris], 140 (1905), No. 18, p. 1190; abs. in Jour. Chem. Soc. [London], 88 (1905), No. 513, II, p. 478*).—Comparative tests of sodium and calcium nitrates on potatoes and sugar beets are reported which show an increase of 1.8 per cent of starch in the potatoes and 1.37 per cent of sugar in the beets in favor of the plats fertilized with calcium nitrate as the average of several years' experiments. The calcium nitrate is prepared by the action of sodium nitrate on calcium chlorid, the sodium chlorid separating out on concentration.

On some constituents of Manchester soot, E. KNECHT (*Mem. and Proc. Manchester Lit. and Phil. Soc., 49 (1905), pt. 3, No. 14, pp. 10; Chem. News, 91 (1905), No. 2376, pp. 259–261*).—A detailed study is reported from which the following averages are estimated: Ammonium sulphate 10.7, ash 19.6, acid constituents 10.9, and hydrocarbons (benzene extract) 13 per cent.

The Tunisian phosphates, L. PERVINQUIÈRE (*Rev. Sci. [Paris], 5. ser., 4 (1905), No. 12, pp. 353–361, figs. 3*).—An account is given of the discovery, character, and exploitation of these phosphates, especially the very rich deposits of Gafsa. Analyses reported show these phosphates to contain from 60 to 66 per cent of tricalcium phosphate, 10 to 15 per cent of calcium carbonate, and 1.25 to 2.50 per cent of alumina and iron oxid.

On the action of organic acids on phosphates, A. QUARTAROLI (*Staz. Sper. Agr. Ital., 38 (1905), No. 1–2, pp. 83–113; abs. in Jour. Chem. Soc. [London], 88 (1905), No. 514, II, p. 549*).—A series of studies is reported which leads to the conclusion that the organic acids which usually occur in plants first render insoluble phosphates soluble and then convert them into dihydrogen phosphates. Any free phosphoric acid which may be produced is converted in the plants into a dihydrogen salt. This is explained by the lower acidity of organic acids as compared with phosphoric acid and by their greater affinity as compared with acid phosphates.

Potash for mangolds and potatoes on moor soils, H. VON FEILITZEN (*Svenska Mosskulturför. Tidskr., 19 (1905), No. 2, pp. 91–100, pls. 4, fig. 1*).—The author conducted experiments with mangolds and potatoes in vegetation vessels placed in ground of 1 square meter surface area.

The most economical results in fertilization of these crops with potash on moor soils were obtained by applying the high-grade salts. It was found, and is plainly shown by lithographic reproductions of the crops grown under different systems of fertilization, that abnormal changes in the vegetative parts of these crops appeared whenever the soil was in marked need of potash.—F. W. WOLL.

Fertilizer experiments with lime, M. HOFFMANN (*Arb. Deut. Landw. Gesell., 1905, No. 106, pp. XIV+276, figs. 2*).—This article discusses the chemistry of lime and reports in detail a series of experiments made from 1899 to 1903 on 150 farms in 17 different regions of the German Empire under the auspices of the fertilizer section of the German Agricultural Society, cooperating with local societies or experiment stations.

Of the 150 experiments undertaken only 79 were properly carried out according to the five-year plan which included one crop of legumes and 2 of potatoes, but excluded bare fallow.

In the majority of cases applications of lime were beneficial. On light soil poor in humus and in dry seasons, however, the carbonates proved preferable to the more caustic quick lime. Practical deductions regarding methods of application of different forms of lime are drawn.

The injurious effect of gypsum in vegetation experiments in zinc pots, D. Meyer (*Fühling's Landw. Ztg., 54 (1905), No. 8, pp. 261–267*).—Previous experiments having shown that applications of gypsum resulted in a decrease in yield in the case of certain crops grown in zinc pots on a soil composed of sand and 2½ per cent of peat, further experiments were undertaken to determine the cause and extent of this action, as well as the behavior of different crops grown under such conditions.

Parallel experiments in zinc pots and in earthenware pots showed that the yields were uniformly larger in the latter, but that different plants vary widely when grown under the same conditions. The decline in yield following applications of gypsum in zinc pots was especially marked in the case of leguminous plants. The injurious effect of the gypsum was overcome by applying with it a certain amount of calcium or magnesium carbonate, and was not observed when the artificial soil mixture was made up of sand and 10 per cent of ordinary field soil.

Further experiments are considered necessary to determine the exact cause of the injurious effect of the gypsum and the behavior of different crops toward this substance under varying conditions.

On the injurious action of gypsum in vegetation experiments in zinc pots, B. Tacke (*Fühling's Landw. Ztg., 54 (1905), No. 10, pp. 331, 332*).—A brief note on Meyer's article referred to above.

The author calls attention to the earlier work of Fleischer [a] and Tacke and Immendorff [b] with gypsum on acid upland moor soils, which indicated that the injurious effect of gypsum observed, especially in the case of leguminous plants, was due to the setting free of acids to which such plants are especially sensitive. A similar explanation is offered for Meyer's results, the injurious effect of the gypsum being heightened in the case of the zinc pots by the action of the zinc dissolved by the free acids, [c] as indicated by the author's experiments on acid moor soils.

Some of the more recent investigations on the use of commercial fertilizers, Rippert (*Fühling's Landw. Ztg., 54 (1905), No 18, pp. 608–620*).—A review of investigations relating especially to the comparative fertilizing value of nitrogen in form of ammonia and nitrate and of different forms of phosphates and potash salts.

It is pointed out that in judging of the efficiency of a given fertilizer account must be taken of a number of different factors, including geographical position, climate, amount of precipitation, geological character of the soil, chemical and physical properties, depth of the surface soil, as well as the character of the subsoil.

The investigations discussed include experiments by Kruger, Klöpfer, and Schneidewind on the comparative fertilizing value of ammonium salts and nitrates used alone or in mixture with peat or soil and applied as top dressing or mixed with the soil (E. S. R., 15, p. 130; 16, p. 554); experiments at Lauchstädt on the use of phosphoric acid in connection with manure of various kinds, and on the relative value of Wolters phosphate, superphosphate, and Thomas slag (E. S. R., 16, p. 654); and experiments by Schneidewind, Meyer, and Wagner on the comparative value of potassium sulphate, potassium chlorid, 40 per cent potash salt, and kainit, as well as on the influence of the associated salts in potash fertilizers (E. S. R., 16, pp. 660, 760, 861).

Analyses and valuations of commercial fertilizers, J. P. Street, W. P. Allen, and V. J. Carberry (*New Jersey Stas. Bul. 187, pp. 21*).—Analyses of 232 samples of

[a] Landw. Jahrb., 1891, p. 607.

[b] Mitt. Förd. Moorkultur, 1899, p. 175.

[c] Landw. Jahrb., 27 (1898), Ergänzungsh., IV, p. 259 (E. S. R., 10, p. 941).

fertilizers, representing 96 manufacturers, are reported with a schedule of trade values of fertilizing materials for 1905.

Analyses of commercial fertilizers, H. J. WHEELER ET AL. (*Rhode Island Sta. Bul. 108, pp. 12*).—"This bulletin contains the results of such analyses of bone, tankage, and of ready-mixed potato fertilizers as have been found on sale in Rhode Island during the spring of 1905."

Analyses of commercial fertilizers (*South Carolina Sta. Buls. 110, 111, 112, 113, pp. 4 each*).—Tabulated analyses of 160 fertilizers.

Fertilizer analyses, fall season, 1904, to spring season, 1905, B. W. KILGORE (*Bul. N. C. Bd. Agr., 26 (1905), No. 7, pp. 77*).—The names and guaranteed composition of fertilizers registered for 1905, and analyses and valuations of 679 samples of commercial fertilizers and 108 samples of cotton-seed meal, examined during the fall of 1904 and spring of 1905, with explanations regarding terms used in fertilizer analyses, freight rates, valuation, etc.

Mineral products of the United States, calendar years 1895 to 1904, D. T. DAY (*U. S. Geol. Survey, 1905, Aug., folio*).—The quantity and value of the different products during the years named are given. Among the products of special interest from an agricultural standpoint are gypsum, of which 940,917 short tons, worth $2,784,325, were produced in 1904; marl, 25,000 short tons, worth $20,000; and phosphate rock, 1,874,428 long tons, worth $6,873,625.

Working in Great Britain of the fertilizers and feeding stuffs act, 1893 (*Minutes of Evidence before Dept. Com. Bd. Agr. and Fisheries [London], 1903, pp. III+236*).—A detailed report of evidence, a summary of which was noted in E. S. R., 16, p. 961.

AGRICULTURAL BOTANY.

Report of the botanist, J. W. BLANKINSHIP (*Montana Sta. Rpt. 1904, pp. 219–224*).—An account is given of the various lines of investigation carried on by the author during the period covered by this report. A considerable portion of his time was given up to the study and determination of the botanical collections that have been made, and some work was done in collecting, naming, and mounting parasitic plant disease material, with the hope of getting together sufficient material for a publication on the parasitic diseases of the State.

A brief account is given of a disease of cottonwoods which seems to be of an infectious nature and which attacks the different species of cottonwood growing in a number of the largest cities of the State. The same species in the wild state do not seem to be affected. The principal symptom of disease is the yellowing of the foliage accompanied by bleeding from the limbs and trunks, and when cut the wood shows a diseased condition of the tissues extending downward from the points where the bleeding takes place. The author suggests the name "cottonwood yellows" for this disease, and its diagnosis and treatment are to be the subject of further investigation.

In cooperation with the horticulturist, collections have been made of a number of plants to test their adaptability for ornamental cultivation. Notes are also given on a number of introduced plants that threaten to become troublesome as weeds, etc.

The physiological effects of Bordeaux mixture, R. SCHANDER (*Landw. Jahrb., 33 (1904), No. 4–5, pp. 517–584; abs. in Jour. Bd. Agr. [London], 12 (1905), No. 7, pp. 413–416*).—After discussing the effect of copper on plants and the use of Bordeaux mixture as a fungicide, the author gives an account of an extended series of experiments to test the effect of Bordeaux mixture upon the host plant, wholly aside from its action as a fungicide.

The various theories regarding the supposed stimulating effect of Bordeaux mixture are reviewed, and the author rejects the idea of a stimulating effect acting through

the epidermis of the leaves, stating that wherever the copper penetrates the cuticle it acts injuriously upon the protoplasm of the leaf cells. The copper left in the soil as a result of repeated sprayings can not be other than injurious to the plant, especially if present in appreciable quantity.

The beneficial action of this fungicide is attributed to a number of factors, the principal of which are the action of the lime, the repression of many insects by spraying, and the influence of a thin coating of copper on the assimilation and transpiration of the plant. The latter of these factors is believed to be the most important, and to it much space is given. The author considers that the thin coating of copper hydrate on the leaves protects the chlorophyll against the injurious action of too intense light and diminishes the transpiration of the leaves. No chemical action takes place, the beneficial results being due solely to the physical action of the thin layer of copper in reducing the intensity of light. As a practical application of this theory, it is suggested that the strength of Bordeaux mixture might be regulated to suit the character of the season, exposure, etc.

Attention is called to the occasional injury to foliage and fruit from the use of Bordeaux mixture. This seems due in many instances to the use of too little lime in making the fungicide, but similar results have been observed when there was an excess of lime used. The amount of injury seems to vary for different plants, and it is influenced by different climatic conditions. In general the excess of lime seems to check the injurious effects of copper sulphate, but in the case of apples and peaches it is not wholly able to prevent it, and in addition a superabundance of lime very greatly reduces the adhesiveness of the fungicide. The excess of lime is also associated with a reduction in the amount of copper hydrate, and, as a consequence, its fungicidal action is diminished.

The author inclines to the belief that in practice it will be found best to use equal weights of lime and copper sulphate. There appears to be no reason for not following this proportion in spraying grapes, apples, pears, and potatoes. For spraying peaches 2 parts of lime to 1 part of copper sulphate should be employed, and the number of applications should be as limited as possible, sprayings never being made during rainy or cloudy weather.

Notes on water transfer in plants, H. H. DIXON (*Sci. Proc. Roy. Dublin Soc., n. ser., 11 (1905), No. 2, pp. 7-12*).—In considering the possibility of the participation of living cells of the stem of a plant in the elevation of the transpiration current, the author has reviewed the experiments of Ursprung, who concluded that the cells assist by directly elevating the water or partially supporting a hydrostatic head, and by keeping the vessels and tracheids in a condition suitable for transmitting water. The author carried on experiments with living stems and attached leaves, and he gives quite a different interpretation of the results obtained.

When portions of the stem were killed by heat the leaves beyond wilted, indicating that the cells of the stem exercised no especial function in the elevation of water. Where only very short portions of the stem were killed little injury appeared, but when 2 to 5 cm. of the stem was killed the leaves showed injury in proportion to the length of stem destroyed. This injury had a progressive effect, which is attributed to the introduction into the leaves of poisonous or plasmolyzing substances from the dead cells. This action was repeatedly shown by immersing freshly cut stems in decoctions made by boiling stems of the same kind and cooling the fluid. As compared with stems immersed in fresh water, wilting took place much earlier with those immersed in the decoctions.

In order to show that this effect was not due to clogging, the bottom of the immersed stems was cut off at frequent intervals, and the injurious properties of the decoctions were retained after repeated filterings. Some slight injury may have been due to clogging of the water-conducting tissues of the plant by comparatively impermeable substances, but the filtering would have removed most of these. It is

possible that the application of heat in these experiments may to some extent have permanently interrupted the water supply by breaking the water columns, on the continuity of which the water supply of the aerial portions depends.

On the movements of petals, Esther P. Hensel (*Univ.* [*Nebr.*] *Studies, 5* (*1905*), *No. 8, pp. 38*).—A report is given of an investigation of the physical causes which bring about the opening and closing movements of certain flowers. In this investigation experiments were carried on with the dandelion, four o'clock, morning glory, evening star, evening primrose, and flax, and observations made upon a large number of other flowering plants.

It is shown that the opening of the dandelion flowers can be controlled by keeping the flowers at a lower temperature than normal, and when the opening has been retarded they can be caused to open by the application of either dry or moist heat. It was found possible to close any ephemeral flower before its time by an extra amount of heat, either moist or dry. It is impossible to open an ephemeral flower by placing the plant in a lower temperature, since this checks growth, and opening with this type is a matter of growth rather than one of stimulus.

In the study of the different plants, light, humidity, and water content of the soil were eliminated as possible physical factors, and it was found that heat, by its variations during 24 hours, is the direct cause of movement in those types of flowers that bloom for more than one day. The closing of ephemeral flowers can be delayed several hours by a temperature which is constantly lower than normal. The cause of the periodic movements of flowers lasting more than a single day is attributed to the influence of variations of temperature, acting not through turgescence, but by stimulation of the protoplasm.

A preliminary report on the Hymeniales of Connecticut, E. A. White (*Conn. State Geol. and Nat. Hist. Survey Bul. 3, pp. 81, pls. 40*).—The author gives a list, together with descriptive and critical notes, of the fleshy and woody fungi known to occur within the State of Connecticut. The aim has been to compile as far as possible a complete and accurate list of native species rather than to prepare original keys, technical descriptions of species, etc.

Notes on amanitas, W. A. Kellerman (*Mycol. Bul., 3* (*1905*), *Nos. 41, pp. 161–164, figs. 3; 42, pp. 165–168, figs. 3*).—Illustrated notes, technical descriptions, and general accounts are given of a number of species of Amanita, of which *A. verna* and *A. solitaria* are figured and described. Both of these species are said to be highly poisonous.

A yellow race of Bacillus pseudarabinus from the quince, R. G. Smith (*Proc. Linn. Soc. N. S. Wales, 29* (*1904*), *pt. 4, pp. 860–862*).—While making a study of the bacterial flora of some branches of quince a number of species were collected, one of which appeared in great abundance and was made the subject of considerable investigation

The general morphology of the organism seemed to indicate that it was closely related to *Bacillus pseudarabinus*, except that the bacterium from the sugar cane was always white while that from the quince was yellow, varying from a pale buff on gelatin to a deep yellow on potato. Further study convinced the author that there are no specific differences in the organisms but that they are white and yellow races of the same species.

The bacterial origin of Macrozamia gum, R. G. Smith (*Proc. Linn. Soc. N. S. Wales, 29* (*1904*), *pt. 4, pp. 863–868*).—In continuation of his investigations on the bacterial origin of certain gums, the author reports the isolation from *Macrozamia spiralis* of a species of bacillus to which the name *B. macrozamiæ* is given. The morphology of the organism and the characteristics of the gum it forms are described.

FIELD CROPS.

Variety tests of grains, A. ATKINSON (*Montana Sta. Rpt. 1904, pp. 210–217*).—The average results obtained at the station with 23 varieties of spring wheat, 16 of barley, and 14 of oats grown on one-sixtieth acre plats from 1900 to 1904, inclusive, are given in tables.

Nineteen varieties of wheat gave an average yield of 50 bu. or more per acre, the 5 leading varieties and their yields being as follows: Kubanka, 59.9; Glyndon 692, 59; Glyndon 650, 58.7; Glyndon 715, 56.8; and Russian 2955, 56.3 bu. per acre. Wild Goose ranked first with an average weight of 62.4 lbs. per bushel. The latest varieties, Glyndon 768, Boulton blue stem, and Red fife, required 127 days to mature, and Bart Tremenia and Pringle Champion, the earliest sorts, 120 days.

New Zealand, a 2-rowed barley, gave uniformly good results during the 5 years and ranked first with a yield of 82.5 bu. per acre. Berkeley, a 2-rowed beardless variety, stood last in yield with an average of 46 bu. per acre, and also in weight per bushel with 51.4 lbs. Guy Mayle, a hulless variety, gave an average weight of 64.6 lbs. per bushel, standing first in this regard. No. 5590, obtained from this Department, gave the second largest yield, averaging 77.7 bu. for 4 years, and Mandscheuri, California Prolific, Italian, Manhattan, and Improved Cheyenne produced over 70 bu. for the 5 years.

Fourteen varieties of oats ranged in average yields from 101 to 123.5 bu. per acre, with Progress, Wide Awake, and Improved American as the leading sorts. Swedish Select, not included in this test, produced 133.4 bu. per acre in 1904. Victoria stood last in productiveness but ranked first in weight per bushel with 42.8 lbs., and in earliness, with a growing period of 110 days. The latest varieties, American White and Bland White, required 122 days to ripen. All varieties weighed over 39 lbs. per bushel.

The yields of the different field crops grown on the station farm are recorded and a brief description of cooperative tests is given. In 1902 tests were carried on by 50 farmers in 16 counties; in 1903, by 204 in 21 counties; and in 1904, by 84 in different parts of the State.

Summary of press bulletins [on field crops] (*Oklahoma Sta. Rpt. 1905, pp. 32–41, 42–49*).—Previously published articles on the culture of spelt, cowpeas, corn, and cotton are reprinted. Spring-sown spelt produced at the station 9.8 bu. of grain per acre and 0.68 ton of straw, and a fall-sown crop, 6.9 bu. of grain and 0.82 ton of straw. Spelt has not given promise of furnishing pasture during fall and winter.

Field crops at Wagga Experimental Farm, G. M. McKEOWN (*Agr. Gaz. N. S. Wales, 16 (1905), No. 4, pp. 337, 338*).—Among 24 varieties of wheat Federation stood first with a yield of 22 bu. 15 lbs. per acre. Of different quantities of seed per acre, 40 lbs. gave the highest yields. Drilling proved more satisfactory than broadcasting.

The improvement of poor pastures, T. H. MIDDLETON (*Jour. Agr. Sci., 1 (1905), No. 1, pp. 122–145*).—The results for 2, 3, and 8 years of 6 experiments in manuring poor pastures are described. On a light soil potash produced but little effect, and on heavy soils phosphatic fertilizers gave highly profitable returns. In the first years the use of other fertilizers was not justified by the results, but where the work was carried on for 8 years lime was profitable after the first 3 years and potash the last 2 years. Nitrogenous fertilizers were but little effective. Phosphatic fertilizers promoted the growth of *Trifolium repens*, *T. minus*, and *Medicago lupulina*. These plants improved the soil and increased the stand of grasses. Lime favored the increase of grasses in the herbage. The first few years the available potash of the clay soil was apparently sufficient for the leguminous plants, but later the use of potash fertilizers on ordinary poor pastures became necessary. Basic slag, owing to its content of

phosphoric acid and lime, is considered useful in beginning the improvement of poor clay pastures. Specific directions for the treatment of poor pasture lands and the considerations upon which they are based are given.

Fertilizer experiments with Jerusalem artichokes, H. BLIN (*Jour. Agr. Prat., n. ser., 9 (1905), No. 17, pp. 548, 549*).—The culture of Jerusalem artichokes is discussed and the results of fertilizer experiments are reported.

An application of 15,000 kg. of barnyard manure, 300 kg. of superphosphate, and 200 kg. of muriate of potash per hectare, spread over the entire surface of the field, gave a yield of 38,323 kg. as compared with 30,556 kg. where manure alone was used, and 31,879 kg. where manure and superphosphate were applied together. When applied in the drill the application of manure and superphosphate resulted in a yield of 33,423 kg., and the complete application in a yield of 42,213 kg.

From these results it is concluded that potash is the dominating element in the culture of Jerusalem artichokes, and that applying the fertilizer in the drill gives better results than applying it broadcast, because a larger amount of potash is made immediately available to the plants.

Remarks on the "popping" of Indian corn, F. H. STORER (*Bul. Bussey Inst., 3 (1904), pt. 4, pp. 74-79*).—Experiments are reported to disprove that the popping of pop corn is due to the oil in the grain, and to determine whether popped corn contains any more soluble starch or other form of dextrin than the original grain.

Whole grains were leached with ether until the oil was removed and were then dried slowly in the air. When these grains had become thoroughly dry they popped upon being heated, although they contained no oil. The experiment also indicated that perfect dryness in the kernel is required for the best success in popping. Samples of popped corn grounds dried at 100° C. contained 19.30 per cent of matter soluble in water, and unpopped corn treated the same way yielded 21.12 per cent. Only mere traces of matters capable of reducing cupric oxid were determined in both kinds of samples, with, perhaps, the larger trace in the sample from the unpopped corn.

Samples of meal from popped corn dried at 95 to 100° C. contained 7.45 per cent of moisture, and meal from unpopped corn 12.13 per cent. It did not appear that any soluble starch is formed during the act of popping. A test in preparing soluble starch from popped and unpopped corn left the impression that rather more soluble starch was secured from the unpopped than from the popped sample.

Studies on the property of popping by several investigators are reviewed, and other experiments in this line by the author are described. He found that the removal of the outer skins of rice pop-corn kernels prevented popping, and this was the case whether the kernels had first been soaked in ether for 3 or 4 days and dried, or not. Of whole kernels cut in two crosswise of their length only the outer halves, or those farthest from the cob, popped when heated; and the same result was obtained after soaking in ether for 5 days and drying for 1 or 2 hours at 100° C. But when the kernels were cut in two lengthwise both parts popped readily in some trials. When the kernels were divided into quarters the parts lying near the cob did not pop, while in some of the outer portions the property was not destroyed.

"It is plain from the foregoing trials that the skin of the grain exerts a very decided influence on the act of popping. It would appear, indeed, that both the structure of the individual starch grains in the kernel and the toughness of the restraining skin which envelopes them all, act to control or modify the manner in which the moisture in the starch grains when suddenly heated is converted into steam of such high tension that the explosive act of popping results, whereby both the skin of the seed itself and the envelopes of most of the starch grains in the seed are ruptured."

Cotton growing on sandy upland soils, G. W. CARVER (*Alabama Tuskegee Sta. Bul. 7, pp. 11, figs. 2*).—Former work in this line has been previously noted (E. S.

R., 17, p. 16). These experiments were made on a light sandy soil, which produced cowpeas in 1903. The cowpea stubble was plowed under, the land treated with 100 lbs. each of acid phosphate and muriate of potash mixed with 10 tons of barnyard manure and swamp muck per acre, and wheat, oats, rye, vetch, and other crops grown for grazing. These crops were pastured and later turned under. Before the cotton was planted the land was again fertilized, as has just been described. The following yields per acre were secured:

Variety and soil test with cotton.

Variety.	Seed cotton.	Lint.	Seed.	Lint at 10 cts. per lb.	Seed at 70 cts. per 100 lbs.
	Pounds.	*Pounds.*	*Pounds.*		
King	1,290	450	840	$45	$5.88
Russell Big Boll	1,340	470	870	47	6.09
Willet Red Leaf	1,290	400	890	40	6.23
Berry Big Boll	1,600	520	1,080	52	7.56
Peterkin	750	280	470	28	3.29
Crossland	1,250	480	770	48	5.39
Culpepper	1,100	390	710	39	4.97
Excelsior Prolific	1,240	420	820	42	5.74
Mixed seed	970	350	620	35	4.34

Brief notes are given on each variety and on the slight disease attack observed in the experiment. The value of clean culture was brought out in a trial in which different amounts of cultivation were given.

The commercial cotton crop of 1903–4, J. L. WATKINS (*U. S. Dept. Agr., Bur. Statis. Bul. 34, pp. 101*).—Statistics for the commercial cotton crops for 5 years, 1899–1900 to 1903–4, are summarized.

The distribution of the crop from the different States and Territories for every year of the period is shown and the number of bales shipped in the different States from the various railway stations is recorded. The distribution of the Sea Island cotton of the crop of 1903–4 is also given, together with miscellaneous statistics for a series of years bearing on the acreage, yields, prices, and values of the crops; exports and imports; the cotton-spinning industry; and the cost of picking. The world's consumption and production of cotton is shown in tables and briefly discussed, and the imports and exports are given for different foreign countries.

The commercial crop of 1903–4 was greater than the crop of 1899–1900 by over 900,000 bales, but smaller than any other crop since that season. During the last 5 years the crop in Arkansas showed an extreme fluctuation of 336,728 bales; in Georgia, 326,619; in Mississippi, 379,264; and in Texas, 1,088,094. In Alabama and the Carolinas the output has been comparatively steady, while, with the exception of the unfavorable season of 1903–4, the crop in Indian Territory, Louisiana, and Oklahoma has steadily increased. In 4 years the increase in Indian Territory was 234,836 bales; in Louisiana, 194,680, and in Oklahoma, 111,447 bales. The average commercial movement from the cotton States and Territories for the 5-year period was approximately 10,200,000 bales, as compared with an average of 9,657,000 bales the previous 5 years.

This bulletin is the last in the series dealing with the commercial movement of cotton issued by the Bureau of Statistics of this Department, this line of work having been transferred to the Bureau of the Census.

The color of hemp seed, C. FRUWIRTH (*Fühling's Landw. Ztg., 54 (1905), No. 10, pp. 325–330*).—The results of investigations show that of light gray and light and dark-grayish brown fruits of hemp, those light gray in color were lowest in weight and germination. The color of the fruit was transmitted to the larger proportion of the fruits of the progeny, and it was observed that in the same plant the fruits were quite uniform in color and shape.

Potato culture, A. J. McClatchie (*Arizona Sta. Bul. 51, pp. 541–545*).—General directions for growing potatoes in Arizona are given.

In the Salt River Valley the most favorable time for planting is the early part of February. At Yuma planting is done a little earlier, and in the Upper Gila a little later. The tubers usually reach their full size early in June. Fall crops planted late in August and early in September produce tubers during November, but do not reach full maturity. Burpee proved to be the most desirable variety for planting at the station, and Early Rose and Triumph also gave good results.

Sugar-beet culture, A. J. McClatchie (*Arizona Sta. Bul. 51, pp. 533–536, fig. 1*).—Directions for growing sugar beets, based on experiments conducted by the station during the past 6 years and previously noted (E. S. R., 13, pp. 342, 641), are given.

In the experience of the station the seed may be planted either during the latter part of September and the early part of October, or from the latter part of January to the middle of March. Fall planting requires irrigation every 10 days until December, and usually 2 heavy applications of water in February, while winter-planted beets are irrigated from April to June, the total quantity of water varying from 1.5 to 3 acre-feet. Beets planted in the fall mature late in March and then readily produce seed stalks. The winter plantings are ready for harvesting in July. After they have reached their maximum size they begin to lose in sugar and purity and soon decay.

In experiments conducted for 4 years in the Salt River Valley the yields ranged from 5 to 18 tons of beets per acre, averaging 9.7 tons for fall planting and 11.5 tons for winter planting. The sugar content in fall and winter-planted crops averaged 13.1 and 14.8 per cent, respectively. The cost of growing beets in this locality is estimated at from $30 to $40 per acre.

The influence of environment upon the composition of the sugar beet, 1903, H. W. Wiley (*U. S. Dept. Agr., Bur. Chem. Bul. 95, pp. 39, charts 3*).—The cooperative work here reported was conducted as previously described (E. S. R., 15, p. 670).

The season's work at each station is discussed in detail, and data descriptive of the soils, including the chemical analyses of both soil and subsoil, are given. The data for the season are summarized in the following tables:

Average results with Kleinwanzlebener sugar beets, 1903.

Locality.	Yield per acre.	Average weight of beets.	Analytical data.		Meteorological data: May to October.		
			Sugar in the beet.	Coefficient of purity.	Temperature.	Precipitation.	Sunshine.

Laramie, Wyo		.73	.910	.10
Fort Collins, Colo	21.3	.67	.144	.15

The soil data represent the averages of figures for soil and subsoil. The geodetic data, except for Laramie, Wyo., and Union, Oreg., have been previously given. The altitude of Laramie is 7,130.5 and that of Union 2,689.6 ft.

The results again indicate that the content of sugar rises as the latitude increases. An intimate relation between the percentage of sugar in the beet and the length of day is also indicated. The figures likewise show that, "as a rule the temperature varies inversely as the sugar content, being highest when sugar is lowest," and vice versa. The percentage of sugar in the beet and the altitude show a general agreement, although this is not uniform, and it is concluded that the only effect of altitude is due to a decrease in temperature. The distribution of rainfall appears to have had no direct effect upon the content of sugar, although it is stated that there might be such a distribution as to influence the quality of the beet unfavorably. The data for the year are considered less decisive and less complete than for the previous seasons.

[Cooperative tests with sugar beets and alfalfa], V. K. CHESNUT (*Montana Sta. Rpt. 1904, pp. 233-235*).—About 50 lbs. of Kleinwanzlebener beet seed produced in the State of Washington, and secured by this Department, was distributed in Montana and the beets raised were tested.

The richest lot contained 22.8 per cent of sugar. The largest estimated yield of sugar per acre, 5,825 lbs., was obtained on the station farm. Vilmorin Imperial, French Red Top, and Utah sugar beets grown in comparison with this seed were inferior in every particular with the exception that the Utah-grown seed showed a purity 1.08 per cent greater than the Kleinwanzlebener. The average of 22 beets grown in various parts of the State from the seed distributed by the station contained 16.9 per cent of sugar with 82.73 per cent purity.

Experiments in inoculating alfalfa seed with cultures obtained from this Department indicated that the treatment produced more vigorous seedlings. Reports on the individual tests have not yet been made.

Experiments in the culture of sugar cane and its manufacture into table sirup, H. W. WILEY ET AL. (*U. S. Dept. Agr., Bur. Chem. Bul. 93, pp. 78, pls. 5, figs. 6*).—This bulletin is a report on investigations conducted at Waycross and Cairo, Ga., in 1903 and 1904, in continuation of previous work (E. S. R., 15, p. 245).

In 1903 experiments were conducted at Cairo on 2 fields, both old and sandy land. Fertilizers were applied in different quantities and combinations, either in the furrow or broadcast. On some plats the entire application was made at one time, while on others 2 or 3 partial applications were made at different times. In some cases the cane was planted on top of the fertilizer, which had been applied in the furrow. The season was unfavorable and the stand was poor.

The "normal" fertilizer mixture consisted of 1,200 lbs. acid phosphate, 400 lbs. cotton-seed meal, 200 lbs. nitrate of soda, and 200 lbs. muriate of potash. The results from the use of 800, 1,200, or 2,000 lbs. of the normal formula per acre showed very slightly increased profits from the larger quantities of fertilizer, and it is concluded that for seasons like 1903, 1,200 lbs. per acre is sufficient. The use of this normal formula in 2 applications gave the largest yield of cane per acre as compared with other methods, and bore out the conclusions from the experiments of 1902. The analyses of the juices showed no appreciable differences in this connection.

The yields obtained on the 2 fields proved conclusively that sugar cane can not be grown profitably on that soil without fertilizers. The unfertilized plats averaged 8.25 per cent of sucrose against an average of 10.2 per cent on the plats fertilized with the normal formula, while the purity for the unfertilized and fertilized plats averaged 69.4 and 72.9, respectively.

On practically the same soil the yield in 1902 was 9.12 tons per acre and the sucrose content, 15.72 per cent, or about double the tonnage and sugar content of 1903. The average yield of 16 unfertilized plats was 4.23 tons per acre, and of 30 plats fertilized with 800 to 2,000 lbs. of the normal formula per acre, 12.96 tons, or a gain of 8.73 tons and a profit of $20.68 per acre from the use of the fertilizer.

The indications from the special fertilizer experiments were that 800 to 1,200 lbs. of the normal mixture furnished sufficient of the individual ingredients. As in 1902, cotton seed proved too expensive as a fertilizer for cane on this soil at the present prices of seed and other fertilizer ingredients.

The experiment field which had grown plant cane in 1902 was used this season for a test with stubble cane. The stubble was treated in the usual manner, and in April an application of 400 lbs. per acre of the normal formula fertilizer was applied around the roots and in June another application of 400 lbs. was made. This land was better in quality than that devoted to the experiment described above, and hence the general yield was greater. The rattoon crop of 1903 apparently derived but little, if any, benefit from the application of ammonia made the year before, but was largely benefited by the potash and phosphoric acid applied at that time. Cotton seed also failed to show any residual effect.

In 1904 the experiments were again conducted on 2 fields, A with 42 plats and B with 46. Field A, a good grade of pine land with a stiff clay subsoil, was seeded to oats in the winter of 1902, followed by cowpeas in the summer of 1903. In these tests the normal formula was revised, as follows: Acid phosphate 1,200 lbs., cotton-seed meal 300 lbs., nitrate of soda 100 lbs., and muriate of potash 200 lbs., on the theory that all the phosphoric acid and potash and about half of the nitrogen should be applied at the time of planting, and the other half of the nitrogen, in the form of nitrate of soda, in 1 or 2 later applications.

The results showed a great difference in the productivity of the 2 fields, which was apparently due to the fact that cowpeas had been grown upon field A. The unfertilized plats on field A gave an average yield of 15.82 tons of hay per acre, while the corresponding plats on field B gave only 4.39 tons. The percentage of sucrose from these same plats on field A and field B was 14.07 and 12.31, respectively. The reducing sugar was also less and the purity of the juices higher for field A than for field B, so that in every respect field A showed a great superiority for cane production.

The average yields of 3 plats receiving the normal formula fertilizer were 26.62 and 17.22 tons per acre for field A and field B, respectively. The average increase per acre on field A apparently due to the fertilizer was 10.8 tons, and on field B, 12.83 tons. The percentage of sugar in the cane grown on the poorer soil and the reducing sugar and the purity were about the same as on the richer land.

The results at Waycross for 1904 are given in tables without comment. The largest yields of cane per acre were obtained from the use of 2,000 lbs. of the normal formula.

The manufacturing data comprise a report on the installation and operation of a sirup factory at Waycross. A detailed description and plan of the factory, including the machinery and apparatus, is given, and the results of the season's work in milling the cane and manufacturing the sirup are reviewed and summarized. Grinding was begun November 3 and finished December 9, the campaign covering 37 days, during which time 11,344 gal. of sirup, with an average density of 15.4° Brix., was produced.

Changes and improvements in the plant at Waycross are suggested and a report on the inspection of other plants is given. The chemical data include directions for sampling and preserving juices for analysis, methods for sirup examination with directions for the preparation of standard color solutions, and tabulated analyses of sugar cane juices and sirups for 1903 and 1904.

Manurial experiments with sugar cane in the Leeward Islands, 1903-4, F. WATTS ET AL. (*Imp. Dept. Agr. West Indies, Pamphlet 36, 1905, pp. 48, dgms. 4*).—Former results in this series of experiments have been previously reported (E. S. R., 16, pp. 44, 45).

This season the 36 different tests were repeated 10 times with plant canes and 8 times with rattoon canes. As in former years, the fertilizers were applied in varying quantities and different combinations. The guano, potash, and phosphate series did not give remunerative returns. The best results were obtained from the use of either sulphate of ammonia or nitrate of soda alone. The largest gain, which amounted to $8.78 per acre, was obtained from the use of 60 lbs. of nitrogen as nitrate of soda. Nitrogen in the form of sulphate of ammonia stood second, with a financial gain of $7.11 per acre.

It was further shown that the application of nitrogen all at one time gave better results than when it was divided and applied at 2 different times. The results pointed out in general that 20 tons of barnyard manure per acre without commercial fertilizers is adequate for plant canes and that rattoon canes, in addition to good tillage, require a dressing of from 2.5 to 3.5 cwt. of nitrate of soda or 2 to 3 cwt. of sulphate of ammonia per acre.

Seedling and other canes in the Leeward Islands, 1903-4, F. WATTS ET AL. (*Imp. Dept. Agr. West Indies, Pamphlet 33, 1905, pp. 61*).—A summary is given of tests with plant and rattoon canes in Antigua and St. Kitt's and of experiments in the chemical selection of sugar canes, the raising of new seedlings, and in the treatment of plant tops and cuttings with germicides before planting. Ordinary cultivation was given in all tests with canes to make the results comparable with common practice.

In the plant-cane test in Antigua, Sealy Seedling ranked first in the production of sucrose in the juice with 9,914 lbs. per acre. Canes B. 156, B. 306, B. 208, and D. 95, mentioned in the decreasing order of sucrose production, ranked next to Sealy Seedling. These same varieties also stand among the first 7 in the average results for 3 years. Sealy Seedling and B. 306 ranked high in the rattoon test.

B. 393 and B. 208 stood first among the plant canes tested in St. Kitt's. White Transparent, Mont Blanc, and B. 306 appeared to be most drought-resistant, while the results with B. 208 indicated the need of a greater rainfall. In the rattoon test for the year D. 115, B. 306, and B. 208 led in the production of sucrose in the juice, and these same varieties retained the lead in the average results for 3 years, with B. 306 ranking first and D. 115 second.

As a result of using cuttings either high or low in sugar content, there was a gain of about 10 per cent in sucrose in the cane from the high sugar cuttings over those from the low sugar cuttings. Treatment with Bordeaux mixture tended to preserve cane cuttings while in the soil and increased the number of plants grown from cuttings by 62 per cent. Tarring the ends of the cuttings gave an increase in the number of plants grown of only 34 per cent.

Sugar-cane experiments in Cuba (*Agr. News [Barbados], 4 (1905), No. 81, p. 146*).—Among different new varieties of sugar cane under test in 1904, B. 208, D. 95, and Caledonia Queen ranked first in sugar content and purity.

Variation in the chemical composition of the swede, S. H. COLLINS (*Jour. Agr. Sci., 1 (1905), No. 1, pp. 89–107*).—This article summarizes the work of 5 years with swedes and shows the results of analyses of 14 varieties grown in different localities.

The individual root, its size, the fertilizers applied, the variety, the season, and the soil and locality are discussed as factors influencing the composition. The relative merit of varieties was found to be fairly uniform over a large area. The results show an average of 12.39 per cent of dry matter in swedes from the North of England. A list of the varieties in the order of merit, according to the percentage of total dry matter based on the average of all results to the end of 1904, is given. Fell Bronze Top and Webb Imperial are the leading varieties.

The manurial requirements of the swede crop, J. PERCIVAL (*Univ. Col. Reading, Agr. Dept., Ann. Rpt. Field Trials and Expts., 11 (1905), pp. 1–19*).—Cooperative fertilizer experiments were made with swedes.

The fertilizers were used in quantities supplying the essential elements at the following rates per acre: Nitrogen 10, 20, and 40 lbs.; phosphoric acid 40, 80, and 160 lbs.; and potash 20, 40, and 80 lbs. On nearly all farms the omission of potash reduced the yields. The application supplying 40 lbs. of nitrogen, 160 lbs. of phosphoric acid, and 80 lbs. of potash produced the largest increase in crop. While the heavier applications gave an increase in yield, the cost of this increase rose with the quantity of fertilizers applied. The use of fertilizers seemed to improve the stand and the power of the plants to resist insect attacks.

Experiments on the influence of fertilizers upon the yield of timothy hay when grown on Dunkirk clay loam in Tompkins County, New York, J. W. GILMORE and S. FRASER (*New York Cornell Sta. Bul. 232, pp. 32–46, figs. 5*).—The chemical and mechanical analyses of Dunkirk clay loam soil upon which these experiments were conducted are reported. In the fall of 1903 the plats received commercial fertilizers, stable manure, and lime, and the following spring they were sown to oats and timothy at the rate of 9 pk. and 15 lbs. per acre, respectively. Commercial fertilizers were again applied in the spring of 1905, but no manure and lime were used.

In 1904, 8 unfertilized plats produced 53.8 bu. of oats per acre, while 14 fertilized plats produced 59.6 bu. The use of a complete fertilizer high in nitrogen and phosphoric acid, and of 20 tons of stable manure per acre, was apparently most effective in increasing the yield of oats; but in these as in all other cases the increase did not pay for the treatment.

The yield of timothy hay in 1905 on 8 untreated plats was 2,160 lbs. per acre; on 3 plats receiving only mineral fertilizers, 2,890 lbs.; on 8 plats treated with nitrate of soda, 4,676 lbs.; and on 2 plats receiving stable manure, 4,805 lbs. Two applications of 320 lbs. each of nitrate of soda and acid phosphate and 80 lbs. of muriate of potash per acre gave an apparent increase in yield of 10.3 bu. of oats and 4,137 lbs. of timothy hay. A single application of 10 tons of stable manure apparently increased the yield of oats by 5.3 bu. and of hay by 2,595 lbs., and 20 tons of manure, by 11.2 bu. of oats and 4,025 lbs. of hay per acre. From seed in the manure red and alsike clover were introduced into the meadow. Estimating the cost of the manure at 50 cts. per ton, the net gain from the use of 10 tons was $10.55, and from 20 tons $15.14. The use of nitrogen in the fertilizers gave a marked increase in hay but only a small increase in the yield of oats.

The results of the experiment are believed to indicate that if the proportion of nitrogen to phosphoric acid had been greater the returns would have been more profitable. Muriate of potash applied either alone or with nitrate of soda gave a net gain. Lime had no influence on the growth of timothy, but in other experiments

on this type of soil has shown a marked effect upon the growth of alfalfa. The results as a whole are regarded as emphasizing the importance of the systems of farm management which will bring to this type of soils the largest supply of readily available nitrogen, and as pointing out in this connection the value of growing leguminous crops and of properly preserving stable manure.

The influence of the season on the composition of wheat, F. WOHLTMANN (*Deut. Landw. Presse, 32* (*1905*), *No. 36*, *pp. 309-311*).—The fluctuation in dry matter, ash, and protein content of American, Turkestan, and German varieties of spring and winter wheat for the seasons of 1896 to 1904, inclusive, is reported and the influence of the weather conditions in this connection is discussed.

The American varieties comprised 23 of spring wheat and 45 of winter wheat, while only 5 German varieties and apparently only 1 variety of Turkestan wheat, all spring-wheat varieties, entered into the experiment. In dry matter the fluctuations were not very great between the wheats from different sources, but in ash and protein content the differences were quite marked. The protein content in American spring-wheat varieties showed a fluctuation of 32 per cent, in the Turkestan wheat 25 per cent, and in the German varieties 38 per cent.

A wheat with numerous aliases, C. E. THORNE (*Ohio Sta. Bul. 152*, *pp. 210, 211*).—Five plats of wheat from seed procured from as many different localities and known under different names were apparently all of the same variety, and although large claims have been made for the wheat under the name of Prosperity, the yields were not equal to those of Velvet Chaff, a variety of medium productiveness, as shown by 10-year tests at the station.

Mendel's laws of inheritance and wheat breeding, R. H. BIFFEN (*Jour. Agr. Sci., 1* (*1905*), *No. 1*, *pp. 4-48*, *pls. 2*, *dgm. 1*).—This article discusses Mendel's law as applied to wheat breeding, reviews the work of several investigators, describes the differentiating characters of wheat and the method of artificial cross pollination, and reports the results of experiments begun in 1900 with a view to improving English varieties.

Brief descriptions are given of 18 varieties used in crossing and of the resulting crosses, together with a detailed account of the various characters and their behavior in the cross and in the first generation. In summing up the author presents the following grouping of characters showing pure dominance and resembling those described in peas by Mendel:

Dominant.	*Recessive.*
Beardless heads.	Bearded heads.
Velvety glumes.	Smooth glumes.
Keeled glumes.	Round glumes.
Loose heads.	Compact heads.
Red chaff.	White chaff.
Red grain.	White grain.
Thick and hollow stem.	Thin and solid stem.
Rough leaf surface.	Smooth leaf surface.
Bristle stem.	Smooth stem.
Large sclerenchyma girders and angular stem outline.	Small sclerenchyma girders and almost circular stem outline.
Hard, translucent endosperm.	Soft, opaque endosperm.
Susceptibility to yellow rust.	Immunity to yellow rust.

Irregular dominance was observed in the crosses in velvety and glabrous glumes and gray and red or white glumes. In other cases the pairs of characters showing no dominance and in which the cross was intermediate between the parents were

loose and compact heads, large and small glumes, long and short grains, and early and late maturity.

Some practical suggestions concerning seed germination, J. J. THORNBER (*Arizona Sta. Bul. 51, pp. 536-541*). Experiments were made to study the effect of mechanical and hot water treatment on the germination of the highly moisture-resistant seeds of a number of semiarid plants. The author found that when the hard resistant seed coats were rendered permeable to water by scratching, cutting, or grinding, the germination of the seeds under normal conditions took place immediately. In the tests with hot water treatment upon several kinds of seeds, such as locust, acacia, and mesquite, the best results were obtained by placing the seeds in hot water for 2 minutes, then soaking them in lukewarm water for 12 to 24 hours, removing the swollen ones, and again subjecting the rest to the treatment until they swelled. Four lots of 50 catclaw seeds each, immersed for different lengths of time in water at 85 to 88° C. gave the following results: One minute immersion, 8 seeds swollen and 33 germinated; 2 minutes, 27 swollen and 36 germinated; 3 minutes, 40 swollen and 41 germinated; and 4 minutes, 40 swollen and 33 germinated.

A list is given of seeds which were successfully germinated by stratifying them during the winter and planting early in the spring in well-prepared soil.

The vitality of seeds, W. J. BEAL (*Proc. Soc. Prom. Agr. Sci., 26 (1905), pp. 89-93*).—Previously noted (E. S. R., 16, p. 622).

HORTICULTURE.

Report of the [Oregon horticultural] commissioners, E. L. SMITH ET AL. (*Bien. Rpt. Bd. Hort. Oregon, 8 (1905), pp. 7-48, pls. 10, figs. 7*).—An account is given by the commissioner at large, the commissioners of each of the 5 fruit districts into which Oregon is divided, and the secretary of the board of horticulture, on the progress of fruit culture in the different districts of Oregon with statistics in certain instances as to the amount of fruit grown in different districts and individual orchards, and notes on various other factors affecting the fruit industry of that State, such as methods of culture, canning factories and evaporators, orchard and nursery inspection, etc.

Horticulture in Oregon, H. E. DOSCH (*Bien. Rpt. Bd. Hort. Oregon, 8 (1905), pp. 219-235, pls. 2*).—A general discussion of this subject, with the estimated cost of establishing and maintaining peach, apple, and prune orchards and vineyards in different parts of Oregon, and a discussion of markets.

Horticultural department, R. W. FISHER (*Montana Sta. Rpt. 1904, pp. 239-248*).—A brief outline of the work of the year with ornamental trees and shrubs and with vegetables. Onions were seeded in the greenhouse and transplanted in comparison with field-sown seed. The transplanted onions gave the better yields. Early planting in the field, however, proved much better than late planting.

Vegetable gardening, S. B. GREEN (*St. Paul: Webb Pub. Co., 1905, 7. ed., pp. 252, figs. 123*).—This well-known book on vegetable gardening for northern latitudes has been revised to some extent and enlarged. A number of test questions have been included, which better adapts it for use in the class room, and a different arrangement has been made in the grouping of the vegetables treated.

Notes on the forcing of tomatoes, cucumbers, and melons, C. E. HUNN and J. CRAIG (*New York Cornell Sta. Bul. 231, pp. 15-29, figs. 9*).—In forcing experiments with tomatoes the best 4 varieties for general midwinter forcing were Lorillard and Combination of the American varieties and Frogmore and Holmes Supreme of the English varieties.

Many trials have been made with soap solutions, tobacco preparations, and hydrocyanic-acid gas for the control of the white fly in the greenhouse. The hydrocyanic-

acid gas has proved most satisfactory when properly used. The best conditions, as found in the authors' experiments, are absolute darkness, still air, temperature below 60° F., and a dry house. Under these conditions it has been possible to keep down the white fly by fumigating once each month with 1 oz. of cyanid of potassium, 2 oz. of sulphuric acid, and 4 oz. of water to each 1,000 cu. ft. of house space. When fumigations were made in daylight with larger amounts of cyanid there was considerable injury to the foliage of tomatoes and severe injury to the foliage of chrysanthemums, geraniums, and begonias.

The time required for forcing a crop of melons is placed at approximately 6 months, and the cost of a full crop is about $1 per melon. The English types of melons have been found to give the best results in forcing.

Notes are given on the beginning of the cucumber forcing industry in New England by Dr. J. Fisher, and on commercial methods of growing cucumbers in Massachusetts by G. M. Kendall, from which it appears that the best soil in which to force cucumbers is a sandy loan mixed with about one-third fresh horse manure. The vine is trained up to about 10 ft. and nipped off. Each lateral is also nipped off at the first joint beyond the cucumber. White Spine is the variety chiefly grown. The temperature of the house should be about 65° at night and 90° to 100° on good sunshiny days.

At the station, the authors have grown chiefly the long English type of cucumber. This type is grown in shaded houses, as the large succulent leaves burn if exposed to full sunlight. General directions are given for their culture and care in the greenhouse.

Soil treatment in greenhouse culture, H. J. Wheeler and G. E. Adams (*Rhode Island Sta. Bul. 107, pp. 157-167*).—An experiment was made to determine the initial and residual effects of stable manure and different kinds of commercial fertilizers when used for different greenhouse crops.

In the test 1,400 lbs. of subsoil was used in each of 4 sections. The soil was first treated with lime to correct acidity. Section 1 was then fertilized with horse manure at the rate of 75 tons per acre. Sections 2, 3, and 4 were given identical amounts of potash, phosphoric acid, magnesia, and nitrogen in different commercial forms. On section 2 such chemicals were used as would not be likely to leave any injurious residues in the soil.

On section 3 potash was applied in the form of muriate instead of nitrate, as in section 2, and sulphate of ammonia was used as a source of part of the nitrogen applied. Both these sections received in addition mixed timothy and redtop hay cut in lengths of half an inch to an inch and thoroughly incorporated in the soil. Section 4 was treated exactly like section 2 except that no chaffed hay was used.

The first crop grown was radishes. The manured section led all the others in yield and size, 1,400.6 gm., sections 2, 3, and 4 following in regular order, the latter yielding only 952.2 gm. Section 2 yielded nearly as well as the manured section, 1,376.7 gm.

A second crop of radishes was then grown after additional fertilizers had been added. The smallest yield with this second crop was on section 1, where stable manure was used, and the largest on section 2, where care had been taken to avoid chemicals which might leave toxic residues in the soil.

This crop was then followed by tomatoes on half of each section and cucumbers on the other half. The largest total yield of tomatoes, 11,852 gm., was obtained on section 3, showing that the residuals of the chemicals used had no toxic effect for this crop. The yield of cucumbers on the manured section was nil, due to lack of nitrogen, caused by denitrification processes which were especially favored by the use of such large amounts of manure under the favorable conditions afforded by the greenhouse.

Section 2 gave the largest total yield, 1,724 gm.; section 3 yielded 1,272 gm., indicating that the sulphate and chlorid residues of the fertilizers used on this plat were injurious to cucumbers, while section 4, which had no chaffed straw, yielded the smallest crop of all, 353 gm.

Report on the fruit industry of Great Britain, A. G. BOSCAWEN ET AL. (*London: Dept. Com. Fruit Cult., 1905, pp. III+39*).—This is a report of the committee appointed by the Board of Agriculture and Fisheries, to investigate the present condition of fruit culture in Great Britain and to consider methods for its promotion and encouragement.

The total acreage under orchards in 1904 was 243,008, of which 236,705 acres were in England, 2,490 acres in Scotland, and 3,813 acres in Wales. There were also 77,947 acres in small fruits, of which 70,612 acres were in England, 6,072 acres in Scotland, and 1,263 acres in Wales. The fruit industry of Great Britain while small appears to be the only form of agriculture which has exhibited any sign of progress in recent years. The various difficulties and drawbacks to the fruit industry of Great Britain were examined into at length from the standpoint of knowledge of the industry, land tenure, taxation, railway grievances, foreign competition, labor, etc.

As a result of the investigation, it is believed that there is opportunity for a considerable extension of the fruit industry. Forty recommendations are made. One of these is to the effect that a special department of the board be established which shall consist of a bureau of information and an experimental fruit farm. It is recommended that horticulture be taught in elementary schools and country districts, and that the study of practical horticulture in training colleges be encouraged.

Studies on apples, W. D. BIGELOW, H. C. GORE, and B. J. HOWARD (*U. S. Dept. Agr., Bur. Chem. Bul. 94, pp. 100, pls. 5, figs. 30*).—Details are given of an extended investigation on the chemical changes which take place in the storage, respiration, and growth of apples and on the insoluble carbohydrates or marc of apples. The results of microscopic and macroscopic examinations of apple starch are also given. Preliminary to the experimental details an extensive review is given of the work on the ripening and respiration of fruits as observed by many other investigators.

In the present work the varieties Ben Davis, Bough, Early Strawberry, Huntsman, Northern Spy, Rhode Island, Winesap, Winter Paradise, and Yellow Transparent were used. These are described and the nature of the soil on which they were grown noted. Analyses are given of these varieties when picked at different dates and when held in common storage and in cold storage. From the results secured in this work it appears "that the changes in composition (the content of starch, sugar, and acids) in cold storage do not greatly differ from those which occur in common storage, the chief difference being in the rapidity with which the changes take place."

The results of respiration experiments with apples in common and cold storage indicate that the fruit kept in common storage at the higher temperature ripened much more rapidly than that kept in cold storage. In comparing the amount of carbon dioxid eliminated from the fruit in these experiments with the malic-acid curve, it did not seem possible that the carbon dioxid could be accounted for by the disappearance of malic acid, as some other authors have considered to be the case.

"On the other hand, the curve representing the content of total carbohydrates, expressed as invert sugar, is approximately the reverse of the curve representing the evolution of carbon dioxid. The probability that the carbon dioxid results from the decomposition of carbohydrate bodies is strengthened by the fact that after protracted storage the apple has apparently lost vitality, and changes in composition proceed much more slowly than in the early days of storage."

In considering the growth of apples, the work was not begun until after the "June drop" was over. It was found in this work "that the less mature the fruit is when gathered the more rapid are the changes tending to maturity after picking. It would

seem, therefore, that from a commercial standpoint apples which are fairly mature may be expected to retain a more constant composition than those picked in an immature state."

The differences in the chemical changes which occur in the growth of winter and summer apples are traced in considerable detail. It was found that green apples ordinarily mature much more rapidly when stored than when left on the tree and that the apples picked the earliest mature more rapidly than those picked at a later date. The methods of analysis followed by the authors in this work are given in detail, together with methods followed by other investigators along the same line.

In the work on the insoluble carbohydrates or marc in apples a review is given of the characteristics of pectin bodies as observed by many other investigators with different fruits and vegetables. A table is given showing the results of analyses by the authors of apple marc. In the microscopic and macroscopic examinations of apple starch it was found that the size of the starch grain varies widely according to the condition of maturity of the fruit. A table is given showing the results of measurements of starch grains from several varieties. Generally speaking, the starch grains from within the core line are smaller than those from the torus flesh. In the ripening of apples the intercellular air in the flesh of the fruit seems to increase constantly as the fruit approaches maturity. The specific gravity appears to diminish from 2 to 5 per cent.

The "mealiness" of apples was found to be due largely to the softening of the middle lamella of the cell walls which occurs in the last stages of ripening. In mealy apples the cells under pressure are, for the most part, separated from each other instead of being torn apart individually as in less mature fruit. Mealy apples may contain as much juice as apples not so ripe, but do not appear to because of the separation of the cells instead of their splitting or tearing apart in crushing. Photographs are given showing the starch content of apples and its position in the apple at different stages of maturity.

Pear culture, A. J. McClatchie (*Arizona Sta. Bul. 51, pp. 554–557*).—The statement is made that this fruit is easily grown in Arizona, the tree being little affected by the heat and the blossoms seldom injured by frost. "It is free from diseases or insect pests, bears more regularly than any other fruit, ripens good fruit through a longer season, and is longer lived than any other." Popular directions are given for its culture in Arizona with suggestions as to varieties for planting.

Japan and hybrid plums, H. N. Starnes (*Georgia Sta. Bul. 68, pp. 38, pls. 8, figs. 34*).—In a previous bulletin (E. S. R., 16, p. 67) the value of native and European plums in Georgia was considered. In the present work the success of Japan and hybrid plums in the State is noted, the varieties grown being described at considerable length. Tables are given showing the dates of blooming and fruiting of each variety, including one table in which the fruiting periods of native plums are combined with Japan and hybrid plums.

Generally speaking, the Japan and hybrid plums are much more useful in Georgia than native or European varieties. "They are larger, handsomer, better shippers, and usually firmer and of finer quality than any of the natives, except certain members of the Americana and Miner groups. They are also, as a rule, less subject to curculio." From the data given in the tables of blooming and fruiting, it appears that more than half of the varieties that are earliest to bloom are latest to ripen fruit.

Among the maladies of plums special attention is given to "wilt," crown gall, and the borer. The "wilt" is believed to be bacterial in character, but attempts at inoculation have thus far failed. The varieties so far entirely exempt from "wilt" are Apple, Bartlett, America, Marietta, Excelsior, and Babcock, all except Babcock being hybrids.

Relative to the borer, the author states that contrary to previous belief 90 per cent of the larvæ emerge from their channels in the base of the tree trunk in the vicinity

of the station about the first of August instead of much earlier, as it was assumed they would do. The remedy suggested for this insect is to wrap the base of each tree about the last week in July for 18 in. from the ground in brown paper or newspaper, tying it with twine and wire. After this the base of each trunk should be mounded up 10 in. high around the paper covering. About the last week in October the paper is removed and the worms dug out.

Contribution to the study of varieties of olives called "table or pickling olives" (*Bul. Dir. Agr. et Com.* [*Tunis*], *9* (*1905*), *No. 36, pp. 393–398*).—Analyses with reference to oil content and physical characters are given for 5 varieties of olives grown in Tunis, with a discussion of the same.

Pickling olives for home use, W. W. Skinner (*Arizona Sta. Bul. 51, pp. 550–554*).—Popular directions are given for pickling olives on a small scale.

Cultivation of oranges in Dominica, H. H. Bell (*Imp. Dept. Agr. West Indies, Pamphlet 37, 1905, pp. 52*).—A popular pamphlet on the culture of oranges in Dominica, including some statistics of the Jamaica orange industry.

A new banana from Madagascar, P. Claverie (*Compt. Rend. Acad. Sci.* [*Paris*], *140* (*1905*), *No. 24, pp. 1610–1612*).—A botanical account is given of a new variety of banana which the author names *Musa perrieri*.

On the effects of ringing, Leclerc du Sablon (*Compt. Rend. Acad. Sci.* [*Paris*], *140* (*1905*), *No. 23, pp. 1553–1555*).—The author ringed pears, quinces, and Japanese euonymus, aged 3 to 4 years, on February 9 before vegetation started, and a second lot May 8 after the first shoots had formed. At intervals of 2 months thereafter the trees belonging to each of the 3 groups were harvested and analyzed.

The results obtained with pears are given in detail as regards roots, stem, and leaves. The roots of the trees ringed in February contained more reserve material than the control trees not ringed, while the stems contained less. After April, however, as a result of assimilation by the leaves, the roots of the ringed trees were much poorer in reserve material than those of the control trees.

On the whole the experiment is believed to show that toward the end of winter and the commencement of spring the reserve material goes from the roots to the stem. From May to October the current of elaborated material is from the stem toward the roots. Like results were obtained with quinces and Japanese euonymus.

Winter storage of nursery stock, M. Cooper (*Amer. Florist, 25* (*1905*), *No. 902, pp. 329–333, figs. 3*).—The author states that the winter storage of nursery stock has become a permanently established feature of the nursery business.

From his own investigations and the results of experimental work by others he concludes that the best results in such houses will be obtained if they are maintained at a uniform temperature of 28 to 30° F. At this temperature very little ventilation will be necessary; the loss of vitality through drying out or shriveling is slight; and there is a minimum tendency to mold and mildew. Packing material around the roots and spraying with water would be unnecessary.

Diagrams are given showing methods of construction of a suitable storage house for nursery stock and suggestions made regarding the establishment of the refrigerating apparatus. The experiences of a number of nurserymen with cold storage are quoted.

Forcing strawberries, C. E. Hunn and J. Craig (*New York Cornell Sta. Bul. 231, pp. 5–14, figs. 7*).—This is the second report of the station on this subject (E. S. R., 9, p. 353). The various factors studied were varieties best adapted to forcing, time required to mature the crop, the effects of varying temperatures, and economic methods of handling the plants.

Nearly 100 American varieties, 8 French varieties, and 5 English forcing varieties have been forced in the greenhouse. Neither the English nor French varieties have given satisfactory results. Experiments with American varieties indicate that the midseason varieties are preferable to either extra early or late varieties. The 3

varieties found most desirable for forcing are Glen Mary, Marshall, and President, each of which possesses distinct merits of its own.

Plants for forcing are secured by rooting the runners in 2-in. pots filled with rich soil. From these 2-in. pots it has been found that the plants can be shifted directly into the 6-in. forcing pots instead of more frequent shifting as has been previously considered desirable. Plants that have had a long period of rest and have been frozen hard have been found to give better results when forced than others which have had only a short rest.

As regards temperature for strawberries, "starting with dormant plants taken from the cold frame, heat should be raised gradually from 30 to 45° by the end of the first week, increasing the heat until the plants are in bloom, when they should be growing in a temperature of from 60 to 65°. From the time pollination begins, the house should range from 65 to 70°; and while the fruit is swelling, the heat should never be allowed to fall below 70°."

In one experiment when the plants were coming into bloom part of them were removed to a carnation house where the temperature was kept at near 52° F. When the fruit on the plants kept in the warm house was ripe, the fruits on the plants kept in the cool house were small and hard, uneven in form and poor in coloring. When these immature fruits were removed from the plants and the plants carried into the warm house they matured a fair crop of berries in about 4 weeks' time, showing that if occasion arises the fruiting period of strawberries can be delayed by keeping them at a low temperature. A list is given of the varieties tested for forcing at the station.

Small fruit preserving in bulk (*Agr. Economist, 38 (1905), No. 424, p. 107, fig. 1*).—An illustrated account is given of the method of preserving small fruit in bulk as observed by the cooperative growers in New Zealand.

The fruit is placed in casks holding when full about 3.5 tons and stirred by beaters simultaneously with the introduction of sulphur-dioxid gas, which is forced into the vat from below through pipes. The process is used chiefly with raspberries and black currants. The fruit thus treated presents a somewhat bleached appearance, but when it is boiled the sulphur evolves "and the fruit reverts to a bright natural color."

In jam making this fruit is first boiled for about 20 minutes before the sugar is added in order to drive off the sulphur.

Experiments in electrifying grape cuttings and rooted plants with a current of high tension, F. HONCAMP (*Centbl. Agr. Chem., 34 (1905), No. 6, pp. 394–396*).—Experiments were made along these lines to see whether an electric current of high tension would injure grapevines if this means were taken to combat Phylloxera. As a result of the experiments it is believed that in combating Phylloxera by electricity no fear need be entertained as to harmful results to the plants from this source.

The wild coffees of French Guinea, A. CHEVALIER (*Compt. Rend. Acad. Sci. [Paris], 140 (1905), No. 22, pp. 1472–1475*).—An account of the wild coffees of French Guinea in Africa, including *Coffea stenophylla*, *C. affinis*, and a new species *C. maclaudi*.

A botanical description is given of the latter species. It appears to be a shrub about 12 to 15 ft. high found growing at an altitude of about 2,100 ft. A kilogram of dried coffee contained 10,600 grains. The coffee made from this species had a somewhat bitter taste like all wild coffees but was agreeable, resembling much the coffee from *C. excelsa*.

Nut growing, J. B. PILKINGTON (*Bien. Rpt. Bd. Hort. Oregon, 8 (1905), pp. 328–330, pls. 2*).—The author believes nut culture will become a permanent industry in Oregon.

In this paper especial attention is given to the culture of English walnuts and filberts. One orchard is cited that was grown from second generation seedlings, which is giving very satisfactory results. The seedling trees are larger at the same age and grow more rapidly than grafted trees. It is maintained, however, that grafted trees are more desirable than seedling trees provided they can be obtained at reasonable cost.

Special care must be taken in planting these nuts. Only the late-blooming French varieties should be planted. Those which bloom early are likely to be nipped by frost and not produce fruit. A successful filbert orchard is noted in which the varieties Barcelona, Du Chilly, Red and White Avelenes are grown. These trees are grown as standards. The preceding season they were 9 years old and bore 25 lbs. of nuts each.

A few modern peonies, G. C. WATSON (*Amer. Florist, 24 (1905), No. 890, pp. 989, 990, pl. 1*).—Illustrations and descriptions are given of 26 named varieties of peonies.

Hybridizing the peony, G. HOLLIS (*Horticulture, 2 (1905), No. 3, pp. 59, 60, figs. 5*).—The author has produced a large number of varieties of peony by hybridization and selection. A number of these are briefly described. Suggestions on culture are included.

A répertoire of colors to aid in the determination of the colors of flowers, leaves, and fruits (*Répertoire de couleurs pour aider à la détermination des couleurs des fleurs, des feuillages, et des fruits. Rennes: Imprimerie Oberthür; Paris: Librairie Horticole, 1905, pp. 82, pls. 365*).—This work, illustrating 365 tones of colors, was published by the French Chrysanthemum Society and R. Oberthür, with the collaboration of H. Dauthenay et al. The names of the color tones are given in English, German, French, and Italian, and are accompanied with a complete index in each language.

What is horticulture? L. H. BAILEY (*Proc. Soc. Prom. Agr. Sci., 26 (1905), pp. 31-40*).—Presidential address before the Society for Horticultural Science at its annual meeting in December, 1905, previously noted (E. S. R., 16, p. 423).

FORESTRY.

The forest reserves of California, A. F. POTTER (*Forestry and Irrig., 11 (1905), No. 8, pp. 384-387*).—Up to June, 1905, 14 forest reserves, approximating 14,250,000 acres, had been established within the State. Six of these reserves, established since January 1, 1905, are briefly described. Extensive experiments are under way in tree planting on brush-covered areas to determine the adaptability of different species of conifers in reforesting treeless areas.

Reforesting in California, T. P. LUKENS (*Forestry and Irrig., 11 (1905), No. 8, pp. 347-349*).—An account of the efforts that are being made to reforest the mountain watersheds in southern California with descriptions of methods of seed sowing and methods of planting the different shrubs and trees used for the purpose.

Forest fires and the forest in the California Sierras, W. F. HUBBARD (*Forestry and Irrig., 11 (1905), No. 8, pp. 354-364, figs. 9*).—The author discusses the effects of fire in the denser timbered regions of the Sierras, in the more open forest, and in the chaparral field, and methods of fire regulation and control for the protection of virgin timber, old logged land, and land as it is logged.

Forests and forestry in Connecticut, A. F. HAWES (*Forestry and Irrig., 11 (1905), No. 7, pp. 301-305, figs. 2*).—The author states that the forest area of Connecticut is steadily increasing, but the character of much of the wood growth is poor.

Chestnut is the most important tree of the State, and white pine the next. About a quarter of the total area of the State is nearly worthless land, which is gradually

coming up to gray birch, pitch pine, and juniper. The advantages of thinning are pointed out and records given of the productiveness of different small areas.

Under the provisions of a late law about 1,000 acres of sprout land has been purchased by the forester of the State at a cost of $1.63 per acre, upon which experiments in planting, thinning, etc., will be carried out.

Connecticut's new forest law (*Forestry and Irrig.*, *11* (*1905*), *No. 7*, *pp. 306–308*).—The text of the recent law passed in Connecticut with reference to fire wardens and the protection of forests from fire is given.

Notes on the flora, especially the forest flora, of the Bitter Root Mountains, L. H. Pammel (*Proc. Iowa Acad. Sci.*, *12* (*1904*), *pp. 87–100*, *pls. 6*).—An account of the survey of that part of the Bitter Root Mountains west and south of Hamilton, containing considerable data relative to the proportions of the different species of coniferous trees and their rates of annual growth at different altitudes and in different years. Mention is also made of introduced and weedy plants in that section of the country.

Forest management in Bavaria and Saxony, C. S. Orwin (*Jour. Southeast. Agr. Col. Wye*, *1905*, *No. 14*, *pp. 249–261*).—The author reports upon a tour of inspection of the oak and beech woods of the Spessart district of Bavaria, the pine woods of Bamberg in Bavaria, and the spruce woods of Saxony, describing the objects of management in each case, methods of regeneration, etc.

The leaf-shedding disease (*Hysterium pinastri*) is stated as one of the worst scourges of the pine. It has been controlled by spraying with Bordeaux mixture. The spraying is done once a year in July or August for 4 or 5 years.

Reports on forest administration in Burma for the year 1903–4, J. Copeland et al. (*Rpts. Forest Admin. Burma*, *1903–4*, *pp. 189*).—An account of the extent and character of the State forests and their management as regards working plans, protection, sylviculture, and exploitation, with a financial statement as to receipts and expenditures.

During the year tapping experiments were performed on Chavanessia creepers. The quantity of rubber yielded by this plant did not pay for the cost of extraction. When the plant was cut down to the root and then chopped into small pieces no better results were obtained.

The experimental garden in the Tenasserim Circle contains 79.5 acres of Hevea rubber trees planted in 1878–9.

A series of systematic tapping experiments was carried out with these trees with the following results. Trees 2 to 4 ft. in girth yielded an average of 4.4 oz. of rubber per tree; 4 to 5 ft., 7 oz.; 5 ft. and over, 16 oz. The latex of the older trees was much richer in rubber than the younger trees. Thus, 100 cc. of latex from trees 2 to 3 ft. in girth yielded 1.38 oz. of rubber. From trees 3 to 4 ft. in girth the yield was 1.73 oz.; from trees 4 to 5 ft. in girth, 2.26 oz.; and from trees 5 ft. and over, 2.94 oz.

The experiments indicated that a man could tap from 10 to 20 trees a day, according to their girth, and could collect on an average 550 cc. of latex, representing 6.6 oz. of dry rubber.

Administration report of the forest department in the Bombay Presidency, including Sind, for the year 1903–4, G. P. Millett et al. (*Admin. Rpt. Forest Dept. Bombay*, *1903–4*, *pp. 202*).—An account of the extension and constitution of State forests in the different circles of the Presidency, and of their management during the year, with a statement of the financial results. In the report of the Sind Forest Circle a list of the vernacular terms used in the report with reference to different species of trees, etc., is given.

Rubber cultivation in the West Indies (*West Indian Bul.*, *6* (*1905*), *No. 2*, *pp. 139–149*).—This consists of a paper on Castilloa Rubber in Tobago, by M. Short, with a discussion of the same by members of the agricultural conference.

At Tobago the author states that Castilloa requires no shade. The experiments at that place indicate that about 12 ft. apart is the best distance for Castilloa trees. Tapping experiments indicate that from ¾ to 1 lb. of rubber per annum may be safely reckoned on as the average yield of trees 13 to 14 years old. Trees 9 years old yield about half as much. In discussing this paper J. H. Hart stated that experiments carried out in Trinidad proved that Castilloa required shade in that place.

The article is concluded with an appendix in which Castilloa as a shade tree for cacao is discussed.

The India rubber of commerce, M. CHAMNEY (*Transvaal Agr. Jour., 3 (1904), No. 9, pp. 99–103*).—An account is given of the India rubber of commerce, or caoutchouc, in which historical statements are given regarding its discovery and utilization and figures presented showing the sources of supply and the consumption. The principal supplies come from Brazil, Central America and Mexico, Africa, Java, Borneo, Madagascar, and India. The world's supply in 1889, the latest figures obtainable, was about 1,253,000 cwt., while the consumption was 1,250,000, leaving a margin of only about 3,000 cwt.

The principal species producing the caoutchouc are listed, of which the genera are Willughbeia, Landolphia, Castilloa, Ficus, Hevea, and Manihot, and in addition since this list was prepared large supplies of India rubber have been obtained from two or more species of Kickxia, large apocynaceous trees found in central and western Africa.

New trees introduced by the Government, W. H. EVANS (*Chautauquan, 41 (1905), No. 4, pp. 345–347*).—An account of the various forest, fruit, and ornamental trees introduced by the United States Department of Agriculture from its beginning.

An adaptation of methods in forest work, W. F. HUBBARD (*Forestry Quart., 3 (1905), No. 2, pp. 91–98*).—In the preparation of a fire plan for a lumber company operating in the western yellow pine type of forest, it was desired to make an estimate of the present and future yields of timber on each quarter section separately.

As it was not feasible to spend time and money on a number of strip surveys, a variation of that method by running a series of cruisings which would give an actual tally of the trees on the tract was adopted. Comparative estimates of the future yield on a quarter section, from cruising valuation surveys and from strip valuation surveys, are given to show the closeness of the estimates by the 2 methods.

DISEASES OF PLANTS.

Diseases of the apple, cherry, peach, pear, and plum; with methods of treatment, E. M. WILCOX, (*Alabama College Sta. Bul. 132, pp. 79–142, pls. 9, figs. 2*).—This bulletin, which is largely compiled from departmental and experiment station publications, is designed to enable fruit growers to recognize some of the more common diseases of the plants mentioned in order that they may assist the station in securing data regarding the distribution and severity of the diseases in the various counties of the State.

The author has avoided technical discussions of the organisms causing the diseases as far as possible, but gives suggestions which will aid in the recognition of the diseases, and discusses methods of treatment. The material is arranged under the different headings by host plants, and chapters are devoted to the preparation of fungicides and spraying machinery. Bibliographies of the more important literature are appended to the different headings.

Some bacterial diseases of plants prevalent in Michigan, W. G. SACKETT (*Michigan Sta. Bul. 230, pp. 203–220, figs. 6*).—Popular descriptions are given of pear blight, bacteriosis of beans, black rot of cabbage, wilt of cucurbits, soft rot of the sugar beet, and the blight of the potato, tomato, and eggplant.

Fungus diseases of cotton, L. LEWTON-BRAIN (*West Indian Bul., 6* (*1905*), *No. 2, pp. 117-123*).—Notes are given on the rust, leaf spot, mildew, and anthracnose of cotton, after which a disease known locally as black boll is described.

This disease seems to be characterized by the decay of the internal parts of the boll, usually starting at the base. The seeds swell inside and the lint is destroyed. The first outward sign of disease is a curious deformation of the boll, which is followed by the other symptoms already mentioned. As the disease progresses the lint becomes slimy, changing color from yellow to dark brown or black, and finally the enlarged, partially germinated seeds practically fill the interior of the boll.

The only foreign organism present in diseased bolls is a short rod-shaped bacillus, and this appears constantly present in the diseased tissues. Until inoculation experiments have been carried on it can not, however, be definitely claimed that this bacillus is the cause of the disease.

A new disease in potatoes (*Jour. Bd. Agr.* [*London*], *12* (*1905*), *No. 1, pp. 37, 38*).—It is stated that *Sphærella tabifica*, a parasitic fungus especially known as attacking beets and mangels, has been recently observed occurring on potatoes. As in the case of beets and turnips, the fungus first makes its appearance on the leaves, afterwards passing into the roots, causing their destruction. On account of the fact that different crops are subject to the attacks of this fungus, care should be taken to provide rotations with nonsusceptible plants. It is believed that the application of gas lime to the soil would to a considerable extent destroy the parasite.

A disease of potatoes (*Jour. Bd. Agr.* [*London*], *12* (*1905*), *No. 5, pp. 294-296, fig. 1*).—A diseased condition of potatoes of the variety Evergood is reported, in which the surface of the tubers was studded with small brownish warts, and although a number of fungi were present no species seemed to be sufficiently constant to be considered the cause of the trouble. A careful study of the variety showed that the primary cause of the disease was the excessive development of lenticels in this particular variety. The experiments from which this conclusion is drawn are to be described later.

Blackleg in potatoes (*Jour. Bd. Agr.* [*London*], *12* (*1905*), *No. 5, pp. 296-298*).—A brief account is given of a disease of potatoes due to *Bacillus phytophthorus*, and precautionary measures to be taken for the prevention of the disease are quoted from a recent publication (E. S. R., 15, p. 374).

It has been found that potatoes, beans, carrots, turnips, cucumbers, sugar beets, mangels, etc., are susceptible to the disease, and rotations should be provided in which these plants do not occur for a number of years. Whole tubers should be planted instead of being cut into sections, as is usually the case. Care should be taken to obtain seed from districts where the disease is not known to exist, and lime or strong nitrogenous manures should not be used.

Review of the principal diseases of sugar cane, L. LEWTON-BRAIN (*West Indian Bul., 6* (*1905*), *No. 1, pp. 33-37*).—The author presents a brief summary of the principal facts regarding the rind disease caused by *Trichosphæria sacchari*, the pineapple disease due to *Thielaviopsis ethaceticus*, and the root disease attributed to *Marasmius sacchari*. Incidentally the author mentions the fact that bananas are subject to attacks of *M. semiustus*, a species related to that causing the root disease of sugar cane.

Club root in turnips (*Jour. Bd. Agr.* [*London*], *12* (*1905*), *No. 3, pp. 161, 162*).—Based upon experiments carried on for a number of years it is suggested that 2½ tons of common lime slaked to a fine powder and applied to an acre of infested soil will usually result in securing a crop reasonably free from this disease. It is noted from the results obtained that the effect of the lime may be more apparent on the second than on the first crop which follows its application.

The cucumber leaf blotch, A. D. HALL (*Jour. Bd. Agr.* [*London*], *12* (*1905*), *No. 1, pp. 19-21*).—A brief description is given of the cucumber leaf spot, caused by

Cercospora melonis, and the results of various methods of treatment for its prevention are stated.

The treatment of the soil by watering every fourth day with a solution of copper sulphate was tried, and while at first it seemed successful, later the plants were badly attacked by the fungus, and those which had been treated seemed particularly susceptible to the red spider. A second series of experiments was inaugurated, in which the plants were treated with a copper sulphate solution and with ammonium copper carbonate, but from the results obtained it seems that the use of copper fungicides does not offer any very satisfactory method of combating this disease.

The most hopeful method of treatment the author believes is the utilization of disease-resistant varieties. Where forcing houses have become badly infested with the fungus some other crop should be grown for a number of years.

A mushroom disease (*Jour. Bd. Agr. [London], 12 (1905), No. 1, pp. 47–49, fig. 1*).—An account is given of a disease of cultivated mushrooms which is due to the parasitic fungus *Hypomyces perniciosus*.

This fungus attacks parasitically the mycelium of the mushroom, causing it to become distorted and resulting in curious malformations of the spore-bearing form of the mushroom. On account of the rapid growth of the parasite all beds should be removed before spores are produced, otherwise the houses may become thoroughly infested.

If this should occur the houses in which mushrooms are grown should be completely emptied and thoroughly sprayed at intervals of 10 days with a strong solution of copper sulphate, 3 or 4 applications being given. At the same time the house should be kept warm and moist to favor the germination of the spores of the parasite, which are destroyed by the treatment suggested.

Some of the results of three years' experiments with crown gall, G. G. HEDGCOCK (*Science, n. ser., 22 (1905), No. 552, pp. 120–122*).—A summary is given of the author's experiments on crown gall, which is found on the almond, apple, apricot, ash, blackberry, chestnut, cherry, grape, hop, oak, peach, pear, plum, prune, poplar, quince, raspberry, rose, walnut, and willow.

A number of forms of the disease are recognized, some of which are little known. Those occurring on the apple, pear, and quince are said to be quite similar and have not yet been proven to be contagious. Those occurring on the almond, apricot, blackberry, cherry, peach, plum, prune, and possibly the chestnut and walnut are similar in nature and origin and are often very contagious. Those on the grape and rose appear to be slightly contagious, but can not be classed with either of the preceding groups, as far as present information goes. The crown gall on the hop is caused by a slime mold resembling *Plasmodiophora brassicæ*, the cause of club root in cruciferous plants.

Experiments with apple, quince, and pear seedlings grown under sterilized conditions show that the apple and pear crown gall of the ordinary type, in which there is an absence of side roots or hairy roots, is not contagious. In experiments carried on for 2 years the average result obtained from inoculation of selected apple nursery stock was 10 per cent of diseased plants, with 15 per cent of the control plants affected.

The author states that the apple crown gall is of 2 types, one a more or less woody gall with few or no roots growing from it, while the other form is commonly called hairy root from the numerous side roots that are put out. Galls may or may not occur in connection with this form, and for the present it is considered a distinct disease.

Careful cross-inoculation experiments show that the crown gall of peach, plum, cherry, raspberry, almond, and apricot are identical. The peach and raspberry are most susceptible to wound inoculation, but also become diseased through infected soil. It has been impossible to transfer this disease to the apple, pear, or quince.

14462—No. 5—06——5

The results from an experiment with 300 2-year-old apple trees, selected with care as to uniformity of size and root system, seem to indicate that the disease has no immediate effect on the duration of the life of the tree where other diseases do not intervene. Field observations bear out the conclusion that the disease does not kill the young trees as often as has been previously believed.

There is frequently found on the roots of apple seedlings, and more rarely on grafted apple trees, a gall of a softer nature, which may prove to be slightly contagious. This is to be a subject for further investigation. On grafted trees most of the galls occur at the lower end of the scion at the point of union with the root. The author states that the work of the previous 2 years is being repeated in different localities, in all 120,000 apple seedlings and root grafts being under observation.

Observations on some vine diseases in Sonoma County, California, O. Butler (*California Sta. Bul. 168, pp. 29, pl. 1, figs. 5*).—Descriptions are given of the red-leaf disease, grape shrivel, and root rot, all of which have been under investigation by the author during the past year or more.

The red-leaf disease, which was first noticed in 1903, is treated at some length, a description being given of the disease, its relationships and resemblance to other diseases pointed out, and the results of experiments for its control presented. The red-leaf disease may affect the shoots, leaves, peduncles, pedicel, and fruit of the vine; the canes on one side or, more rarely, the entire vine may be attacked. The effect that is produced on these different plant organs is described at length. The disease seems to be more or less closely related to folletage, rougeot, and the California vine disease, most nearly resembling the rougeot.

Winter and summer spraying experiments have been carried on for the control of this disease, and while the vitality of the vines seemed to be increased, as shown by the greener appearance of the foliage, yet the treated vines did not show any very great improvement over the untreated ones. The author believes that the red-leaf disease is due to the same causes as folletage and rougeot, namely, a disturbance of equilibrium between the absorption of water by the roots and its transpiration by the leaves. An examination of the soil showed that it was very deficient in phosphoric acid, and it is thought that proper fertilization will help the vines to at least withstand the red-leaf disease.

Grape shrivel is the name given a disease which is characterized by the shriveling of the berries. This shriveling seems to be the most important character of the disease, the symptoms appearing in the leaves being easily referable to drought or imperfect nutrition. The fruit of diseased vines, when it does not shrivel, often ripens prematurely. This prematurely ripened fruit is frequently edible, though at times very distasteful. The disease does not show on the foliage at first, but later is characterized by a discoloration of the leaves, which seems to be caused largely by changes in chlorophyll. No external indications are shown on the vines, but when cut in cross or longitudinal sections the wood and pith show discolorations.

Experiments carried on with a number of varieties, in which different methods of treatment were tested, have led to the conclusion that the cause of grape shrivel is due to imperfect nutrition. It was found that different varieties and different stocks were affected quite differently, and in combating this disease account must be taken of the affinity between the stock and the graft and of the resistance of the stock to phylloxera. The resistance of the stock to the phylloxera may be heightened by fertilization, but if this is not sufficient a change should be made to a more resistant stock. The use of carbon bisulphid in protecting stocks of low resistance from attacks of phylloxera is not under present conditions considered an economic possibility.

The root rot is of fungus origin and in its usual form is recognizable by the soft, watery, yellowish-brown woody cylinder, which is more or less permeated with the mycelium of the parasite. The disease usually takes from 2 to 5 years to kill the

vines, although in some rare cases they have been killed in a single season. The growth of vines affected with the root rot resembles that of vines affected with phylloxera, but in the rapid form of the disease there is no gradual wasting away. The foliage of the vines becomes chlorotic and, if the weather is unfavorable, the leaves rapidly dry up and fall off.

As soon as the disease appears in the vineyard, all badly affected vines should be removed, and the vines surrounding them treated with a 3 per cent solution of copper sulphate or a 7 per cent solution of iron sulphate. This may be done by digging a small basin about the trunk of the vines and pouring into it a gallon or more of either solution. Vineyards once affected with this disease are, unless thoroughly drained, always subject to it. Therefore it is essential that portions of vineyards which are replenished should be treated every 2 or 3 years by one of the methods above described. The root rot is said to attack many varieties, but some seem to be less subject to this rot than others, and such should be employed as stock for grafting.

Fungus diseases of cacao, L. LEWTON-BRAIN (*West Indian Bul., 6 (1905), No. 1, pp. 85–94*).—Descriptions are given of canker of cacao due to *Nectria* sp., die back caused by *Diplodia cacaoicola*, the brown rot of the pods due to the same fungus, and the ripe rot caused by *Phytophthora omnivora*.

The thread blight, caused by an undetermined fungus, is described at considerable length. This disease is said to be very characteristic, the fungus appearing as dark-brown threads or strands, closely appressed to the bark. When young the threads are thin and white, but they become dark after having attained a good attachment to the bark. The fungus spreads by means of its mycelium and can be kept in check only by thorough and constant pruning, to which the author recommends the additional treatment of spraying with a lime-sulphur wash.

A disease of conifers (*Jour. Bd. Agr. [London], 12 (1905), No. 3, pp. 177–179, fig. 1*).—The occurrence on spruce seedlings of the fungus *Herpotrichia nigra* is reported.

The fungus had attacked the leaves causing their destruction, but instead of falling from the dead plants they were bound together by mycelium and remained as a compact brown mass about the branches upon which they had grown. This parasite is said to be most prevalent in nurseries at rather high elevations, and has been reported as attacking spruce, mountain pine, juniper, etc. Its occurrence has been noted in Germany and Norway for some time, but it has only been recently observed in Great Britain. On account of the serious nature of the attack, all diseased seedlings should be collected and burned as soon as observed.

Larch canker (*Jour. Bd. Agr. [London], 12 (1905), No. 5, pp. 307–310, figs. 5*).—A description is given of a wound parasite (*Dasyscypha calycina*) which attacks the European larch to an injurious extent. The canker seems to be especially associated with the larch aphis (*Chermes laricis*), and to prevent injury by the aphis it is recommended that seedlings and young trees should be sprayed with a kerosene emulsion. As a rule, trees under 10 years of age attacked by canker are either killed outright or their growth is badly stunted, and all precautions should be taken against frost injuries, improper situation in planting, insect punctures, etc.

Spraying machines, W. E. BEAR (*Jour. Bd. Agr. [London], 12 (1905), No. 1, pp. 8–18, figs. 10*).—Descriptions are given of a number of forms of hand and power spraying apparatus. The comparative merits and efficiency of the different classes of machines are shown.

ECONOMIC ZOOLOGY—ENTOMOLOGY.

Zoological yearbook, 1904, P. MAYER (*Zool. Jahresber., 1905, pp. VIII+640*).—As in former annual reports of this author, brief abstracts are given of the more important investigations published during the year on the different groups of the

animal kingdom. Extensive bibliographies are presented, including titles of the abstracted articles and also numerous less important ones.

The bobwhite and other quails of the United States in their economic relations, S. D. JUDD (*U. S. Dept. Agr., Bur. Biol. Survey Bul. 21, pp. 66, pls. 2, figs. 10*).—The food habits and economic importance of the 7 species of quail known to occur in the United States are discussed in some detail.

Particular attention is given to a study of the bobwhite for the reason that this bird has been more carefully observed and its feeding habits are better known. From an examination of 918 stomachs of the bobwhite it was found that its food consisted of about 83 per cent vegetable matter and 16 per cent animal matter. The vegetable food consists of grain, weed seeds, and other material. A long list is given of the species of weed seeds found in the stomachs of bobwhites. The insect food is discussed according to its systematic position. Similar accounts are presented of the masked bobwhite, California quail, gambel quail, mountain quail, scaled quail, and Mearns quail.

The feeding habits of all the species of quails considered in the bulletin are quite similar, the variations which occur being partly referable to the variable food in the different parts of the country. The bobwhite is the only species which appears in the Eastern States, while the others are generally distributed from Texas to Oregon. The range of these species is continuous along the southern border of the country, but along the northern border there is an extensive interruption in the Great Plains.

Birds known to eat the boll weevil, V. BAILEY (*U. S. Dept. Agr., Bur. Biol. Survey Bul. 22, pp. 16*).—On account of the serious damage caused by the boll weevil in the Southern States, a special effort was made to obtain reliable information concerning birds which feed upon this pest and the amount of assistance which may be expected from them in protecting the cotton crop.

Considering the fact that for the past 12 years the weevil has been steadily spreading over the cotton belt, it appears that birds can not be depended upon to exterminate the pest. As a result of field observations and examination of birds' stomachs in the laboratory a considerable list of birds was determined as feeding upon the weevil. This list includes Carolina wren, titlark, tomtit, western meadow lark, Florida meadow lark, common phoebe, redwing blackbird, white-throated sparrow, western savanna sparrow, brown thrasher, Texas bobwhite, brewer blackbird, cowbird, jackdaw, mockingbird, butcherbird, killdeer, and others of less importance.

The total number of stomachs examined, exclusive of mourning doves and quail, was 570 and of this number 78 contained boll weevils. The weevils were not numerous at the time when the birds were collected. As a result of his study of the question, the author urges the protection of insectivorous birds within the cotton belt.

Bacteria used in the destruction of rats and mice, L. BAHR (*Centbl. Bakt. [etc.], 1. Abt., Orig., 39 (1905), No. 3, pp. 263–274*).—Thus far the bacteria which have been used for the destruction of rats and mice belong to the Coli group.

The bacteria used against rats include the forms cultivated and recommended by Danysz and Issatschenko. Mice are much more susceptible to bacterial infection than rats and succumb to the action of certain bacteria toward which rats are quite immune. A number of feeding experiments were carried out during which rats were fed cultures of Ratin. These cultures produce either an acute infection with enteritis and septicemia without involving the lungs or a chronic infection which exhibits pulmonary symptoms. When Ratin was fed to various species of mice, including *Mus musculus* and *M. agrarius*, the following results were obtained:

White mice, grey house mice, field mice, red mice, and wood mice were nearly all destroyed by the culture. *Mus agrarius*, horse, dog, fowls, cat, and calves 2 months old were not affected in any way by receiving the cultures. Young sucking calves, however, showed considerable weakness accompanied by enteritis, enlarged spleen,

and other symptoms. The author believes, therefore, that some precaution must be observed in the use of these cultures in order to avoid the infection of farm animals.

Entomological department, R. A. COOLEY (*Montana Sta. Rpt. 1904, pp. 225–232*).—Grasshoppers were less injurious than in previous years. A test of the Criddle mixture gave somewhat unsatisfactory results in the hands of ranchers. Some injury was caused to apple trees by a cicada (*Tibicen cruentifera*). Notes are also given on spotted blister beetle, apple aphis, cabbage aphis, field mice, and honey bees.

A circular of information, J. KOTINSKY (*Bd. Comrs. Agr. and Forestry Hawaii, Dir. Ent. Circ. 1, pp. 8*).—The work of the division of entomology is briefly described, with notes on the collection and study of insects.

The western cricket, C. P. GILLETTE and S. A. JOHNSON (*Colorado Sta. Bul. 101, pp. 16, pls. 2*).—*Anabrus simplex* first attracted attention as a pest in Colorado in 1904.

The eggs are deposited about July 1, to a depth of about 1 in. preferably on hills. In some cases 2,000 to 3,000 eggs were counted per square foot of soil. The crickets feed on range grasses, sage brush, cereals, alfalfa, potatoes, garden vegetables, etc. The pests may be herded away from cultivated crops or may be kept away by ditching or fencing. They may also be killed with kerosene, crude oil, or poisoned bait. Plowing, burning, and crushing are also mentioned as remedies. Certain dry hills seem to constitute the permanent home of the pests, but migration takes place when the eggs hatch in large numbers. The insects travel only by daylight.

Leaf hoppers and their natural enemies, R. C. L. PERKINS (*Hawaiian Sugar Planters' Sta., Dir. Ent. Bul. 1, pts. 1, pp. 1–70; 2, pp. 71–85, pl. 1; 3, pp. 86–118, pls. 4; 4, pp. 119–158, pls. 3*).—The parasites of leaf hoppers considered in the first part belong to the family Dryinidæ.

This family appears to confine its attacks to leaf hoppers. A detailed description is given of the method of attack, the effectiveness of these parasites in controlling the leaf hoppers, and other points in their life history. In this discussion the genus Echthrodelphax and other related genera are taken as typical cases. Apparently all leaf hoppers which become parasitized with Dryinidæ are ultimately thereby destroyed. The anatomy of these parasites is discussed, and a systematic account is presented to assist in the identification of species, many of which are described as new.

Agamopsyche threnodes, described in detail in the second part, is parasitic on the sugar-cane leaf hopper and appears to be parthenogenetic. Sometimes more than one larva is found on a single leaf hopper, but perhaps only one reaches maturity. The parasite is referred to a new family described under the name Epipyropidæ, and several other new species of this family are described under the genera Paleopsyche and Heteropsyche.

In the third part the anatomy, systematic position, and life history of the Stylopidæ are discussed, with notes on the effect of their parasitism on leaf hoppers. The male parasites usually have a more serious effect on the host than do the females, and the host is killed. The genera Halictophagus and Elenchus are defined and notes given on the larvæ and puparia of Stylopidæ. Various species of these genera are described, many of them as new.

The fourth part is devoted to a consideration of the family Pipunculidæ. The majority of species in this family belong to the genus Pipunculus, and about 80 species have been recorded for this genus. The flies under discussion are parasitic on various families of Homoptera, including Cercopidæ, Jassidæ, and Fulgoridæ. The anatomy and life history of the genus is discussed in some detail for different stages. A number of species from Australia and Hawaii are described as new, and an analytical table is presented to assist in their ready identification. A brief bibliography of the subject is appended to the bulletin.

Late fall spraying for the San José scale, J. B. SMITH (*New Jersey Stas. Bul. 186, pp. 14, figs. 6*).—Tests were made of the effectiveness of insecticide application

in the fall as opposed to spraying in the spring. In some cases the applications were made before the foliage had fallen. A number of proprietary soluble petroleum insecticides were used as well as lime and sulphur and kerosene-limoid. In general the damage to the foliage even of peach trees was slight, while the scales were effectively destroyed. The author believes that fall spraying is more effective than spring spraying and that the fall should be generally recommended as the proper time for insecticide applications against scale insects.

Experiments during the summer of 1905 indicate that summer applications of insecticides for scale insects can not be depended upon to do more than hold the scale in check while considerable harm to the trees may result. During these tests in summer spraying tobacco extracts, fish-oil soaps, kerosene emulsion, crude and distillate petroleum, kerosene-limoid, and various combinations of lime and sulphur were used. In all cases the effect upon the scales was unsatisfactory or the trees were too much injured.

As a result of the author's experiments along this line it is recommended that trees be sprayed in New Jersey as soon as possible after October 15 or as soon as the leaves begin to mature. In case of bad infestation it may be well to repeat the application within two weeks. With regard to a choice of insecticide the author prefers the mineral oils and several proprietary preparations of these oils in a soluble form. It is urged, however, that none of the oil emulsions should be allowed to get cold and that they should be used in as fresh a condition as possible. In the author's opinion the second choice falls on kerosene-limoid and the third on lime and sulphur combinations. The life history of the scales is also discussed.

Peach insects, R. I. SMITH (*Ga. Bd. Ent. Bul. 17, pp. 55–105, figs. 23*).—This bulletin, as stated by the author, contains practical information prepared to meet the growing demand of peach raisers for directions concerning the control of insects injurious to peach trees. The important insects of peach trees are discussed with detailed notes on their appearance, habits, life history, and control. The more important species considered are San José scale, Putnam scale, cherry scale, peach lecanium, West Indian peach scale, plum pulvinaria, fruit-tree bark-beetle, peach-tree borer, plum curculio, plant lice, and tent caterpillars.

The gypsy and brown-tail moths, A. H. KIRKLAND (*Off. Supt. Suppressing Gypsy and Brown-tail Moths* [*Mass.*], *Bul. 1, pp. 27, pls. 11, figs. 9*).—A copy is given of the recent Massachusetts law relating to gypsy and brown-tail moths. According to this law a superintendent for suppressing the gypsy and brown-tail moths is appointed and an appropriation of $300,000 made available for use during the years 1905–1907. The present bulletin is largely occupied with a description of the gypsy and brown-tail moths and an account of their habits, life history, and distribution with notes on the most effective remedies for controlling them.

Trypeta ludens in Mexico, J. ISAAC (*Sacramento: California State Hort. Com., 1905, pp. 40, pls. 4, figs. 17*).—On account of the importance of this pest and the extent of its ravages in Mexico, the California commission sent the author to investigate the present status of the pest in Mexico and the effectiveness of the means adopted there for its control.

The author visited the greater part of the orange-growing districts of Mexico with this idea in view and collected much information regarding the distribution of the pest, its origin, parasites, and other points of importance to California orange growers. The insect is described in detail in all of its stages. It appears that the life cycle requires about 3 months so that there may be 4 generations per year. In the high lands of Mexico the pest appears not to be very common, while in the State of Morelos it is serious.

The remedies adopted in Mexico for the control of this insect include burning or burial of infested oranges, keeping fowls in orange orchards, spraying with an infu-

sion of *Haplophyton cimicidum*. The natural checks to the spread of this pest are changes of temperature and the presence of parasites. *Trypeta ludens* appears not to be native to Mexico but is probably introduced from some part of South America. It attacks not only sweet oranges but also the mango and guava.

The parasitological commission of Mexico recommends that all infested mangoes, lemons, oranges, and guavas be collected daily and deposited in a suitable place for destruction once a week. Such fruit should be destroyed either by burning or burying to a depth of 20 in.

Insects of the pecan, H. A. GOSSARD (*Florida Sta. Bul. 79, pp. 281–318, pls. 7, figs. 2*).—The present bulletin contains essentially a brief monograph of the important insect pests of the pecan.

Pecan bud-moth (*Proteopteryx deludana*) is one of the most serious of these pests. The insect is described in its different stages and notes are given on its habits. Several natural enemies are known, but their effectiveness is not yet determined. Spraying with arsenicals including Paris green and arsenate of lead did not give encouraging results. The use of lime-sulphur-salt wash was much more satisfactory. Infested pecan buds were fumigated for 30 minutes with hydrocyanic-acid gas. The buds were not injured by the treatment, but the moths seemed not to be destroyed. Not more than 15 to 20 per cent of the buds survived on account of later infestation. In nursery practice it seems to be necessary to remove the cocoons with a knife.

The pecan case-borer (*Acrobasis nebullela*) is also a serious pest and is described with notes on its habits and life history. This pest is also attacked by parasites and birds. In the control of this insect it appears that the remedies most successful in use against the pecan bud-moth are also best for use against this species. Notes are also given on the appearance, habits, life history, and means of combating species of Catocala, *Sesia scitula*, *Datana integerrima*, fall webworm, twig girdlers, oak pruner, hickory-nut weevil, hickory bark-borer, white ant, cottony maple scale, etc.

Insects injurious to forests, A. L. HERRERA (*Com. Par. Agr.* [*Mexico*] *Circ. 29, pp. 4, figs. 8*).—Particular attention is given in this circular to a discussion of Dendroctonus and related forest insects with reference to artificial insecticides and methods which have been found to be effective in controlling these pests and also to their natural enemies.

Texas fever ticks (*Oklahoma Sta. Rpt. 1905, pp. 28–30*).—Attention is called to those features in the life history of cattle ticks which makes it possible to exterminate the tick by a system of rotation of pastures and direct treatment of cattle for tick infestation. The great advantages of tick extermination are briefly discussed.

Means for the destruction of mosquitoes, A. F. MANKOWSKI (*Centbl. Bakt.* [*etc.*], *1. Abt., Orig., 39 (1905), No. 3, pp. 277–279, figs 3*).—Brief reference is made to experiments previously carried out by other investigators in the infection of mosquitoes with various species of bacteria.

In the study of mosquitoes in Bessarabia a mite was found infesting mosquitoes under the wings and various other parts of the body. An examination of the parasites showed them to be undoubted mites about $\frac{3}{8}$ mm. long. From one to six parasites were found on each infested mosquito, and about 30 per cent of all mosquitoes studied were infested. The importance of this parasite appears to be quite great, since the number of mosquitoes and the extent of malaria were considerably reduced during the year.

Report of the inspector of fumigatien appliances, 1904, P. W. HODGETTS (*Toronto: Ontario Dept. Agr., 1905, pp. 11, figs. 3*).—The practices of various nurserymen with regard to transplanting and handling of stock are briefly described. The effects of severe winter cold upon San José scale were studied. It was found that the severity of winter had little effect in controlling the numbers of the scale. The insect was more seriously affected by cold on peach and plum trees than on apple trees. In

the author's opinion the lime and sulphur wash is the best remedy for the San José scale.

Annual report of the Beekeepers' Association of the Province of Ontario for 1904 (*Ann. Rpt. Beekeepers' Assoc. Ontario, 1904, pp. 87, figs. 4*).—At the 25th annual meeting of the Ontario Beekeepers' Association, held in Toronto November 15–17, 1904, a number of papers were read which may be briefly noted in this connection.

The general status of beekeeping was discussed in the president's address by J. W. Sparling. A paper on extracted honey, read by M. Pettit, suggested that all white honey should be removed by the first of August in order to avoid any mixture of dark honey. In the production of extracted honey it is recommended that the weather, climate, and locality be studied in order to choose the most suitable breed of bees and style of hives. Honey should not be extracted until well ripened, and should be sealed up as soon afterwards as possible.

F. C. Harrison spoke on the diseases of bee larvæ, calling attention to the principal means by which contagion is spread among bees, and giving detailed notes on foul brood, black brood, pickled brood, chilled brood, and starved brood. It is thought that some of these terms may be synonymous, as it seems unlikely that all are distinct diseases.

Papers were also presented on A Season with the Bees and How to Manage Them, by A. E. Hoshal; The Influence of Bee Journals, by W. J. Craig; Queens and their Influence on Bee Culture, by W. Z. Hutchinson; Foul Brood, by H. J. Sibbald; Winter Losses, by W. F. Holtermann; Sanfoin as a Bee Plant, by J. Fixter; Prevention and Control of Swarming by Means of the Hedden Hive, by J. D. Miller.

J. Fixter presented the results of experiments upon methods of protecting hives for outside wintering, a study of cellars for wintering bees, methods of introducing queens, and feeding with honey and sugar in winter quarters.

Bee products in Arizona, R. H. Forbes (*Arizona Sta. Bul. 51, pp. 523–532, figs. 2*).—Statistics are presented regarding the present status of apiculture in Arizona. A list is given with times of blooming of the more important honey crops of the Territory. At present, alfalfa is less available than formerly as a honey crop, on account of the fact that it is cut at an earlier stage than in previous years, and also on account of the prevalence of the alfalfa butterfly which feeds upon the honey. Determinations were made of the sugars contained in the flowers of alfalfa and certain native bee plants.

The quality and composition of samples of Arizona honey are also discussed. The average amount of moisture in honey from Arizona was found to be about 2 per cent less than that of eastern honey. The ash was of about normal quantity and composition. Analytical data are presented regarding honey samples and notes are given on adulteration and by-products. The honey of Arizona contains a maximum amount of sugar and very little nonsaccharine substances and is usually of desirable color and flavor. In liquefying honey it is recommended that the process be carried on at a comparatively low temperature in order to avoid injuring the quality.

Sericulture, P. Vieil (*Sériculture. Paris: J. B. Baillière & Sons, 1905, pp. VIII+360, figs. 50*).—This volume is one of the series which constitute the agricultural encyclopedia published under the direction of G. Wery.

The subject is discussed under 7 heads, including the history of sericulture; anatomy and physiology of the silkworm; diseases of the silkworm; rearing silkworms; care and production of the silkworm eggs; the qualities, treatment, and manufacture of silk; and artificial silks, including silks from other sources than the true silkworm. In an appendix the author discusses the culture of mulberries.

The silk-growing season of 1904, G. McCarthy (*North Carolina Sta. Rpt. 1904, pp. 55, 56*).—It is reported that public interest in silk growing continues to increase.

A number of silk growers' associations have been formed, silk manufacturing plants have been established, and instruction given in silk raising in industrial schools. It is believed that when properly carried on, the business of silk raising may bring reasonably profitable returns to children and adults who are incapable of doing severe manual labor.

FOODS—HUMAN NUTRITION.

Studies of the digestibility and nutritive value of bread and of macaroni at the University of Minnesota, 1903–1905, H. SNYDER (*U. S. Dept. Agr., Office Expt. Stas. Bul. 156, pp. 80, pls. 4, fig. 1*).—Continuing earlier work (E. S. R., 15, p. 63), digestion experiments were made with different grades of flour ground from Oklahoma hard winter wheat and Oregon soft winter wheat. In 18 experiments with men, white (straight-grade) flour was more completely digested than either Graham or entire-wheat flour, and yielded a larger amount of digestible nutrients and available energy.

In 3 digestion trials, in which finely pulverized bran was added to white flour in the same proportion as is removed in milling, the addition of the bran lowered the digestibility of the flour so that a smaller amount of digestible nutrients and available energy was obtained from the bran flour than from the white flour with which the bran was mixed.

In 3 digestion trials, in which finely pulverized wheat germ was added to white flour in the same proportion as is removed in milling, the addition of the germ did not materially change the digestibility of the flour, and the amount of total digestible nutrients and available energy in the germ flour and the white flour was about the same. There was no material gain in total digestible nutrients by the addition of the germ to the white flour. The germ flour produced a smaller sized, sweeter, but less porous loaf than the white flour. Because of its fermentable character wheat germ is excluded from white flour.

Studies were also made of the digestibility of macaroni made from American-grown durum wheat, of breakfast foods made from the same sort of wheat, and also of the changes which take place in semolina in macaroni making.

According to the author, during the process of manufacture of macaroni water is removed in drying the macaroni and the starch and gluten apparently undergo a slight hydration. When macaroni is cooked in water about 2.25 per cent of the soluble matters present are extracted, which suggests that as little water as possible should be used in cooking the macaroni when strict economy is desirable.

As shown by experiments with healthy men, the macaroni used had approximately the same digestibility and supplied about the same amount of nutrients, pound for pound on a dry-matter basis, as bread made from straight-grade flour. Consuming either large or small amounts of bread made from durum wheat flour with the macaroni exercised no appreciable effect upon the digestibility of the nutrients and the availabillty of the energy present.

The durum wheat breakfast food resembled quite closely in composition the macaroni made from similar wheat. It was not quite as thoroughly digested, though its digestibility was fairly high as compared with many vegetable foods. The observed differences in digestibility of the breakfast food and the flour products are undoubtedly due to methods of manufacture, the flour products being rather finely ground and therefore in a condition favorable for the action of the digestive juices.

The contamination and adulteration of bread and of the milling products employed in its preparation, H. STIEGELER (*Pure Products, 1 (1905), No. 5, pp. 245–251*).—Weed seeds, mineral adulterants, inferior starches, and other adulterants of wheat and bread are spoken of, and methods of detection briefly noted.

Gluten bread (*Lancet [London], 168 (1905), No. 4260, p. 1075*).—An analysis is briefly reported.

Malt extract in bread making, R. L. CORBY (*Pure Products, 1 (1905), No. 4, pp. 187-189*).—The effect of substituting malt extract for cane sugar in bread making is discussed, the data presented being on the whole unfavorable to this practice.

Wheaten flour, T. MACFARLANE (*Lab. Inland Rev. Dept. [Canada], Bul. 98, pp. 14*).—Data are given regarding the analysis of 75 samples of flour purchased in open market in different districts of the Dominion of Canada and 11 samples of known characteristics which were examined for purposes of comparison.

No indication was found of adulteration with mineral matter or with other and lower priced grains than wheat. In the case of part of the samples the analyses were more detailed than with the remainder, special attention being paid to the material soluble in alcohol, i. e., reducing sugar or dextrose, sucrose, nonnitrogenous substances, and gliadin.

In addition to other constituents the amount of material extracted by water after treatment with alcohol was also determined. The extraction with alcohol was carried on in Macfarlane tubes, the flour sample being distributed through crysotile fiber and the tubes furnished with an asbestos filtering bed. The gluten and gliadin content of the flour samples and related topics are discussed.

Cereal foods, L. H. MERRILL (*Maine Sta. Bul. 118, pp. 117-135*).—The classification of cereal breakfast foods, their composition, manufacture, relative economy, etc., are discussed and digestion experiments reported in which several different brands constitute varying proportions of the diet. The following table summarizes the experimental data:

Coefficients of digestibility of cereal breakfast rations and cereal breakfast foods alone—Experiments with men.

Diet.	Number of experiments.	Total organic matter digested.	Protein digested.	Proportion of total energy in digested food.
		Per cent.	*Per cent.*	*Per cent.*
Rolled oats with a mixed diet	17	96.2	90.1	95.3
Rolled oats with a simple diet	16	95.4	84.7	94.2
Rolled oats alone	16	92.3	78.4	89.8
Rolled wheat with a mixed diet	3	96.2	93.2	95.3
Rolled wheat with a simple diet	3	95.2	91.6	94.6
Rolled wheat alone	3	92.4	85.0	90.7
Force with a mixed diet	3	95.7	92.7	95.2
Force with a simple diet	3	94.6	89.6	91.1
Force alone	3	90.4	76.1	88.8
Grape-nuts with a mixed diet	3	96.6	92.8	95.6
Grape-nuts with a simple diet	3	94.0	87.6	93.1
Grape-nuts alone	3	91.7	76.1	89.4
Shredded whole wheat with a mixed diet	3	95.5	92.1	94.5
Shredded whole wheat with a simple diet	3	92.8	84.1	91.4
Shredded whole wheat alone	3	87.7	57.7	84.1
Hecker's hominy with a mixed diet	4	97.1	88.9	96.3
Hecker's hominy with a simple diet	4	97.3	83.6	96.4
Hecker's hominy alone	4	....	74.5	94.4
Granulated corn meal, mixed diet	2	97.2	89.0	96.9
Granulated corn meal, simple diet	4	97.2	82.3	95.9
Granulated corn meal alone	4	....	73.2	93.1

"Where the cereals were used with a mixed diet they had but little apparent effect upon the digestibility of the total food. As regards the digestibility of the total organic matter, the corn products made a very favorable showing. At the same time a larger proportion of the energy of the food was utilized by the body than where the wheat and oat products were used. On the other hand, the use of the corn foods seemed to depress the digestibility of the protein of the total food.

"When the simple diet was used, the corn products again made a favorable showing as regards both total organic matter and energy, least favorable of all, however, in digestibility of protein. If we value these foods in proportion to the digestibility of their protein when used with a mixed diet, we must place rolled wheat first and the corn products last.

"When the digestibility of the cereals alone is calculated, more striking results are obtained. It will be noticed that the rolled wheat now ranks first, not only in the digestibility of the total organic matter, but also with respect to the protein. The rolled oats rank next, and the corn preparations and shredded wheat the lowest of all.

"One of the most noticeable differences in these cereal foods is found in the digestibility of the protein when the cereal is eaten with a simple diet. This difference is most marked in the various wheat products, especially when the results are calculated to the cereal alone."

The nitrogen content of barley and malt, PRIOR (*Allg. Ztschr. Bierbrau. u. Malzfabrik., 32 (1904), p. 231; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 9 (1905), No. 7, pp. 426, 427*).—The author discusses the relationship between nitrogen content and the quality of malt, and outlines experiments which he proposes to undertake.

The distribution of nitrogenous material in barley, E. JALOWETZ (*Allg. Ztschr. Bierbrau. u. Malzfabrik., 32 (1904), pp. 259, 260; abs. in Ztschr. Untersuch. Nahr. u. Genussmtl., 9 (1905), No. 7, p. 426*).—According to the author's investigations, the upper part of the grain (water free) contained 17.75 per cent protein, the middle portion 11.19 per cent, and the lower end 14.44 per cent. The data are discussed with relation to malt making.

The purin bodies of food stuffs, I. W. HALL (*Philadelphia: P. Blakiston's Son & Co., 1904, 2. ed., rev., pp. 202 + XIII, pls. 2, fig. 1*).—In this second and revised edition the author states that part of the volume has been rewritten and new matter added, including the results of analyses, experimental and bibliographical data, etc.

Among the questions discussed are the chemistry and physiology of food purins, methods of estimating food purins and their action, the fate of such bodies in metabolism, the effect of drugs upon the elimination of purin bodies, purins in relation to disease, and related topics, the volume as a whole being a digest of his own investigations and those carried on by others. The author has devised an improved method of estimating purin bodies and reports data showing the amount present in different food products.

Some of the general conclusions follow: "Of the known purin bodies, hypoxanthin, xanthin, guanin, and the methyl-xanthins, caffein and theobromin are found in food stuffs, and uric acid and traces of xanthins and methyl-xanthins are met with in the urine. . . . In food stuffs, the purin bodies occur in 2 forms, 'free' and 'bound.' Both the glandular and muscular tissues contain approximately equal amounts of 'free-purins,' but the glandular tissues yield very large and the muscles only very small quantities of bound-purins (nucleins).

"The estimations of the purin bodies contained in meats show that considerable quantities are present, but that little difference exists between the amounts contained in white and dark meats. Certain vegetable foods have been found to contain purin bodies. Amongst these are peas, beans, oatmeal, asparagus, and onions. This furnishes a reason for the high uric acid excretion which follows their ingestion. From several varieties of beer and porter purin bodies have been isolated, and their percentage amounts estimated."

Urinary purin occurs principally in the form of uric acid. In experiments reported the amount was increased by feeding fish, fowl, beef, beans, and beer. "The increase of urinary purin reflects the metabolic activity of the individual in regard to nucleins. The feces may contain unabsorbed nucleins as well as certain purin sub-

stances from the digestive juices and cell nuclei, and estimations of these bodies should be included in all metabolic experiments.

"When the 'free' purins are injested, they are rapidly oxidized and decomposed. About 50-60 per cent of hypoxanthin leaves the body as urinary purin (principally uric acid) within 4-6 hours, and the same percentage of uric acid appears in the urine after 8-10 hours. The bound purins, however, take 1-2 days before they are fully excreted. The remaining 50 per cent of the food purin is excreted as urea, or as bodies intermediate between uric acid and urea.

"By the quantitative estimations of purin bodies in food stuffs an exact forecast of the exogenous urinary purin is possible, and its amount can be limited when necessary by prescribing a certain diet. . . . The endogenous purin is partly derived from leucocytes, but mostly from the cell changes which result in the maintenance of bodily functions. . . . Uric acid is a necessary result of normal nuclein metabolism. In disease it is symptomatic of conditions which hinder or prevent its solubility and excretion, and does not itself cause the lesions which accompany uricacidæmia." The volume contains an extended bibliography of the subject.

Heat values and food values, H. P. Armsby (*Reprinted from Arch. Ped., 22 (1905), Feb., pp. 124-130*).—The author discusses body temperature, the production and liberation of heat in the animal body, and related questions.

He points out that the production of heat in the animal body is incidental to the vital processes, and the heat so produced may to a considerable degree be regarded as an excretum, the body temperature within limits being due to a condition of equilibrium between heat production and heat elimination. "It is important to note, however, that it is not until the original chemical energy has served its physiological purposes that it takes the form of heat. It is not first converted into heat, which is then further converted into muscular or other work; but, on the contrary, it first gives rise to the muscular or other energy required, and the latter, in performing its functions, is degraded into heat.

"In other words, we have no evidence that the animal body is a form of heat engine. It is evident, then, that at least a part of the heat production of the animal is incidental to other purposes. At the same time, of course, the heat thus produced is available to maintain the body temperature, and the question at once arises whether the supply thus incidentally provided is sufficient, or whether additional body tissue must be metabolized simply for the sake of producing heat."

In order to maintain approximately the same body temperature, heat must be eliminated at the same average rate at which it is produced, the three principal ways of eliminating heat being by conduction, radiation, and by the vaporization of water. These processes are collectively referred to as physical regulation, and act through a considerable range of temperature. "Necessarily, there is an upper limit beyond which these means of getting rid of heat become insufficient, and the fatal heat stagnation begins. As we go below this limit the tendency of a falling temperature to withdraw heat from the body more rapidly is met by changes the reverse of those just . . . [referred to], and by their means the outflow of heat is kept practically constant and there is no increase in the amount of heat produced, but rather a slight decrease.

"As we follow this experimentally, however, we reach a point, known as the critical temperature, at which the possibilities of this physical regulation appear to reach their lower limit. The facility with which the surface of the body eliminates heat can not be further reduced, and a continued reduction of the external temperature is met by a marked increase in the heat production—the so-called 'chemical' regulation. The answer to our initial question, then, is that at or above the critical temperature the incidental heat production due to the internal work of the body suffices, or more than suffices, to maintain its normal temperature, while below that point additional body material must be oxidized for this special purpose."

The increased production of heat after food is taken, due to the processes of digestion, the different amounts of heat produced by different foods, and related questions are spoken of. The author points out that the amount of energy required to digest different foods varies, and that this must be taken into account in considering their true energy value.

"The food value of a nutrient as a source of energy to the organism is not measured by the total energy which it can liberate as heat in the body, but by the part of this energy which is available to the organism for physiological uses. The remainder of the 'fuel value' simply serves to increase the generation of heat in the body, a result which may be advantageous or the reverse, according to the surrounding conditions."

Concerning the natural feeding of infants, M. RUBNER and O. HEUBNER (*Ztschr. Expt. Path. u. Ther., 1 (1905), No. 1, pp. 1-25*) —In the experiments reported a healthy infant was under observation for 8 months from birth, and data are recorded regarding the amount of food eaten, the gains in weight, etc. During 5 days, when the child was 5.5 months old and weighed nearly 10 kg., the income and outgo of carbon and nitrogen were determined

For 4 days the food consisted entirely of mother's milk. On the fifth day the child was given a tea which furnished so little nutritive material that this was essentially a fasting period. The composition and energy value of the food and excreta were determined. The respiratory products were measured with a respiration apparatus especially constructed for the experiments, the total amounts of carbon dioxid and water excreted in 24 hours being calculated from the amounts determined for shorter periods.

Disregarding the first day of the milk period, the average amount of nitrogen taken per day was 1.99 gm., the amount excreted in the urine 1.13 gm., and in the feces 0.4 gm. In other words, there was an average daily gain of 0.46 gm nitrogen. The daily diet furnished 63.7 gm. carbon The average amount excreted in the urine was 1.41 gm., in the feces 2.71 gm., and in the respiratory products 61.68 gm., which is equivalent to an average daily loss of 2.1 gm. carbon. During the tea or fasting period the diet contained no nitrogen nor carbon. The total amount of nitrogen excreted in the urine was 1.18 gm. In other words, the body lost this amount in 24 hours. The urine contained 1.29 gm. carbon and the respiratory products 59.5 gm., i. e., there was a loss of 60.79 gm.

The authors discuss the gain in nitrogen and the loss of carbon on the experimental days in which food was taken and explain the apparent discrepancy on the basis of changes in the water content of the body. A comparison of the amount consumed and furnished by the oxidation of food materials with the quantities excreted shows that actually there was a considerable gain of water.

Deducting the energy value of the excretory products from the total amount supplied by the food, the authors calculated the amount of energy metabolized per day, which was equivalent to 67.6 calories per kilogram body weight, or 1,219 calories per square meter surface area. Examination of the experimental data showed that the body used the nitrogen of the diet very economically.

In connection with the experiments some studies were made of the assimilation of nitrogen on a diet of mother's milk as compared with cow's milk. It was calculated that in the case of mother's milk 0.135 to 0.161 gm. nitrogen in the form of true protein was required per kilogram body weight as compared with 0.530 gm. nitrogen in the case of cow's milk. On the basis of the experimental data the amount of nitrogen required is discussed with reference to the diet of both infants and adults, and the fact noted that the quantity may be small provided the energy value of the diet is sufficiently high.

Concerning the mechanism of stomach digestion, P. GRÜTZNER (*Arch. Physiol. [Pflüger], 106 (1905), No. 10-12, pp. 463-522, figs. 13*).—In experiments undertaken

to study the mechanics of digestion animals were killed and the stomachs frozen, the experimental method being described in full.

Some of the author's conclusions follow: It was found that the stomach contents was divided into layers, in general the food which was taken last being surrounded by food taken earlier and thus protected for a time from contact with the stomach walls. The left region of the stomach, the so-called fundus (pars splenica), is the storage portion, and food remains here for hours without coming in contact at all with the gastric juice and during this time the amylolytic action of saliva is continued.

At the same time peptic digestion is going on in the prepyloric and pyloric portions of the stomach, the digestive secretions and muscular contractions being different at different points. In other words, the stomach contents is not at all uniform.

The secretion of ferments and other questions were also studied and discussed.

On the products of digestion of the proteolytic spleen enzym acting in an alkaline medium, E. P. CATHCART (*Jour. Physiol., 32 (1905), No. 3-4, pp. 299-304*).—Using lieno α-protease of Hedin, the following substances were isolated from the products of digestion of coagulated blood serum: Histidin, inactive arginin, lysin, tyrosin, leucin, alanin, amido-valerianic acid, α-pyrrolidin carboxylic acid, glutamic acid, phenylalanin, and ammonia. Aspartic acid was regarded as probably present, as it is formed in large quantity when fibrin is digested by the same enzym.

The influence of fasting and feeding upon the respiratory and nitrogenous exchange, M. S. PEMBREY and E. I. SPRIGGS (*Jour. Physiol., 31 (1904), No. 5, pp. 320-345*).—The experiments reported were carried on with white rats.

Some of the conclusions drawn follow: "During fasting the respiratory exchange quickly reaches a minimum, and then remains remarkably constant during the prolongation of the fast. . . . The effect of food rich in carbohydrates upon the respiratory exchange is well marked within an hour, and steadily increases during the next 2 or 3 hours. The increase in the output of carbon dioxid varied according to the conditions from 14 to 97 per cent of the minimal discharge during hunger." In the majority of cases there was an increase in the absorption of oxygen which ranged from 9 to 35 per cent.

"The increase in the discharge of carbon dioxid after a meal rich in carbohydrates appears to be due to a general increase in the metabolic processes of the body, including the formation of fat, and not solely to the work of digestion. . . . A fast preceding a meal serves as a marked stimulus to the assimilation of food. . . . The respiratory quotient is probably the resultant of quotients above and below the theoretical values for the combustion of proteids, carbohydrates, and fats."

In connection with part of the work an attempt was made to study nitrogen metabolism, but this phase of the work was not continued, as, according to the authors, it was not possible to estimate correctly the percentage composition of the living animal from data obtained by the analysis of a control specimen.

Concerning the metabolism of athletes, H. LAVONIUS (*Skand. Arch. Physiol., 17 (1905), No. 1-2, pp. 196-204*).—The studies reported were made with 2 circus performers.

In the 6 days covered by the investigation the daily diet furnished on an average 217.9 gm. protein and 5,070 calories of energy with one of the subjects and 182.2 gm. protein and 4,254 calories of energy with the other. The subjects worked only 2 or 3 hours each day, but the work was very severe. The body weight in each case was about 84 kilograms. In the 2 cases fat supplied 47.6 and 44.8 per cent, respectively, of the total energy of the diet, quantities which the author considers very unusual. In connection with the investigation the income and outgo of nitrogen were determined.

The toxin and antitoxin of fatigue, W. WEICHARDT (*München. Med. Wchnschr., 51 (1904), Nos. 1, pp. 12, 13; 48, pp. 2121-2126*).—The author states that from the

flesh of guinea pigs dead from fatigue he was able to extract a body which injected into guinea pigs and other animals caused all the symptoms of fatigue.

This body was isolated and found to be very unstable in character, and the author considers it a true toxin. When injected into the circulation of horses an antitoxin was produced which in vitro or in animals counteracted the toxin. As shown by a number of experiments the antitoxin can be taken by man without harmful results. In connection with the report of the experiments, the author discusses the characteristic symptoms of fatigue, its effect upon the body temperature, the production of the antitoxin in the body, and related questions.

The relation of cookery to digestion, BERTHA H. BACHELLER (*Quart. Rpt. Kans. Bd. Agr., 24 (1905), No. 93, pp. 234–237*).—A summary of data on changes which take place in cooking different nutrients and related topics.

Shellfish and the bacilli of typhoid (*Brit. Food Jour., 7 (1905), No. 75, pp. 48, 49*).—A note on E. Klein's investigations for the Fishmongers' Company of the time required by oysters and other shellfish to clear themselves of bacilli.

The phosphorescence of eggs and potatoes, A. NESTLER (*Umschau, 9 (1905), No. 13, pp. 255, 256*).—On the basis of the investigations by H. Molisch,[a] the author discusses the phosphorescence sometimes observed in food products, which is due to *Bacterium phosphoreum*. Methods of cultivating this micro-organism are spoken of. Its development, it is stated, does not render the food products harmful.

Some tea curiosities, L. LODIAN (*Tea and Coffee Trade Jour., 8 (1905), No. 5, pp. 212–214, figs. 5*).—Russian tea tablets and other unusual forms of tea are described.

Tea boquets and scented tea, L. LODIAN (*Tea and Coffee Trade Jour., 9 (1905), No. 5, pp. 243–245, figs. 3*).—Compressed tea and other standard and fancy Russian teas are described. It is stated that tea dust may be profitably compressed into blocks.

The examination of the feces, I. S. WILE (*N. Y. Med. Jour. and Phila. Med. Jour., 81 (1905), pp. 475–478; abs. in Jour. Amer. Chem. Soc., 27 (1905), No. 5, p. 277*).—A summary of data on the composition of feces in health and disease.

Food investigations, V. K. CHESTNUT (*Montana Sta. Rpt. 1904, pp. 236, 237*).—Cooperating with M. E. Knowles, some studies were made of meat preservatives and their occurrence in sausage. Preservatives were found in excessive amounts in several samples, but their use was discontinued when the attention of the sellers was directed to the matter. Brief notes are also given regarding a case of poisoning due to eating freshly opened canned salmon, which apparently contained ptomaines.

Report of State analyst, R. E. DOOLITTLE (*Ann. Rpt. Dairy and Food Comr. Mich., 1904; abs. in Jour. Amer. Chem. Soc., 27 (1905), No. 5, pp. 288, 289*).—Of the 1,279 samples of food products examined under the provisions of the State pure-food law 442 samples were adulterated or sophisticated. In connection with the work special attention is given to the use of methyl alcohol in flavoring extracts and to terpenless lemon extract.

Report of work in food laboratory, H. E. BARNARD (*N. H. Sanit. Bul., 2 (1905), No. 7, pp. 108–113*).—In compliance with the State pure-food law 363 samples of canned goods, cider vinegar, cheese, condensed milk, extracts, honey, maple sugar and sirups, molasses, meat products, etc., were examined, of which 164, or 45.2 per cent, were found to be adulterated or to vary from the legal standard. Twenty-three of the 41 samples of sausage and other meat products examined contained borax or sodium sulphite. A sample of cereal coffee was found to contain a large percentage of coffee in addition to roasted cereals.

Fifth report on food products for 1904, B. W. KILGORE (*Bul. N. C. Bd. Agr., 25 (1904), No. 12, pp. 62*).—Of the 347 samples of flour, breakfast foods, meats, canned

---

[a] Sitzber. K. Akad. Wiss. [Vienna], Math. Naturw. Kl., 114 (1905).

goods, dairy products, etc., examined, 59 samples, or 17 per cent, were adulterated or sophisticated.

No adulteration was detected in the case of the flour, breakfast food, canned fruit, cocoa, butter, cheese, and whiskies examined. The following special articles in nearly every case give the details of analyses made during the year under the State pure-food law and discuss the results: Chemical Preservatives; Canned Meats; Examination of Canned Fish and Oysters; The Examination of Canned Fruits and Vegetables; Prepared Mustards and Salad Dressings; Whisky; and Examination of Flour, by W. M. Allen; Cocoa and Chocolate, Butter, and Cheese, by J. M. Pickel; Breakfast Foods, by C. D. Harris.

ANIMAL PRODUCTION.

Investigations at the sugar experiment station laboratory for 1904, C. A. Browne, Jr. (*La. Planter, 34 (1905), No. 15, pp. 236–240, fig. 1*).—In connection with the work carried on under the author's direction, analyses have been made of a number of feeding stuffs containing molasses.

In his opinion, one of the best materials which can be used to absorb molasses is bagasse. The sample of bagasse molasses feed, i. e., molascuit, analyzed contained 20 per cent of bagasse and 80 per cent molasses. The rind of the cane, it is pointed out, is not so well adapted as the pith for making such a mixture, as it has only about one-sixth of the absorptive power of the pith and is also much harder to digest. It is also pointed out that under local conditions, cotton-seed meal added to a mixture of bagasse and molasses would compensate for the deficiency of protein in the mixture.

A number of different sorts of Louisiana molasses were analyzed and extensive studies of the solids other than sugar in cane molasses, the fermentation of cane products, and of the effect of temperature upon the polarization of raw cane sugars are also reported, as well as the results of physiological experiments upon the maturing of cane.

In the author's opinion, the results obtained with different sorts of molasses show that "the process of manufacture has much to do with the differences in composition. The open-kettle molasses, being less exhausted than the other grades, has naturally more sucrose and less impurities, such as gums, acids, ash, amids, etc. The diffusion molasses, on the other hand, has a larger percentage of impurities, owing to the greater extraction of these ingredients from the bagasse. The effect of liming upon the different samples is very pronounced, those which have received the heaviest treatment being the highest in gums and combined acids. A large part of those compounds which we designate as gums and acids in molasses do not come from the cane, but are the result of the action of lime upon the glucose of the juice." The organic bodies, other than sugar in molasses, it is stated, are largely gums, nitrogenous compounds, acids, and caramel-like substances.

The different gums found in cane molasses, according to the author, may be divided into three classes, namely, those derived from the cane, such as xylan, araban, and galactan, those resulting from fermentation changes in the juice, sirup, or molasses, such as dextran, mannan, and cellulan, and those produced by the action of the clarifying agents during the process of manufacture. The third class would include a number of dextrinoid bodies which seem to result largely from the action of liming upon the glucose of the juice, but the exact nature of these substances has not been definitely determined.

Formic, lactic, and amido acids and butyric and a number of other fatty acids higher than butyric were identified in molasses. Such bodies as glycerin, mannite, lecithin, and cholesterin have also been found occasionally. A body for which the name dimethylketol was proposed was found in a sample of sour molasses. A study

of dried molasses scum showed the presence of 10 per cent water, 11.30 per cent chitin, 31.63 per cent protein, 27.50 per cent fat, 14.00 per cent carbohydrates, and 5.58 per cent ash. The fat was similar in some of its properties to butter fat.

Analyses are reported of cane juice before and after freezing, and the question of injurious effects of frost on cane is considered. As regards the effect of temperature upon the polarization of cane juice, the results obtained indicate "first, that a falling off in the polarization of raw sugars between ports in tropical and temperate latitudes may be due to differences in the temperature of polarization as well as to deterioration, and, second, that tables for correcting polarizations to a standard temperature, based upon variations in the rotation of sucrose alone, are of no value in the polarization of raw-cane products. These observations hold, however, only for single polarization, for if the sugars are double polarized, as by the Clerget method, the levulose error is entirely obviated."

In connection with the physiological experiments on maturing cane, data are reported regarding the juice of stubble canes. Other work of the year is also referred to briefly.

Report upon the properties and utilization of rice oil, C. A. BROWNE, Jr. (*La. Planter, 34* (*1905*), *No. 22, pp. 352, 353*).—Since rice bran and polish are frequetly undesirable as feeding stuffs, owing to the development of acid from the oil present, methods of improving the feeding qualities of the rice by-products were studied.

It was found that heating the bran to 200° F. or over destroyed the ferment which decomposes the rice fat. However, as the rice feed possesses laxative properties, it seemed desirable to remove the oil, and tests showed that this could be satisfactorily accomplished with the aid of a solvent. The oil obtained differs decidedly in character and properties from that of other cereals. It is semisolid at winter temperature, begins to melt at about 75° F., and becomes perfectly transparent at 117° F. At ordinary summer temperature the oil separates into solid and liquid portions.

A sample of rice oil extracted with ether from old bran had the following constants: Specific gravity 0.8907, melting point 24°, acid number 166.2, saponification number 193.5, ether number 27.3, iodin number 91.65, Reichert-Meissl number (volatile acids) 1.1, mean molecular weight of insoluble fatty acids 289.3, melting point of insoluble fatty acids 36°. Some determinations made with a sample of rice oil representing a large extraction gave about the same values. The oil contained about 1 per cent of matter which did not saponify and which in microscopical appearance and physical properties resembled phytosterol. A small amount of phosphoric acid was also present equivalent to 0.5 per cent lecithin.

"The fact that rice oil contains fats of high melting point and fatty acids of high mean molecular weight would indicate the probable presence of such higher fatty homologues as arachidic, behenic, or lignoceric acids. Glycerids of the volatile fatty acids are present only in traces." Since rice oil becomes rancid so readily, the author does not consider that it would prove a satisfactory culinary fat. He suggests that the solid portion which separates at ordinary temperature and constitutes 20 to 50 per cent of the total, would prove useful for candle making and the liquid portion for soap making.

According to his estimates, the present rice crop of Louisiana would yield about 500,000 gal. of rice oil annually. It is pointed out that the utilization of this by-product would prove important, especially when it is remembered that removing the oil improves the feeding qualities of the rice by-products.

The composition of some of the concentrated feeding stuffs on sale in Florida, A. W. BLAIR (*Florida Sta. Bul. 80, pp. 19*).—A number of concentrated feeds on sale in Florida were analyzed to determine whether or not the existing conditions of affairs warranted a State feeding-stuff law.

The goods examined included wheat, bran, shorts, and middlings, cotton-seed meal, crushed cotton seed, corn-and-cob meal, ship stuff, Mack's mule feed, and a number of commercial and mixed feeds. In a table which summarizes the composition of a number of American feeding stuffs, the author also reports analyses of beggarweed hay, and wire-grass hay. The author concludes that, "judged by the samples examined, a large proportion of the concentrated feeding stuffs on the Florida market is, of an inferior quality."

Commercial feeding-stuff law, B. E. McLin (*Fla. Mo. Bul. Dept. Agr., 15 (1905), No. 2, pp. 39–50*).—Data are quoted regarding the composition of a number of common American commercial feeding stuffs, and the Florida feeding-stuff law, which went into effect in August, 1905, is given. The law provides for the inspection and labeling of commercial feeding stuffs, and imposes a tax of 25 cts. per ton on such goods. Penalties are provided for infringement.

The State commissioner of agriculture is entrusted with the carrying out of the provisions of the feeding-stuff law.

Commercial stock feed, E. E. Rose (*Fla. Mo. Bul. Dept. Agr., 15 (1905), No. 3, pp. 58–67*).—Data noted from another publication (see above) are summarized regarding the need of a State pure-food law, and figures are quoted showing the average composition of a number of common commercial feeding stuffs.

Inspection of feeding stuffs (*New York State Sta. Bul. 268, pp. 285–322*).—The list of feeding stuffs licensed for sale in New York in 1905 is given and the results of analyses made under the provisions of the State feeding-stuff law of a number of samples of cotton-seed meal; linseed meal; gluten meal and feed; germ oil meal; corn bran; dried distillers' grains; malt sprouts; dried brewers' grains; hominy feeds; mixed wheat offals, i. e., mixed feeds; compounded, i. e., proprietary or commercial feeds; meat meals and similar goods; mixed poultry feeds; sugar beet by-products; barley feeds and meal; ground oat hulls; oat feeds; wheat breakfast food by-products; alfalfa meal; rye mixed feed; buckwheat middlings; rice feed; and miscellaneous mixed feeds.

Singed cacti as a forage, J. J. Thornber (*Arizona Sta. Bul. 51, pp. 546–549, figs. 2*).—Data regarding the importance of cacti as forage plants are reported, together with analyses noted from another publication (E. S. R., 16, p. 1003). The general conclusions follow:

"The real value of the stems of the cholla, prickly pear, and other cacti for forage is not fully determined. The consensus of opinion among feeders in Australia and Texas seems to be that prickly pear maintains life, but does not fatten animals. The subject is one properly to be investigated, especially in view of the interest in forage cacti current at the present time."

Animal breeding and feeding investigations, D. E. Salmon (*U. S. Dept. Agr., Bur. Anim. Indus. Circ. 77, pp. 527–538, pl. 1*).—Noted from another publication (E. S. R., 17, p. 169).

The effect of lecithin on proteid metabolism when taken with and without asparagin, W. Völtz (*Arch. Physiol. [Pflüger], 107 (1905), No. 7–9, pp. 415–425*).—The results of an extended series of experiments which were made with dogs are reported.

The author's principal conclusions follow: With the same individual under uniform diet and like conditions considerable variations occur in the nitrogen metabolism. The nitrogen metabolism was increased much more when casein and asparagin were fed together than was the case with albumin and asparagin. Replacing a part of the albumin nitrogen by an equal quantity of lecithin nitrogen affected the protein cleavage in the body favorably. Good results were also noted when lecithin and asparagin replaced part of the albumin nitrogen.

The oft-noted increase in protein metabolism when asparagin was fed with proteids containing phosphorus (paranuclein, casein, or brain tissue), as compared with the

increase when fed with albumin, is attributable to the influence of that portion of the proteid molecule which contains phosphorus, namely, paranucleic or nucleic acid.

The influence of different proteids and their derivatives upon nitrogen metabolism with special reference to the effect of asparagin, W. Völtz (*Arch. Physiol.* [*Pflüger*], *107* (*1905*), *No. 7–9, pp. 360–414*).—The experiments reported were made with dogs and led to a number of general conclusions from which the following are taken:

Paranuclein nitrogen is more completely absorbed than serum-albumin nitrogen, though somewhat more of the latter is retained. Asparagin is not fully assimilated, 4.6 to 12.9 per cent having been recovered in the feces. In all the experiments asparagin was found to be inferior to proteids for maintaining or increasing the body protein level. When asparagin was supplied with casein the proteid cleavage was very marked.

When asparagin and serum albumin were supplied together the cleavage of protein induced by asparagin was less marked than when it was fed with paranuclein or nuclein. Under same conditions asparagin fed with serum albumin led to gains in nitrogen.

The action of intestinal juice on enteric secretion, A. Frouin (*Compt. Rend. Soc. Biol.* [*Paris*], *58* (*1905*), *No. 15, pp. 702–704*).—From experimental evidence the conclusion was reached that the absorption of some constituents of intestinal juice acts as an excitant of secretion under physiological conditions.

Does pancreatic juice contain lactase? H. Bierry (*Compt. Rend. Soc. Biol.* [*Paris*], *58* (*1905*), *No. 15, pp. 701, 702*).—Experiments with dogs gave negative results, and confirmed Bainbridge's work.

The proper utilization of food stuffs, A. M. Soule (*Va. Dept. Agr. Ann. Rpt.*, *26* (*1904*), *pp. 61–71*).—A summary and discussion of data on the composition of feeds, feeding and care of farm animals, and related questions.

The assimilation of calcium and phosphorus from different phosphates by grown animals, A. Köhler et al. (*Landw. Vers. Stat.*, *61* (*1905*), *No. 5–6, pp. 451–479*).—The data here reported in full have been noted from a brief account previously published (E. S. R., 16, p. 1005).

Feeding steers on sugar-beet pulp, alfalfa hay, and ground corn, W. L. Carlyle and C. J. Griffith (*Colorado Sta. Bul. 102, pp. 12*).—Continuing earlier work (E. S. R., 17, p. 66), the feeding value of alfalfa hay alone and supplemented by beet pulp, ground corn, and these 2 feeding stuffs together was tested with 4 lots of 12 steers each.

Alfalfa hay and beet pulp were fed ad libitum and the corn in increasing amounts up to 11 lbs. per head per day. The average daily gain in the 14 weeks of the test was 2.7 lbs. per head on a ration containing both beet pulp and ground corn. On alfalfa hay and ground corn it was 1.8 lbs.; on beet pulp and alfalfa hay it was 1.9 lbs.; and on alfalfa hay only it was 1.5 lbs.

The cost of a pound of gain ranged from 4.22 cts. on the ration containing beet pulp and corn meal to 7.63 cts. on alfalfa hay and ground corn. The greatest profit, $12.70, was obtained with the beet pulp and ground corn ration and the smallest profit, $5.44 per lot, with the lot fed alfalfa hay only.

"An average 'feeder' steer 2 years old will make a gain of 1.5 lbs. per day on alfalfa hay alone, and will require approximately 28 lbs. of hay to make 1 lb. of gain. The addition of ground corn to the ration of alfalfa hay will increase the daily gain, increase the market price of the steer by finishing him better in a given time, and will add to the profits if the corn can be procured below 90 cts. per 100 lbs.

"A pound of ground corn is equal in feeding value to 2.8 lbs. of alfalfa hay and to 9 lbs. of sugar-beet pulp for feeding 2-year-old fattening steers. Sugar-beet pulp at present prices is a cheaper and better feed than ground corn when fed with alfalfa hay for fattening mature steers. [It appears] that 3.22 lbs. of beet pulp is equiva-

lent in feeding value to 1 lb. of alfalfa hay when fed in conjunction with the hay giving 2-year-old steers all they will eat of both feeds.

"With alfalfa hay at $5 a ton, it will pay to feed a light ration of ground corn with the hay, provided the corn can be purchased at from 85 to 90 cts. per 100 lbs. With poor alfalfa hay at $5 per ton, sugar-beet pulp is worth $1.50 per ton to combine with the hay for fattening mature steers.

"Fattening steers will gain approximately a pound a day more on a ration composed of alfalfa hay, ground corn, and beet pulp than they will on a ration made up of alfalfa hay and ground corn or on a ration composed of alfalfa hay and sugar-beet pulp, and they will gain almost 1.5 lbs. more each day on the above ration than when fed alfalfa hay alone."

Prolificacy with ewes and breeds of sheep, C. S. PLUMB (*Proc. Soc. Prom. Agr. Sci., 26 (1905), pp. 99–103*).—The value of breeding stock is in a large measure affected by productive capacity, and this subject is discussed with special relation to sheep.

As shown by figures extending over 9 years, gathered from the American Shropshire Association flock books, out of a total of 23,037 lambs 59.2 per cent were singles, 39.2 per cent were twins, and 1.3 per cent were triplets. "It is interesting to note that for a term of 9 years there seems to be no material change in the percentage of number of lambs at birth. Whether the Shropshire is becoming more or less prolific as a breed is open to question."

Data regarding 43 Rambouillet ewes, gathered by the author at the Indiana Experiment Station during a period of 4 years, showed that 41.8 per cent of the lambs were singles, 51.1 per cent twins, and 7 per cent triplets, a prolificacy somewhat greater than that noted with the Shropshires.

The principles and practice of horse breeding, A. S. ALEXANDER (*Wisconsin Sta. Bul. 127, pp. 128, figs. 72*).—Uniformity and persistency in breeding, objectionable qualities of grade sires, unreliability of crossbred sires, the value of pedigrees, the importance of generous feeding, and other questions connected with horse breeding are discussed, as well as training, hoofs, and shoeing, the prevention of navel and joint disease of foals, marketing horses, characteristics of different breeds, and similar questions.

The bulletin also contains a number of short articles by different writers on the care and management of horses and similar topics, as well as a list of American and foreign stud books and a summary of Wisconsin laws pertaining to horse breeding.

The feeding of molasses to work stock, W. H. DALRYMPLE (*La. Planter, 34 (1905), Nos. 19, pp. 302–304; 20, pp. 319–321, 323*).—On the basis of data gathered from a large number of Louisiana planters, the author states that molasses is widely used as a feeding stuff for plantation horses and mules, the average consumption on 42 plantations in the sugar belt being 9.5 lbs. per head per day, the range, according to the statistics gathered, being from 2 to a little over 21 lbs. The data collected confirm the opinion that molasses constitutes a wholesome and easily digested as well as economical constituent of a ration for draft animals.

In a discussion following the paper, additional data regarding the successful use of molasses as a feeding stuff are given, as well as some sample rations. The fact is also brought out that molasses is most successful as a feed when mixed with some absorbent material, such as ground unhusked corn.

The crate-fed chicken industry, F. C. HARE (*Rel. Poultry Jour., 11 (1904), Nos. 9, pp. 873–875; 10, pp. 975, 976, 1004, 1005; 11 (1905), Nos. 11, pp. 1143–1146; 12, Sup., pp. III, IV; 12 (1905), Nos. 1, Sup., pp. IV–VI; 2, pp. 223, 224; 3, pp. 397–399; 4, pp. 466, 467, figs. 20*).—The advantages which attend the crate feeding of poultry are pointed out, and the subject discussed with reference to profitably fattening chickens for market.

The experience of practical feeders in this method of fattening poultry is quoted, the system is explained in detail, and the construction of feeding crates and build-

ings for sheltering them, the comparative value of different feeds, the superior value of raw over cooked feeds, slaughtering, marketing, and dressing, and other topics are considered, and a number of test rations suggested. The problem of standard types for crate fattening is also taken up, and it is pointed out that the desirable characteristics are present in the American class of poultry.

Attention is directed to the fact that after dressing, chickens should be thoroughly cooled before packing, and the author considers it desirable to keep them for 10 to 24 hours at a temperature of 30 to 35°. A one-layer wooden shipping case is, in his opinion, the most desirable for shipping. The tray should be lined with parchment paper and the chickens neatly arranged.

Tests were made of the amounts of edible flesh on crate-fattened and other birds with 6 pairs of Barred Plymouth Rock cockerels each pair weighing on an average 7 lbs. 8 oz. Two birds were killed at the beginning of the test and weighed together, plucked but not drawn, 6 lbs. 8 oz. After cooking the edible flesh was removed and weighed 1 lb. 10 oz. The weight of the bones was 12 oz. and of the offal 2 lbs. 4 oz.

The author states that the chickens killed cost 16 cts. per pound, and calculates that the edible flesh cost 64 cts. per pound. The remaining 10 cockerels were fed in crates for three weeks, the average live weight at the end of this time being 12 lbs. per pair. Two cockerels were killed, their weight when plucked but not drawn being 10 lbs. 12 oz. The cooked edible meat weighed 5 lbs., the bones 18 oz., and the offal 4 lbs. 10 oz. The author assumes that the crate-fed birds cost 20 cts. per pound and calculates that the edible flesh, therefore, cost 42 cts. per pound. He calls attention to the fact that in addition to being cheaper the flesh of the crate-fed birds was markedly superior as regards flavor and quality.

Turkeys—from shell to market, J. C. Clipp (*Va. Dept. Agr. Ann. Rpt., 26 (1904), pp. 154-156*).—On the basis of experience the author discusses the feeding and care of turkeys. For young chicks he recommends sweet milk and raw eggs about twice a week, in the place of hard-boiled eggs and sour-milk curd. Millet and whole wheat are regarded as the most satisfactory grains for turkey chicks.

DAIRY FARMING—DAIRYING.

Influence of feeding sesame cake on the properties of butter fat, J. Denoël (*Rev. Gén. Lait, 4 (1905), Nos. 20, pp. 464-469; 21, pp. 490-496*).—In a test with 16 cows, 2.5 kg. of sesame cake, and at times ½ liter of sesame oil in addition, were fed each animal daily without the butter in any instance showing a red coloration upon the addition of hydrochloric acid and furfurol, not even when the temperature was raised from 60 to 70° C. It is believed that a red coloration reported by some observers as occurring with hydrochloric acid and furfurol alone was due to the use of impure furfurol or an old solution.

The author also reviews the results obtained by various investigators with the Baudoin reaction and discusses the different means which have been proposed for enabling the ready detection of margarin, such as the compulsory addition of sesame oil in the manufacture of margarin, concluding that none of them answers perfectly the end desired.

Feeding fat into milk (*U. S. Dept. Agr., Bur. Anim. Indus. Circ. 75, pp. 43*).—This is a reprint from the annual report of the Bureau of Animal Industry for 1902 of the two articles, Recent Experimental Inquiry upon Milk Secretion, by C. D. Woods (E. S. R., 15, p. 505), and The Physiology of Milk Secretion, by A. W. Bitting (E. S. R., 15, p. 523).

On the feeding value of distillery pulp for milch cows, N. Hansson (*Nord. Mejeri Tidn., 20 (1905), No. 23, pp. 308-311*).—A feeding experiment with 30 cows,

separated into 5 lots, was conducted by the author for the purpose of determining the comparative value of distillery pulp and beet pulp as feeds for milch cows.

The distillery pulp was obtained from ⅔ potatoes and ⅓ Indian corn. Chemical analysis showed it to vary considerably in composition, the water content of seven samples ranging between 91.67 and 95.80 per cent, and the protein content between 1.20 and 2.25 per cent. The average composition was as follows: Moisture, 93.79 per cent; fat, 0.33 per cent; crude protein, 1.62 per cent; carbohydrates, 3.65 per cent; ash, 0.61 per cent; acidity (calculated as lactic acid), 1.27 per cent.

The experiment was continued for 71 days, separated into 3 periods, of which the second was the experimental period proper of 30 days' duration. The results indicated that 14 kg. of distillery pulp fully took the place of 13 kg. of beet pulp. In a ration low in protein, 14 kg. of distillery pulp could not, however, take the place of 1 kg. mixed concentrated feed (sunflower-seed cakes, cotton-seed meal, and wheat bran, fed in the proportions of 0.4:0.4:2.5). This was, on the other hand, apparently the case when a ration rich in protein was fed.—F. W. WOLL.

Dairy herd record, W. J. ELLIOTT (*Montana Sta. Rpt. 1904, pp. 207-210*).—Records of 6 cows for 1 year are reported and comments made thereon.

The discussion of the milk problem from the standpoint of production, C. E. MARSHALL (*Michigan Sta. Bul. 228, pp. 185-195*).—Among the features of the problem considered are the cost of milk production, the ability of individual farmers to produce milk profitably under conditions fulfilling the requirements of the sanitarian, the unwillingness of consumers to pay extra prices for pure milk, the ignorance of consumers and even milk inspectors concerning milk production, the proper handling of milk, etc.

It is estimated that 12 cts. per quart is not too high a retail price for milk when all the conditions under which it is produced and handled are ideal. The author does not believe that 1 per cent of the farmers are capable of producing milk profitably in a pure form. He argues for the production and sale of milk of different grades on a business basis. Such specifications as seem fair for the production of 5-cent milk, 6-cent milk, and so on, should be agreed upon by contract between producer and consumer.

The producer should decide upon what grade of milk he is willing to produce. The consumer should understand clearly the difference between, say, 5-cent milk and 10-cent milk and should decide what grade he wants. The inspector specially trained for this purpose should merely see that the specifications are fulfilled. Forty-one specifications are enumerated, all of which it is believed should be embodied in a contract for the best grade of milk.

Scheme for the sanitary control of the municipal milk supply, G. W. GOLER (*Amer. Med., 10 (1905), No. 17, pp. 696-699, dgms. 3*).—A brief account is given of the establishment and development of the Gouttes de Lait, or infants' milk depots, which, it is argued, should now be aided and extended by the State instead of by private philanthropy.

The plan of municipal control presented provides for a chief sanitary officer and advisory board for the Gouttes de Lait, an advisory board or milk commission for the general milk supply, and a bureau for inspection and laboratory examination. With some modifications, this plan has been in operation in Rochester, N. Y., and some of the results there obtained are here presented. For several years the effort has been made to secure a municipal standing of 100,000 bacteria per cubic centimeter. The average number, however, during 1904 was 253,727. Of the total samples examined, 47 per cent contained less than 100,000 bacteria per cubic centimeter.

A study of the milk supply in New York, S. W. S. TOMS (*N. Y. State Jour. Med., 5 (1905), No. 9, pp. 336-344*).—The author discusses the subject of milk contamination, reports upon the condition of a number of dairies inspected by him, and gives the regulations and rules for the production and sale of milk in Rockland County.

The composition and analysis of milk, H. D. RICHMOND (*Analyst, 30 (1905), No. 355, pp. 325–329*).—The average composition of 15,910 samples of milk analyzed during 1904 was as follows:

Specific gravity, 1.0322; total solids, 12.68 per cent; fat, 3.74 per cent; and solids-not-fat, 8.94 per cent. The average fat content of the morning milk was 3.52 per cent and of the evening milk 3.96 per cent. The average fat content was 0.09 per cent lower than in 1903, as a cause of which it is suggested that on account of weather and soil conditions the fodder crops grown in 1904 were not of the same quality as in the years immediately preceding.

It was found that in burning a sample of milk 0.008 per cent of the chlorin was lost. Analyses are reported of human milk, and of buttermilk prepared by churning sweet cream, sour cream, and sour skim milk. A preparation advertised as a milk preservative and claimed to consist of nothing but constituents of milk was found to contain hydrogen peroxid, sodium chlorid, sodium phosphate, potassium carbonate, and another potassium salt not identified.

Owing to a want of agreement of authorities as to the correct volume of one division of the neck of the Gerber bottle, this and related questions were investigated. The conclusion was reached that 0.126 cc. was the best value for one scale division. The volume of fat obtained by the Gerber method was found to exceed that of the actual fat present, the mean ratio being 1.025. This increase is believed to be due to a change in the composition of the fat. The author estimates the volume of fat between the upper and lower layers of the meniscus as equal to 0.08 per cent, and believes that this amount, which is always neglected in reading, is partly compensated by the decrease of the weight of milk with increasing quantities of fat as delivered by an 11 cc. pipette. The exact diameter of the neck of the bottle is not believed to be of importance.

The analysis of samples of milk referred to the government laboratory in connection with the sale of food and drugs act, T. E. THORPE (*Analyst, 30 (1905), No. 351, pp. 197–205*).—The samples of milk in question are invariably sour and hence a study has been made to determine if this fact prevents a true inference being made as to the character of the fresh milk.

Of 13 samples of genuine milk kept for periods varying from 2 to 14½ weeks the decrease in fat content averaged only 0.06 per cent. These results were not affected by the addition of water. Souring, therefore, does not affect to any important extent the fat in milk.

The loss in solids-not-fat during the same time was 0.24 to 0.87 per cent for genuine milks and 0.23 to 0.68 for watered milks, due mainly to the production of alcohol and volatile acids. The total loss in solids varied as a rule from 0.2 to 0.5 per cent, and it is considered that a determination of solids within these limits is satisfactory from the standpoint of inspection.

Twenty gallons of milk was diluted with one-fourth its volume of water and kept in stoppered bottles at about 18° C. for 10 to 12 weeks. In this were found 76.4 gm. ethyl alcohol, about 390 gm. of normal butyric acid, 116 gm. acetic acid, nearly 2 gm. of an acid of higher molecular weight than butyric acid, ammonia, and traces of propionic acid. "Hence, therefore, it may be considered proved that by far the greatest portion of the volatile products of the fermentation of milk, other than water and carbon dioxid, are ethyl alcohol, acetic and butyric acids, and a small quantity of ammonia."

The methods of analysis employed in the laboratory are described.

The morphology of milk and colostrum secretion, J. ARNOLD (*Beitr. Path. Anat. u. Allg. Path., 38 (1905), No. 2, pp. 421–448, pl. 1*).—According to the histological studies of the author, the secretion of milk fat depends upon a transformation of the cytoplasm of the mammary epithelial cells which are not destroyed in the process. The first drops of fat appear in the basal portion of the cell and in the

region of the nucleus. Vacuoles appear later. The fat globules are expelled without injury to the cells. While mitosis and cell degeneration may occur synchronously with fat secretion, the latter is not dependent upon these two processes.

Nitrogenous substances are found in the large secreted bodies and also in the form of small and large drops in the cytoplasm of the cells and in the alveoli. Colostrum bodies are for the most part derived from leucocytes, in which process both phagocytosis and synthesis take part. Epithelial cells containing fat are, however, also found in the alveoli. The cap-like appendages of colostrum bodies are of different origin. A bibliography is appended.

Investigations of market milk in Leipsic with special reference to the presence of streptococci, H. BRÜNING (*Jahrb. Kinderheilk.*, *62* (*1905*), *No. 1*, *pp. 1–21*).—Forty samples of market milk were collected during the period from July to October, 1904, and examined.

Of the 26 samples of whole raw milk 7 were amphoteric in reaction and 19 alkaline. Five samples showed a fat content below 2.8 per cent, the legal standard in Leipsic. The average of the 26 samples was 3.12 per cent. Storch's reaction for detecting raw milk was positive except in one instance, in which case Schardinger's formalin-methylene blue reaction was also negative. The latter test was negative with goat's milk.

Streptococci were present in 93 per cent of the samples of raw milk, varying in number from 100 to 1,000,000 per cubic centimeter. The morphological and cultural characteristics of some of the different forms are briefly noted. In one instance the intraperitoneal injection of a mouse with an excessive dose of a bouillon culture of a streptococcus isolated from the milk proved fatal. Otherwise the streptococci isolated were nonpathogenic for mice and guinea pigs.

Extended studies of the associative action of bacteria in the souring of milk, C. E. MARSHALL (*Michigan Sta. Spec. Bul. 33*, *pp. 23*).—This is a continuation of investigations previously noted (E. S. R., 16, pp. 299 and 1014).

The history and characteristics are given of the germ designated B, which has been found to hasten the souring of milk when grown in association with lactic-acid bacteria as compared with the time required by the lactic-acid bacteria when grown in pure cultures. The author presents considerable data and discusses at some length the variations in milk in relation to bacterial development, concluding that this variation is at all times of sufficient importance to be borne in mind when milk is used for cultural purposes. The author has also found that litmus added to milk causes irregularity in cultures as compared with the same lot of milk without litmus.

The changes produced in milk by germ B, so far as ascertained, are described. In experiments in butter making, it was found necessary to add 45 per cent of a starter of the lactic-acid organism used in order to cover up the disagreeable odor and taste produced in butter by germ B. The importance of associative action in practical dairying is discussed and it is noted that experiments are now in progress to secure more knowledge upon this subject.

A popular review of Special Bulletin No. 33 on "The associative action of bacteria in the souring of milk," C. E. MARSHALL (*Michigan Sta. Bul. 229*, *pp. 196–201*).—See above.

The bacteria of pasteurized and unpasteurized milk under laboratory conditions, L. A. ROGERS (*U. S. Dept. Agr.*, *Bur. Anim. Indus. Bul. 73*, *pp. 32*).—The author reviews considerable literature on the subject of milk supplies of cities, showing thereby that milk is usually found to be badly contaminated by bacteria, and that while some authorities consider pasteurization an advisable remedy for this condition, others believe that the bacteria which develop in pasteurized milk make it more dangerous than raw milk.

He reports a series of experiments in which quantitative and qualitative comparisons were made of the bacterial flora of raw and pasteurized milk kept at different temperatures and also discusses the influence of lactic-acid bacteria on the development of peptonizing bacteria. No attempt was made to demonstrate the advisability or inadvisability of pasteurization.

The experimental work is summarized by the author as follows:

"Milk was pasteurized under laboratory conditions in a continuous machine at 85° C. (185° F.), the bacteria being reduced from over 10,000,000 per cubic centimeter to less than 500 per cubic centimeter.

"*Milk held at 20° C. (68° F.).*—In the unheated milk the lactic bacteria increased rapidly and the milk became acid in about 12 hours. The peptonizing bacteria increased in 6 hours to about 5,000,000 per cubic centimeter and then decreased slowly.

"In the heated milk the peptonizing bacteria increased rapidly after 12 hours, and the milk was usually curdled in 48 hours, with a disagreeable taste and odor. Occasionally lactic bacteria survived pasteurization and multiplied rapidly after 24 hours, completely inhibiting the peptonizing bacteria.

"*Milk held at 10° C. (50° F.).*—In unheated milk the growth of the bacteria and the consequent curdling of the milk was much retarded. The average milk did not contain sufficient acid to affect the taste until it was over 48 hours old. The proportion of peptonizing to lactic bacteria was greater than at the higher temperature, and the taste of the milk occasionally showed the influence of the former.

"In the pasteurized milk the bacteria increased very slowly, and in nearly every case the milk was unchanged in taste and appearance 96 hours after pasteurization. In only 2 of 14 cases was there a marked increase of peptonizing bacteria. The predominating bacteria were species having little or no effect on milk.

"The lactic bacteria inhibited the development of the peptonizing bacteria only when they had developed sufficient acid to render the milk unfit for use.

"It seems probable that the acid had a distinct inhibitory action on the proteolytic enzyms of the peptonizing bacteria."

The efficiency of commercial pasteurization and its relation to the milk problem, S. C. PRESCOTT (*Technol. Quart., 18 (1905), No. 3, pp. 247-256*).—Tables show the number of bacteria in milk before and after pasteurization.

In one series of 32 tests, 97.1 per cent of the bacteria were killed by exposure to a temperature approximating 164° F. The average efficiency of another machine in 34 tests was 96.1 per cent. In 10 tests where the bacterial content varied from 3,250,000 to 9,700,000 per cubic centimeter, the average efficiency of commercial pasteurization was 99.1 per cent.

The author believes that all pasteurized milk should be sold as such, and that there should be laws regulating the age, acidity, and bacterial content of milk which is to be pasteurized and subsequently offered for sale.

Raw milk as a food for infants, M. HOHLFELD (*Jahrb. Kinderheilk., 62 (1905), No. 1, pp. 22-34, figs. 4*).—The clinical evidence presented indicates that raw cows' milk is much better than boiled milk for feeding infants affected with gastric or intestinal catarrh.

Some creamery problems, E. H. FARRINGTON (*Wisconsin Sta. Bul. 129, pp. 26, figs. 4*).—(1) *Care of cream at the farm.*—It is stated that the usual causes of defective butter from gathered cream are keeping the cream in unsuitable places and holding it too long before delivery at the creamery. Suggestions are given for the proper care of cream at the farm. Causes of variations in tests of separator cream are stated and directions are given for sampling and testing cream.

(2) *Overrun from milk and cream.*—The factors upon which depends the amount of butter that may be made from a given quantity of milk or cream are the test of the milk or cream, the losses of fat in the skim milk and buttermilk, the water content

of the butter, and mechanical losses, each of which is discussed. Differences in overrun from milk and from cream are explained and illustrations of overrun calculations are given. Under ordinary conditions the overrun from milk ranges from 10 to 16 per cent and from cream from 16 to 20 per cent.

(3) *Calculating dividends for milk and for cream patrons at the same factory.*—In the method described and illustrated the number of pounds of fat delivered by the cream patron is increased by 3 per cent to offset the fat in the skim milk taken away by the milk patron.

(4) *Cleaning test bottles.*—An arrangement for cleaning a number of test bottles at the same time is described and illustrated. The bottles are placed in sockets in a frame and held in place by a perforated metal plate through which the necks of the bottles project. By means of this device a dozen bottles may be washed at the same time.

(5) *An alkaline tablet solution bottle.*—A graduated tube with a stopcock is connected with the side of a bottle in such a manner that it may be filled with the test solution merely by tipping the bottle.

Contribution to the knowledge of the variability of the constants of Holland butter, E. C. H. A. M. BEMELMANS (*Contribution à l'étude de la variabilité des constantes des beurres néerlandais. Bréda, 1905, pp. 81; rev. in Rev. Gén. Lait, 4 (1905), No. 22, pp. 521, 522*).—The literature of the subject is reviewed and determinations of the Reichert-Meissl, Köttstorfer, and Zeiss refractometer numbers of the butter from 485 cows are reported in the monograph.

The data show that the Reichert-Meissl number of pure Holland butter may not only exceptionally but does quite generally fall below 24. Considerable differences were observed between the constants of butter from cows stabled and cows pastured.

Some experimental results concerning the butter making process, J. SIEDEL (*Molk. Ztg., 19 (1905), Nos. 24, pp. 599, 600; 25, pp. 627-629; 26, pp. 658, 659*).—The changes taking place in cream during churning are discussed and some experiments reported.

A Swiss cheese trouble caused by a gas-forming yeast, H. L. RUSSELL and E. G. HASTINGS (*Wisconsin Sta. Bul. 128, pp. 26, figs. 10*).—The authors investigated an unusual fermentation occurring in Swiss cheese in a factory in Wisconsin.

Affected cheeses begin to crack open on the edges soon after taken from the press and acquire a sweetish flavor. The loss from this trouble amounted to over $2,000 in one factory. The cause of the trouble was found to be a yeast which was able to ferment milk sugar, the characteristics of which are reported. Certain methods followed in Swiss cheese factories were found to aid in the development of the yeast organism. These are (1) the custom of holding the whey until sour in order to recover the butter fat for whey butter, (2) the use of whole rennets soaked in sour whey, and (3) the barrel method of whey disposal.

In making suggestions for avoiding this abnormal fermentation the immediate separation of the whey in a cream separator, the use of commercial rennet extracts or the soaking of whole rennets in sterilized whey, and greater care and promptness in the disposal of the whey are recommended. A German translation of this article is appended.

Report of the dairy commission on the inquiry made in 1904 concerning the influence of different factors upon the successful management of Emmenthal cheese factories with special reference to artificial fertilizers and feeding stuffs (*Landw. Jahrb. Schweiz, 19 (1905), No. 5, pp. 251-293*).—A study was made of 36 cheese factories in Switzerland the results of which throw light upon the influence of various factors upon the successful and profitable manufacture of cheese in that country, and also serve as a basis for directions which are given concerning the use of fertilizers and feeding stuffs where milk is produced for Emmenthal cheese making.

Cheese experiments at Tann säter, Ringebu, Norway, 1904, O. IVERSEN (*Tidsskr. Norske Landbr., 12 (1905), No. 2, pp. 68-77*).—This contains a report of experiments on the manufacture of goat cheese (gjedmyseost) at a Norwegian mountain dairy, and a contribution to the question of the consolidation of mountain dairies.—F. W. WOLL.

Danish creamery statistics, 1904, J. N. DALL (*Odense, 1905, pp. 186*).—This report is published with government aid by the Bureau of Creamery Statistics. It gives detailed statistics for 524 Danish creameries and contains a large amount of information on the conditions under which each creamery is operating. Analyses of skim milk and buttermilk and statistics in regard to the manufacture of cheese are also given.

A report on the operation of the Danish pasteurization law completes the volume. This report shows that 1,267 Danish creameries were under government control under the law of March 26, 1898, establishing measures for the eradication of bovine tuberculosis. Of these creameries 1,105 are cooperative creameries, 133 proprietary, and 29 estate dairies.—F. W. WOLL.

Dairy control associations in Norway, 1903-4, L. I. FUNDER (*Aarsber. Offentl. Foranst. Landbr. Fremme, 1904, pt. 1, pp. 489-569*).—The first dairy control associations were established in Norway in 1899. They were patterned after the corresponding Danish institutions.

The number of associations in 1903-4 was 145, 26,671 cows being included. The cows are tested regularly at intervals ranging from 13 to 30 days and averaging 19 days for the different associations. Detailed data for all the associations are given in this report. The government contributed about \$6,300 annually to the expenses of the associations, the balance being paid by the farmers whose herds were tested.—F. W. WOLL.

Report of Swedish butter exhibits, 1904, N. ENGSTRÖM (*Land, 1905, pp. 87*).—The report contains the usual information as regards the butter exhibits conducted during the year. The results of determinations of the fat contents of samples of skim milk from Swedish creameries, the refractive indexes of the butter, and its contents of volatile fatty acids are also presented in the report.—F. W. WOLL.

VETERINARY MEDICINE.

Report of proceedings of eighth annual meeting of the Interstate Association of Live Stock Sanitary Boards (*Proc. Interstate Assoc. Live Stock Sanit. Bds., 8 (1904), pp. 110*).—At the eighth annual session of this association held in St. Louis, August 23 and 24, 1904, several papers were read and discussions held which are of interest from the standpoint of animal production and veterinary science.

The objects pursued by the association were outlined by D. F. Luckey in an address of welcome, and the importance of the work of live stock sanitary boards was considered in the president's address, by J. C. Norton. In this address attention was called to work on Texas fever, tuberculosis, rabies, glanders, anthrax, etc. A paper on the control of certain communicable diseases among domestic animals was read by A. Peters, particular attention being given to the work of the Bureau of Animal Industry and State veterinarians in combating foot-and-mouth disease, Texas fever, and tuberculosis.

L. A. Klein discussed the subject of crude petroleum as a cattle dip for the destruction of ticks. Cattle dipped in Beaumont oil did not suffer any permanent injury; a few became stiff and lost appetite for a day or two. The effects upon the ticks were more satisfactory when the hair of the cattle was long in the fall and when the vitality of the ticks was less pronounced. The chief objection to dipping in oil appears to be the long period during which the cattle must be held after dipping. It appears, however, that the average cost of dipping and of feeding and caring for

cattle while they are detained averages 75 cts. per head. Papers were also read on inspection of cattle for breeding and dairy purposes, by F. T. Eisenman, and quarantine conditions in Oklahoma, by T. Morris.

Extracts from the annual report of the principal veterinary surgeon, S. STOCKMAN (*Transvaal Agr. Jour., 3 (1905), No. 10, pp. 244–254*).—In this report particular attention is given to a discussion of African coast fever and rinderpest.

African coast fever or Rhodesian redwater greatly retards the development of animal industry in South Africa, on account of the serious direct losses which it causes in the cattle and on account of the quarantine regulations which must be made against infected districts in order to prevent the further spread of the disease. The methods of treatment and vaccination which have been proposed by Koch and others have proved unsatisfactory in practice. A conference of veterinarians of South Africa adopted resolutions recommending that all cattle in infected and uninfected farms be slaughtered for meat, and that no cattle be raised on such farms until after the lapse of a period of 18 months.

The suggestion has been made that cattle be removed to high range land. Such a procedure, however, is of somewhat doubtful propriety on account of the likelihood of the extension of the areas of infection. The ticks which carry the disease may be destroyed to a considerable extent by burning the grass. Since 1903, 14 outbreaks of rinderpest have been dealt with. In the control of rinderpest the author believes that the use of virulent blood is a source of considerable danger. As the best means for stamping out the disease, the liberal use of serum is suggested, or the thorough application of bile inoculation.

Pathogenic micro-organisms including bacteria and protozoa, W. H. PARK and ANNA W. WILLIAMS (*New York and Philadelphia: Lea Bros. & Co., 1905, pp. VIII+556, pls. 4, figs. 165*).—In the present edition of this work the authors have sought to include the latest information on all subjects discussed, so as to render the volume authoritative for the use of students. Bacteria and protozoa are considered as related subjects, since both classes of organisms may produce diseases of somewhat similar symptoms.

The subjects discussed in the volume include general characteristics and classification of bacteria, technique of bacterial culture, disinfection and sterilization, effect of chemicals and other influences upon bacteria, the use of laboratory animals for diagnostic purposes, agglutination, immunity, and related topics, in addition to specific accounts of various pathogenic bacteria. The discussion of protozoa includes the classification of these organisms and special accounts of trypanosomes and other related organisms.

Pathogenic anaerobes and gangrenous suppuration, E. RIST (*Bul. Inst. Pasteur, 3 (1905), Nos. 1, pp. 1–8; 2, pp. 49–57; 3, pp. 97–104*).—A detailed account is given of the biology and pathogenic properties of blackleg and tetanus bacilli, micrococci, and other organisms in their relation to gangrenous suppurations. A brief bibliography of the subject is appended to the article.

Notes on parasitology and technique, B. GALLI-VALERIO (*Centbl. Bakt. [etc.], 1. Abt., Orig., 39 (1905), No. 3, pp. 230–247, figs. 3*).—Brief notes are presented on the appearance, behavior, and stainability of tubercle bacilli of various origin, blastomyces, trypanosomes, actinomyces, and *Uncinaria duodenalis*.

Results of investigations in the field of general pathology and pathological anatomy, O. LUBARSCH and R. OSTERTAG (*Ergeb. Allg. Path. Mensch. u. Tiere, 9 (1903), pt. 2, pp. 767, pls. 13, figs. 25*).—An elaborate review is presented by various specialists of literature relating to technique in the study of pathological anatomy, general textbooks, general etiology, and general pathology of the more important diseases affecting man and animals. A thorough subject index as well as an author index is appended to the volume.

Immunity reactions within generic groups, L. Zupink (*Ztschr. Hyg. u. Infectionskrank.*, *49* (*1905*), *No. 3, pp. 447–540*).—The author conducted an extended series of experiments for the purpose of determining, so far as possible, the relationship between bacteria by means of the phenomena of immunity.

As a result of this study the conclusion is reached that a more natural system of classification of bacteria is necessary. It is believed that the number of species at present recognized is altogether too great, and that the generic groups recognized by most authors do not properly indicate the relationship between different bacteria. The suggestion is made that a better system of classification may be devised on the basis of the etiological connection of bacteria with animal and human diseases.

It has been shown that there are several diseases which may be produced by bacteria belonging to different species but to the same genus. All immunity reactions known at present take place within generic groups rather than that of the species. Among the different pathogenic bacteria belonging to a single generic group there are often species which produce similar diseases in the different animals, but are of quite different virulence. This fact makes it possible to devise a rational and successful system of treatment, according to which serum therapy may be utilized as based on the action of species of bacteria which are harmless for the animal in question and closely related to other species which produce serious disease.

Active and passive immunization of new-born and sucking animals through the medium of the intestines, E. Bertarelli (*Centbl. Bakt.* [*etc.*], *1. Abt., Orig.*, *39* (*1905*), *No. 3, pp. 285–303*).—The literature relating to this subject is critically discussed.

During the author's studies, which were carried on chiefly with dogs and rabbits, age was found to be a very important factor in the successful immunization through the alimentary tract. It appears not to be a matter of indifference whether the animals are 2 or 20 days old. The processes which are possible at the former age may not be possible at the latter. Detailed accounts are presented of the numerous experiments carried out by the author. It appears that the hemolytic complement is not formed in dogs and rabbits until about the fourth or fifth day. The power of forming this body under the influence of bacteria in the intestines undergoes no striking change after the age of 15 to 20 days is reached.

In all experiments carried out by the author, passive immunization through the alimentary tract was accomplished with considerable difficulty, although absorption of the agglutinins took place quite readily in new-born animals. Nevertheless it appears that the absorption of protective bodies is much more active in young than in grown animals, and the author believes it possible to bring about a passive immunization of young animals by feeding on milk of actively immune animals.

Recent work on the bacteria of the group of tubercle bacilli, Kutscher (*Berlin. Klin. Wchnschr.*, *42* (*1905*), *No. 9, pp. 238–242*).—A brief review is presented of the recent work of von Behring, Römer, Koch, Friedmann, and others in determining the relationship between tubercle bacilli of different origin and in devising systems for vaccination against this disease.

Tuberculosis, Lottermoser (*Ztschr. Veterinärk.*, *17* (*1905*), *No. 3, pp. 109, 110*).—The author presents a brief account of a case of tuberculosis in a 4-year-old cow in which the lungs, liver, mesentery, and serous membranes were affected together with the right eye. A second case of tuberculosis reported by the author was found in the fetus of a cow which was affected with tuberculosis of the bones and other organs.

Primary tuberculosis of the mammary gland, G. D'Alessandro (*Clin. Vet.* [*Milan*], *28* (*1905*), *No. 8, pp. 37–41*).—A general discussion of the mammary form of tuberculosis is presented, with notes on a case in a cow which was observed by the author. In this case the pathological lesions were confined to the udder and apparently were of a primary nature.

The virulence of apparently intact mammary glands from tuberculous cows, H. MARTEL and G. GUÉRIN (*Rev. Soc. Sci. Hyg. Aliment., 2 (1905), No. 2, pp. 153–158*).—A careful study was made of mammary glands from tuberculous cattle for the purpose of determining the presence or absence of tubercle bacilli in these structures.

During the investigations carried on by the authors the mammary glands taken for study showed quite varying conditions. In some cases lesions were present which did not appear to be tuberculous, in others the gland was affected with a streptococcic mammitis; and in still other cases the mammary glands were not affected but the adjacent lymphatic glands showed tubercles. In a few cases neither the mammary glands nor the lymphatic glands showed visible lesions. Material was taken from all of these glands and used in inoculation experiments.

The results obtained show conclusively that the mammary gland of tuberculous cattle may be infectious at any stage of the disease. The importance of this conclusion can not be easily exaggerated since it is thus apparent that the milk of all tuberculous cattle should be excluded from use in order to prevent the distribution of tuberculosis by this means.

The transmission of tuberculosis through the medium of milk and its prevention, C. W. STRANGE (*Iowa Agr., 6 (1905), No. 2, pp. 53–56*).—The possibility of transmission of tuberculosis through the agency of milk is briefly discussed and notes are given on the conditions under which tubercle bacilli may be present in milk.

Milk from tuberculous cows, G. MOUSSU (*Compt. Rend. Soc. Biol. [Paris], 58 (1905), No. 7, pp. 310–312*).—A careful test of the virulence of the milk of tuberculous cows was carried out on 5 calves, 2 of which became tuberculous after being fed on the tuberculous milk; the other 3 did not react to tuberculin and showed no tuberculous lesions although fed for 5 to 6 months on tuberculous milk. The author considers that his experiments indicate clearly the danger of using the milk of tuberculous cows.

Tuberculosis of the elbow joint in cattle, E. WYSSMANN (*Wchnschr. Tierheilk. u. Viehzucht, 49 (1905), No. 8, pp. 113–115*).—A recent study has shown that the tuberculous infection of the elbow joint in cattle is of comparatively frequent occurrence. Brief notes are given on the lesions observed in such cases and on the relation between tuberculosis of the joints and infection by this disease of other parts and organs.

A variety of zoogleic tuberculosis and its relation to pseudoglanders, J. CAGNETTO (*Ann. Inst. Pasteur, 19 (1905), No. 7, pp. 449–476, pl. 1, figs. 3*).—The literature relating to various forms of pseudotuberculosis is critically discussed in connection with bibliographical references.

The author made a study of a form of zoogleic tuberculosis, which closely resembles the usual type of pseudoglanders. The organism obtained from these cases produced orchitis or vaginitis when inoculated into guinea pigs. The disease appeared among laboratory guinea pigs which otherwise appeared healthy and showed no signs of disease until shortly before death. Upon post-mortem examination, numerous purulent nodules of varying size were found in the liver, spleen, various portions of the serous membranes, and on the wall of the intestines. The nodules were quite rare in the lungs. The contents of the nodules were of a bluish-white color and almost fluid consistency.

A detailed discussion is presented of the behavior of the organism obtained from these nodules when grown in various artificial media. The organism was found to be virulent for the guinea pig, pigeon, and white mice, while the rabbit, chicken, cat, and dog were strongly resistant to ordinary doses. The author discusses the relationship between this organism and other related organisms which cause other forms of pseudotuberculosis. Apparently, it belongs to the group *Pseudotuberculosis*

rodentium. The author proposes the name *Bacterium pseudotuberculare orchitophlogogenes* for the organism in question.

The vaccination of calves against tuberculosis, G. MULLIE (*Jour. Soc. Cent. Agr. Belg., 52* (*1905*), *No. 3, pp. 79–83*).—The methods previously adopted in controlling tuberculosis are outlined in some detail, particular attention being devoted to the extensive application of tuberculin and the isolation of reacting animals. A description is given of the method of vaccination proposed by von Behring. This operation does not involve any serious consequences in the cases of young animals, but in older animals some fever is produced together with a cough and other respiratory disturbances.

Vaccination of cattle against tuberculosis, H. VALLÉE (*Rev. Soc. Sci. Hyg. Aliment., 2* (*1905*), *No. 2. pp. 158–162*).—The system proposed by von Behring is outlined by the author, with notes on the work of other investigators along the same line and with similar methods.

In order to test the practicability of von Behring's method 25 cattle have been vaccinated by the author under the auspices of the Société de Médecine Vétérinaire Pratique, and these animals have since been inoculated with virulent tubercle bacilli of bovine origin. The cattle used in this experiment must be kept under observation for some time before the ultimate results of the experiment can be safely announced.

The diagnostic value of tuberculin, S. ARLOING (*Bul. Agr. Algérie et Tunisie, 11* (*1905*), *No. 4, pp. 81–84*).—According to the author's experience the cases in which tuberculin leads to false results, either in a negative or positive manner, do not exceed 3 to 5 per cent. The use of tuberculin is strongly recommended.

The tuberculin test for Missouri cattle (*Mo. Bd. Agr. Mo. Bul., 5* (*1905*), *No. 3, pp. 23, figs. 10*).—The announcement is made that so far as available veterinary funds will permit, the State board of agriculture proposes to make tuberculin tests on breeding and dairy cattle in Missouri without expense to the owners.

The percentage of tuberculosis among cattle in Missouri is not especially high, but the present measures are considered necessary in order to prevent the excessive spread of the disease among cattle. For the information of dairymen and stock raisers, notes are given on the symptoms of tuberculosis, the nature of tuberculin, reliability of the tuberculin test, and the general condition of the Missouri herds with regard to the prevalence of tuberculosis.

Parasitic bronchitis in calves, BERGEON (*Jour. Méd. Vét. et Zootech., 56* (*1905*) *Feb., pp. 91–94*).—An outbreak of this disease was studied by the author in 1903, in a herd of cattle in which there were 16 calves varying in age from 3 to 18 months.

Among this number 4 were in poor general condition, with symptoms of respiratory trouble. Some of the calves died of asphyxia or pulmonary hemorrhage. The postmortem examination of these animals disclosed the presence of *Strongylus micrurus* in the bronchi and bronchioles, the walls of which had been bored full of holes by the parasitic worms.

In controlling this disease the author recommends the isolation of diseased animals and careful attention in securing clean uninfested food and water supply. Some success was had in treating the disease by means of tracheal injections of a mixture containing 20 gm. of creosote in 100 gm. of oil of sweet almonds.

Stiffsickness, F. HUTCHINSON (*Natal Agr. Jour. and Min. Rec., 8* (*1905*), *No. 6, pp. 565–570, pl. 1*).—This disease, which appears among cattle in certain portions of Natal, appears to be confined to localities in which the soil is materially deficient in lime.

When animals are confined in such localities the disease becomes much more serious than when they are allowed to graze at will. Stiffsickness rarely assumes an acute form. Usually the symptoms develop gradually and consist in increasing stiff-

ness, involving finally the spinal column and resulting in paralysis of the hind quarters. The treatment is largely preventive and consists in furnishing suitable quantities of food containing a proper proportion of lime and other mineral constituents.

Anthrax, H. MARSHALL (*Ann. Rpts. Bd. Agr. Del., n. ser., 3-4 (1903-4), pp. 63-68*).—The various forms of anthrax are considered, together with an account of the distribution of the disease in Delaware and the factors concerned in its spread.

Immunizing of northern cattle against Texas fever, R. J. FOSTER (*Industrialist, 31 (1905), No. 27, pp. 419-423*).—The economic importance of the present method of immunizing cattle against Texas fever is discussed. Recommendations were made regarding the age at which cattle should preferably be inoculated, the time of year and place for such inoculation, together with notes on the treatment of the animals during the inoculation fever.

Preliminary note on a protozoan occurring in the eggs, larvæ, nymphs, and adults of ticks, B. H. RANSOM (*U. S. Dept. Agr., Bur. Anim. Indus. Circ. 76, pp. 2*).—An ameboid organism was studied which occurs in cattle ticks and passes from one generation to the next through the eggs. The organism in question occurs in both infectious and noninfectious ticks and can not, therefore, be a stage in the life history of the Texas-fever parasite. The organism is described as new under the name *Chaos acarophila*.

Dipping for cattle and sheep, F. W. WHITE (*Natal Agr. Jour. and Min. Rec., 8 (1905), No. 9, pp. 876-880*).—The relative value of dipping and spraying is briefly commented upon. Dipping is considered preferable and brief notes are given on methods of practical dipping for sheep and cattle on stock farms.

A note on the history of trypanosomiasis in English Sudan, A. LAVERAN (*Compt. Rend. Soc. Biol. [Paris], 58 (1905), No. 7, pp. 292-294*).—A brief description is given of the trypanosomes which have been found in domesticated animals in Abyssinia and Sudan in connection with a historical account of diseases caused by these organisms.

Trypanosoma dimorphon in French Guinea, CAZALBOU (*Compt. Rend. Soc. Biol. [Paris], 58 (1905), No. 9, pp. 395, 396*) —This parasite was found in the blood of horses affected with trypanosomiasis in French Guinea. Brief notes are given on the symptoms of the disease.

Morphological and experimental studies of Trypanosoma paddæ, THIROUX (*Ann. Inst. Pasteur, 19 (1905), No. 2, pp. 65-82, pl. 1, figs. 15*).—This trypanosome which was found in the blood of *Padda oryzivora* is described in detail, and notes are given on agglutination phenomena observed in reference to this organism and on its behavior when cultivated in various nutrient media. Inoculation experiments were undertaken with a number of other birds in addition to the rice padda, many of which proved to be susceptible. Rats, mice, and frogs were refractory.

The treatment of trypanosomiasis by arsenious acid and trypanroth, A. LAVERAN (*Compt. Rend. Acad. Sci. [Paris], 140 (1905), No. 5, pp. 287-291*).—The author continues an account of his experiments in treating trypanosomiasis in rats, mice, and other small rodents by means of arsenious acid and trypanroth.

It was found possible by means of this treatment to cure or prevent the disease in these animals. Each treatment consisted of an injection of 0.1 mg. for each 20 gm. weight of the animal, followed 48 hours later by twice that quantity of trypanroth. The animals subjected to this treatment lost weight temporarily, the skin became red, but no serious trouble was incurred.

Infectious anemia of horses, E. THIERRY (*Jour. Agr. Prat., n. ser., 9 (1905), No. 5, pp. 149-151*).—This disease appears under acute, subacute, and chronic forms. It is apparently due to an organism of ultramicroscopic size. A similar disease has been noticed in sheep.

Infectious anemia of the horse, CARRÉ and H. VALLÉE (*Bul. Mens. Off. Renseig. Agr. [Paris], 4 (1905), No. 9, pp. 1075-1077*).—The symptoms and forms of this

disease are briefly considered with notes on suitable methods of controlling the disease. It is recommended that infected animals be immediately isolated or slaughtered and the premises thoroughly disinfected.

An epizootic inflammation of the pharnyx in horses, KÜTHE (*Berlin. Tierärztl. Wchnschr., 1905, No. 10, pp. 185, 186*).—This disease occasionally breaks out in extensive epizootics and the author had occasion to observe a number of cases in artillery horses.

The appetite remains fairly good and there is little change in the rate of pulse and respiration. A slight elevation of temperature is usually observed. The incubation period is 7 or 8 days on an average. The disease appears to affect only mature or old horses. The lymph glands become somewhat infiltrated and in some cases develop abscesses. It appears to be somewhat uncertain whether this infectious form of pharyngitis is a distinct disease or a mixed infection.

Glanders and farcy, R. S. HUIDEKOPER (*U. S. Dept. Agr., Bur. Anim. Indus. Circ. 78, pp. 12*).—This is a revision by L. Pearson of an article in the Special Report on the Diseases of the Horse (E. S. R., 15, p. 620).

Glanders and farcy, E. THIERRY (*Jour. Agr. Prat., n. ser., 9 (1905), No. 9, pp. 284, 285*).—The author's opinion regarding the value of mallein in the detection of glanders is that this agent furnishes an absolutely certain means of diagnosing the disease. Mallein, however, does not serve to protect animals against the development of glanders.

Glanders, J. S. POLLARD (*Ann. Rpt. Bd. Agr. R. I., 20 (1904), pp. 110–113*).—The percentage of glanders among horses is said to be considerably on the increase. Attention is, therefore, called to the dangers of infection from this disèase in order to stimulate efforts for controlling it. Since treatment of glanders is not permissible in Rhode Island, it is desirable that the owners of all glanderous horses may notify the officials at once so that they may be destroyed according to law and prevent unnecessary infection with the disease.

Diseases of the nasal cavity resembling glanders, N. I. PETROPAVLOVSKI (*Arch. Vet. Nauk [St. Petersb.], 35 (1905), No. 6, pp. 441–447*).—A short account is presented of inflammatory diseases of the nasal cavity accompanied with nasal discharges and resembling glanders.

Swine plague, MARTENSEN (*Berlin. Tierärztl. Wchnschr., 1905, No. 10, pp. 188, 189*).—A description is given of the symptoms of intestinal catarrh of hogs referred to by Grips, Glage, and Nieberle as swine plague.

According to the author's experience the polyvalent serum recommended by these authors is quite inactive when used against true swine plague. In the author's opinion it is doubtful whether true swine plague assumes a chronic form resembling catarrh. The quarantine measures recommended by Grips and his associates in the control of swine plague are considered as unnecessarily severe.

Notes on swine plague, BUNGE (*Berlin. Tierärztl. Wchnschr., 1905, No. 9, pp. 164, 165*).—An outbreak of this disease occurred among a herd of 26 hogs. For the purpose of preventing the further spread of the disease the author inoculated 13 hogs with hog cholera serum in doses varying from 10 to 20 cc. Some of the animals were subsequently vaccinated with a mixture of hog cholera serum and polyvalent swine plague serum. After this vaccination no further cases of the disease appeared in the herd.

The control of swine plague, LOTHES (*Berlin. Tierärztl. Wchnschr., 1905, No. 6, pp. 101–105*).—The author argues in favor of the strict enforcement of the requirements for notification of the existence of this disease and of the application of suitable antiseptic and sanitary measures. Certain authors suggested a relaxation of the requirements in this regard, but it is believed that no advantage can be secured by such a procedure either to the hog raisers or to the veterinary authorities.

Some diseases of poultry, HÜNEBERG (*Transvaal Agr. Jour., 3 (1905), No. 10, pp. 227-231*).—While fowl cholera is considered incurable the vaccination of fowls against this disease is strongly recommended. In one instance 300 fowls were vaccinated and rendered immune while only 2 cases of cholera developed among the whole flock. The symptoms and post-mortem lesions of the disease are described in considerable detail. Notes are also given on diarrhea, tuberculosis, pip, and liver diseases.

Diseases and parasites of poultry, F. C. ELFORD (*Canada Dept. Agr., Poultry Div. Bul. 9, 1905, pp. 15*).—The prominent diseases of poultry are classified according to their nature and cause. The author gives a description with notes on the symptoms and treatment of gapes, rheumatism, intestinal troubles, limber neck, egg eating, roup, cholera, blackhead, and infestation by various species of lice, mites, and intestinal worms.

RURAL ENGINEERING.

The science of irrigation, C. S. MONCRIEFF (*Nature (London), 72 (1905), No. 1871, pp. 465-471*).—This presidential address before the engineering section of the British Association is a review of the growth and development of irrigation in Italy, Egypt, India, and America, and has been noted editorially (E. S. R., 17, pp. 105-108).

Irrigation and drainage investigations in Montana, J. S. BAKER (*Montana Sta. Rpt. 1904, pp. 249-275, pls. 6*).—A brief account of work carried on by the Montana Station in cooperation with this Department in duty of water experiments and drainage investigations, and including discharge tables of the principal rivers of the State.

Report of progress of stream measurements for the calendar year 1904 (*U. S. Geol. Survey, Water Supply and Irrig. Papers Nos. 124-135*).—"The chief feature of the work is the systematic study of the flow of the surface waters and the conditions affecting the same. . . . The general plan of stream gauging which has been developed is to obtain eventually data in regard to the flow of all the important streams in the United States.

"These papers contain the data that have been collected at the regular gauging stations, the results of the computations based upon the observations and such other information that has been collected that has a direct bearing on these data, including, as far as practicable, descriptions of the drainage areas and the streams draining them."

The following is a list of the different parts in which this work has been reported:

Pt. 1, Atlantic Coast of New England drainages, J. C. Hoyt (No. 124, pp. 157, pls. 2, fig. 1); pt. 2, Hudson, Passaic, Raritan, and Delaware River drainages, R. E. Horton, N. C. Grover, and J. C. Hoyt (No. 125, pp. 114, pls. 2, fig. 1); pt. 3, Susquehanna, Patapsco, James, Roanoke, Cape Fear, and Yadkin River drainages, N. C. Grover and J. C. Hoyt (No. 126, pp. 125, pls. 2, fig. 1); pt. 4, Santee, Savannah, Ogeechee, and Altamaha rivers and Eastern Gulf of Mexico drainages, M. R. Hall and J. C. Hoyt (No. 127, pp. 192, pls. 2, fig. 1); pt. 5, Eastern Mississippi River drainage, M. R. Hall, E. Johnson, jr., and J. C. Hoyt (No. 128, pp. 168, pls. 2, fig. 1); pt. 6, Great Lakes and St. Lawrence River drainage, R. E. Horton, E. Johnson, jr., and J. C. Hoyt (No. 129, pp. 150, pls. 2, fig. 1); pt. 7, Hudson Bay, Minnesota, Wapsipincon, Iowa, Des Moines, and Missouri River drainages, C. C. Babb and J. C. Hoyt (No. 130, pp. 204, pls. 2, fig. 1); pt. 8, Platte, Kansas, Meramec, Arkansas, and Red River drainages, M. C. Hinderlinder and J. C. Hoyt (No. 131, pp. 203, pls. 2, fig. 1); pt. 9, Western Gulf of Mexico and Rio Grande drainages, T. U. Taylor and J. C. Hoyt (No. 132, pp. 133, pls. 2, fig. 1); pt. 10, Colorado River and the Great Basin drainage, M. C. Hinderlinder, G. L. Swendsen, and A. E. Chandler (No. 133,

pp. 384, pls. 2, fig. 1); pt. 11, The Great Basin and Pacific Ocean drainage in California, W. B. Clapp (No. 134, pp. 276, pls. 2, fig. 1); pt. 12, Columbia River and Puget Sound drainage, D. W. Ross, J. T. Whistler, and T. A. Noble (No. 135, pp. 300, pls. 2, fig. 1).

Movable dam and lock of the Rice Irrigation and Improvement Association, Mermentau River, La. (*Engin. News, 54 (1905), No. 13, pp. 321, 322, figs. 5*).—A history and description of a dam used for shutting out the salt water of the Gulf of Mexico during the period when the irrigation pumping plants take more water from the river than is furnished by its natural flow, thus lowering the level of the water in the river below the Gulf level.

Compound centrifugal pumps, W. FRECHEVILLE (*Engin. and Min. Jour., 80 (1905), No. 18, p. 832*).—This article deals chiefly with an account of a plant for lifting 1,000 gals. per minute from a depth of 1,450 ft. in a mine in Spain. Four quadruple centrifugal pumps in series are driven by three phase motors. The pumps have worn well and are guaranteed to have an efficiency of 68 per cent. The surface steam plant and pumps have a combined efficiency of about 50 per cent, producing a water-horsepower hour on 4.8 lbs. coal.

The value of windmills in India, A. CHATTERTON (*Madras, 1903, pp. 3-15, dgms. 2*).—An experimental equipment was erected at Madras consisting of a 16-ft. windmill of American manufacture on a 70-ft. tower, attached to an 8-in. pump with a stroke of 16 in., and connected to suitable measuring tanks.

The 70-ft. tower raised the mill "well above the influence of obstruction to the wind caused by buildings and trees, and the whole country for miles around is a practically dead level plain." The mill was geared back 3½ to 1. Many careful measurements showed the discharge of the pump to be 86 per cent of the theoretical discharge. A tachometer was attached to the windmill for counting its strokes and was read three times daily. The lift of the pump was maintained at exactly 25 ft. The mill and pump were in continuous operation for more than a year. Hourly readings of the wind movement were obtained from the observatory about a mile distant from the mill.

From a comparison of all the observations it was found that they were very satisfactorily represented by the following equation: $X=210\ (y-53)$, in which "x" is the number of United States legal gallons lifted 25 ft. per twenty-four-hour day; and "y" is the total daily wind movement in miles.

"Careful observations on several days with an anemometer fixed to the windmill tower showed that it required a steady breeze of about 7.5 miles per hour to keep the windmill in continuous motion, but that, when the wind velocity exceeded 3 miles per hour, a certain amount of work was done as the result of puffs of wind."

Selecting a considerable number of intervals during which the wind blew with an almost constant hourly velocity greater than 8 miles per hour, it was found that these results were represented with great accuracy by the equation $x = 188\ y$, in which the letters represent the same quantities as before. This equation is based upon the results of some twenty-three different four-hour periods, the minimum wind velocity being 8 and the maximum about 15 miles per hour.

"When the daily wind velocity is below 53 miles per day, the amount of work done by the windmill is negligible, but above that velocity it steadily increased in direct proportion to the increased rate of the movement of the wind. This result is one of extreme importance, because makers of windmills invariably claim that the work done by a windmill is proportional to the cube of the wind velocity; and in their catalogues and price lists they publish fictitious tables showing the work done by the wind at various velocities."

After a discussion of the monthly wind movement, rainfall, and irrigation requirements, the author reaches the conclusion that a 16-ft. mill "will do sufficient work

in Madras to irrigate 10 acres of land planted to almost any crop when the water has to be lifted 25 ft."

The author quotes the results of Perry's experiments on windmills, carried out in this country, and says:

"These results can be very approximately expressed in the following way: The maximum work which can be done by a windmill in a 10-mile breeze is equal to one foot-pound per second per square foot of wind surface. A 16-ft. wind wheel has an area of 201 sq. ft., and should therefore supply in a 10-mile wind 201 foot-pounds of work per second, equivalent to 0.373 horsepower. From the equation y=188 x, it is found that the actual work represented by the water lifted is 0.198 horsepower, or 53 per cent of the maximum work that can be obtained from the wind. Allowing for the friction of the gearing and the loss of energy in the pump, the efficiency is satisfactory and the load on the pump is evidently suitable.

"A careful consideration of these results leads to several very important conclusions, which are evidently confirmed by the experiments on this mill. Although the maximum work which can be done by a windmill is proportional to the cube of the wind velocity, the actual amount of work which it does when pumping water is proportional to the wind velocity, because the work done depends upon the number of strokes of the pump, and the number of strokes of the pump depends upon the velocity of rotation of the windmill, and this, we have seen, is approximately proportional to the wind velocity. This result is fully borne out by these experiments, since the work done is found to be exactly proportional to the wind velocity.

"The practical meaning of this is that a windmill works with the greatest efficiency when the velocity of the wind is just sufficient to keep it in steady motion, and that at any other higher velocity of the wind but a portion of the useful work which the windmill could do is utilized. If a convenient arrangement could be devised whereby the load put upon the windmill varied with the square of the wind velocity the work done by these machines would be much greater. An attempt to realize this is made by the manufacturers who provide means whereby three different lengths of stroke of pump can be obtained; but in practice it is found inconvenient to alter the length of the stroke. The most satisfactory way to vary the load on a windmill is to provide it with two pumps worked through a rocking lever fixed at ground level. One pump can be permanently attached to the rocking lever and the other whenever the wind velocity is sufficient to justify doing so."

By examining all the records of hourly wind movements the author determined the total number of hours during the year when the wind was strong enough to have driven a second pump in addition to the first, and also the number of hours when a third pump could also have been driven. He found that, neglecting any work done by the wind when the average velocity was below 8 miles per hour, the total quantity of water raised by the windmill during the year would have been increased by 52.4 per cent if another pump could have been attached when the wind was favorable, and the addition of a third pump when the wind was sufficiently strong would have increased the work done by a further 24.3 per cent.

The author also examined the results that would have been obtained by the use of a 10-in. pump as compared with the 8-in. The 10-in. pump would have required a wind velocity of over 9 miles per hour before it could operate, but in the stronger winds it would have had so much greater capacity than the 8-in. that the total amount of water raised would have been practically the same for each month throughout the year as with the 8-in. pump. "All windmills arranged for lifting water should be arranged so as to be able to drive two pumps during periods when the wind velocity is sufficiently high."

RURAL ECONOMICS.

Some aspects of the organization of French agriculture, W. G. A. (*Dept. Agr. and Tech. Instr. Ireland Jour., 5 (1905), No. 4, pp. 653-666*).—This article is a discussion of agricultural cooperation in France.

There are local, departmental, and national organizations in France. "The local association is the school of true cooperation," while the larger associations can secure better terms in making purchases or sales and in securing favorable conditions of credit or of transportation. The cooperative associations have proved useful in the purchase of manure and seed, in the production of wine and spirits, in the sale of milk, live stock, grain, fruits, vegetables and flowers, in the establishment of credit banks which serve as savings banks as well as a means of securing loans at a reasonable rate of interest, in the development of a system of mutual insurance which safeguards the basis of credit, in the promotion of education, and in the improvement of rural social conditions.

"In French agriculture there is a new organic force which is continually manifesting itself in fresh vigorous developments. It is not simply an organization, it is an organism, which is at work. France is a country in which words representing what are called abstract ideas have a great influence and power of expression. The spirit of the new movement is best expressed in terms 'solidarité' and 'mutualité.' The principles of joint action, of combining to help one's self and one another, and of provision for the economic emergencies of life—of, in a word, social foresight—are underlying forces."

The economics of land tenure in Georgia, E. M. Banks (*Columbia Univ. Studies Polit. Sci., 23 (1905), No. 1, pp. 1-142, dgms. 8*).—This is an essay on landownership and tenancy in Georgia from the first settlement of the country to the present time.

Especial attention is given to the reorganization of southern agriculture after 1865, to the credit system, to the ownership of land on the part of negroes, and to the general characteristics of the negro farmer. The different plans of farming, based on the relations of the farmer to the soil, are summarized as follows:

"(1) The cropping system, in which the cropper is only to a slight extent manager and capitalist. The cropper is for the most part a laborer, and gets one-half of the crop wages. There are indications that the system has already begun to decline in Georgia.

"(2) The 'third and fourth' system, in which the renter is the chief manager and important capitalist, and pays the landlord one-third of the grain and one-fourth of the cotton as rent. This system has been rapidly disappearing, so that now it is found only here and there in the State. . . .

"(3) The 'standing rent' plan, in which the tenant is managing entrepreneur and capitalist. Under this plan the tenant pays the landlord a definite amount of the product—usually a fixed number of pounds of cotton. It has shown a great increase during the past decade.

"(4) The money rental plan represents the highest form of tenancy. In this the tenant is managing entrepreneur and capitalist. As yet this plan does not have a wide use in the State, though it, too, is on the increase. . . .

"(5) Small farms operated by owners. . . . Such farming is on the increase in Georgia.

"(6) The plantation system . . . gives scope for the exercise of a higher order of managing ability than does any of the others. It is farming on a large scale as opposed to farming on a small scale. . . . This method of farming is on the increase."

Water rights on interstate streams: The Platte River and tributaries, R. P. TEELE and E. MEAD (*U. S. Dept. Agr., Office Expt. Stas. Bul. 157, pp. 118, pls. 4, figs. 3*).—This report is a discussion of two features of stream ownership and control; one is the division of the water of the stream between States, and the other is the relation of the rights of appropriators of water and of riparian proprietors to each other where both exist on the same stream.

The total area irrigated by the Platte River and its tributaries is about 2,000,000 acres. Most of the irrigated lands upon the South Platte River are in Colorado, but the farmers of other States make extensive use of the waters of the North Platte. The area irrigated from the North Platte and its tributaries in the three States is as follows: Colorado, 157,965 acres; Wyoming, 413,000 acres; Nebraska, 338,220 acres. With these important interests in three States and with a tendency for the farmers farther up the river to increase their diversions of water, the importance of some form of interstate agreement or Federal regulation becomes apparent.

The average flow of the North Platte at Guernsey from April to September is 4,013 cu. ft. per second, and the decreed rights to water from the North Platte and Platte below the point of its junction with the South Platte aggregate 11,173 cu. ft. per second, or nearly three times the supply. This situation is well understood, but the need of water and its prospective value is so great that appropriations are being made more aggressively than ever before.

Fortunately it happens that the physical conditions are such that Colorado will not be able to appropriate much of the water now being used by the Wyoming farmers. The irrigable areas along the North Platte in Colorado are very limited and most of the appropriations from the North Platte in Wyoming are in the last 30 miles of the river's course in that State, and because of the long distance between this irrigated region and Colorado it is not probable that use in Colorado will affect Wyoming irrigators. In general it seems to be true that a very large proportion of the water diverted for purposes of irrigation finds its way back sooner or later to the river, so that the same water may be used several times along the course of the stream, and the higher up the stream the water is first diverted the greater the area which may be made productive by its use.

While the diversions of water from the North Platte River in Colorado seem to make no difference in the flow of that river near the Wyoming-Nebraska line, it seems to be true also that the diversions of water in Wyoming near the Wyoming-Nebraska line have little influence upon the flow of the river 180 miles below the State line near the city of North Platte. A large number of irrigators and ditchmen in the vicinity of North Platte and along the ditches below that city were interviewed and none of them seemed to feel that the diversions in the upper States diminished their supply of water.

The general sentiment seemed to be that the increased use of water in Wyoming and along the upper valley in Nebraska would improve rather than injure the supply for the ditches below. The supply for these ditches has always been short in the late summer, and can not be much worse. There owners, therefore, look with favor upon the enlarged use of water above in flood seasons in the hope that the return seepage will maintain the flow below in the late summer.

So important is the element of return seepage that it is believed there is little likelihood of any interstate conflict on the North Platte unless it should be between ditches heading close together immediately above and below the State line. If the State of Wyoming should grant the right to divert all of the water flowing in the river immediately above the State line, without regard to the diversions which have been made under the laws of Nebraska just below the State line, the agricultural interests of the latter State would be seriously injured, but if the prior rights in Nebraska are recognized by Wyoming no serious conflict should arise.

The general conclusion is reached that "under existing physical conditions and in view of the dates of the acquirement of existing rights, the enforcement of rights as based on the laws of the three States will do no substantial injustice to the irrigators in any one of the States. As between the States, therefore, the whole question resolves itself into the matter of distributing the water of these streams to existing rights regardless of State lines. This can be accomplished by agreement between the States, and if it is not done in that way justice will demand that the Federal Government provide for this distribution."

On the subject of water rights within States this report emphasizes the importance of retaining the ownership of the water in the possession of the owners and operators of the land. The character of water rights in different States is discussed with reference to their influence upon the ownership of water. In Colorado the right to a certain number of cubic feet of water per second is granted to ditch companies, whereas in Wyoming and Nebraska the certificate of appropriation names the appropriator and the diverting ditch, but gives to the land described a right to water sufficient for its irrigation, fixing, however, a maximum limit to the amount which can be taken.

Crop Reporter (*U. S. Dept. Agr., Bur. Statis. Crop Reporter, 7 (1905), Nos. 3-6, pp. 17-54*).—These numbers for July, August, September, and October, 1905, contain reports on crop conditions in the United States and in foreign countries, the visible supply of grain and cotton in the United States, foreign trade in agricultural products, the prices of agricultural products, the consumption of wheat per capita in the principal importing and exporting countries, and the new German tariff on agricultural products in its relation to exports from United States to Germany. The August number contains a comprehensive review of the British fruit market.

Measures for the advancement of agriculture in Iceland, S. SIGURDSON (*Tidsskr. Norske Landbr., 12 (1905), No. 6, pp. 284-288*).

MISCELLANEOUS.

Eleventh Annual Report of Montana Station, 1904 (*Montana Sta. Rpt. 1904, pp. 178-278*).—This contains a financial statement for the fiscal year ended June 30, 1904, a report of the director, and departmental reports, parts of which are abstracted elsewhere.

Twenty-Seventh Annual Report of North Carolina Station, 1904 (*North Carolina Sta. Rpt. 1904, pp. 127*).—This contains reports of the director and heads of departments on the work of the station during the year; a financial statement for the fiscal year ended June 30, 1904; an article on The Availability of Potash and Phosphoric Acid in the Soil, abstracted elsewhere; reprints of 5 press bulletins and of Bulletins 186-189 of the station on the following subjects: Insect and fungus enemies of the peach, plum, cherry, fig, and persimmon (E. S. R., 15, pp. 591, 594); grapes and small fruits (E. S. R., 15, p. 585); the Granville tobacco wilt (E. S. R., 15, p. 684); feeding farm horses and mules (E. S. R., 15, p. 901).

The subjects of the press bulletins are as follows: To prevent the black rot of the grape, the watermelon wilt, a dangerous tobacco disease, black rot of the cabbage, and the silk-growing season of 1904 (see p. 480).

Twenty-Third Annual Report of Ohio Station, 1904 (*Ohio Sta. Bul. 152, pp. XXV*).—This includes an announcement concerning the work of the station; the organization list; brief biographical sketches of F. Whittlesey, J. H. Brigham, S. H. Ellis, and J. F. Hickman; a report of the board of control; a financial statement for the fiscal year ended June 30, 1904; and a report of the director summarizing the work of the station during the year.

Fourteenth Annual Report of Oklahoma Station, 1905 (*Oklahoma Sta. Rpt. 1905, pp. 15–66*).—This contains a report of the director, a summary of the press bulletins issued during the year, meteorological observations noted elsewhere, and a financial statement for the fiscal year ended June 30, 1905.

The press bulletins are to a large extent a repetition of matter published in the regular bulletins of the station. The subjects treated include: Texas fever ticks, distribution of vaccine for blackleg, protecting Bermuda grass, spelt or emmer, growing cowpeas, harvesting and storing cowpea seed, corn smut, cultivating corn, cotton culture, cotton seed and cotton-seed meal for dairy cows, rations for dairy cows, apple scab, destroying insects and fungi, and preservatives in cream. Some of the press bulletins containing new matter are noted elsewhere in this issue.

Press bulletins (*Ohio Sta. Bul. 152, pp. 209–216*).—Reprints of press bulletins on the following subjects: Distribution of chinch-bug fungus; spraying for grape rot; a wheat with numerous aliases (see p. 462); the corn crop; dodder in alfalfa and clover seeds; testing seed corn; some common orchard scale insects; lime is not a fertilizer; annual picnic at the experiment station; and the Hessian fly and the wheat midge.

Agricultural directory for Denmark, 1905, H. C. LARSEN (*Landökonom. Aarbog [Copenhagen], 6 (1905), pp. 188*).—This is a complete directory of Danish agricultural public institutions and societies for the promotion of Danish agriculture in its various branches. A list of agricultural periodicals and books published in Denmark during 1904 is included in the directory.—F. W. WOLL.

Report of the agricultural department of Norway, 1904 (*Aarsber. Offentl. Foranst. Landbr. Fremme, 1904, pt. 1, pp. LXXXI+595*).—The report gives the usual accounts of the various agencies for the improvement of Norwegian agriculture, with reports on the harvest of 1904, special reports by the government agricultural engineers, entomologist, instructors, horticulturist, and dairy experts; also reports of the agricultural experiment stations, the milk control stations, dairy control associations, and horticultural and dairy schools. A summary of the average temperatures and precipitation for the year is given at the close of the volume.—F. W. WOLL.

Report of the agricultural department of Sweden, 1903 (*K. Landtbr. Styr. Underdåniga Ber. 1903, pp. 420+V*).—The report contains the usual accounts for the year of the agricultural institutions for the advancement of Swedish agriculture, the agricultural societies, agricultural and dairy schools, agricultural engineers and instructors in the various agricultural branches. A summary report of the work of the state chemical stations and seed control stations for the year is included at the close of the volume.—F. W. WOLL.

Southern Rhodesia (*London: British South Africa Co. [1905], pp. 155, figs. 124, map 1*).—A book containing general information of value to settlers. Brief statements regarding the different agricultural pursuits of the country are given.

Vademecum for the agriculturist, R. and H. HITSCHMANN (*Vademekum für den Landwirt. Vienna: M. Perles, 1905, 11. ed., pp. XVI+1286, ill.*).

NOTES.

Alabama College and Station.—L. N. Duncan, a graduate of the Alabama Polytechnic Institute in the class of 1900, has been appointed assistant in agriculture in the college and station. Fifty steers are now being fed to ascertain the relative values of southern feeding stuffs. This is a repetition of a similar experiment made in the winter of 1904–5. This work is conducted in cooperation with the Bureau of Animal Industry of this Department, as was that of last year.

California University.—A large and successful gathering of public school officers, teachers, and farmers' institute workers was held at the university December 26–29, 1905. Over 7,000 were in attendance. The subject of agricultural education was in the foreground and was discussed from various points of view. The meeting was attended by Dr. A. C. True, of this Office, who presented papers on Why the Friends of Agricultural Progress Believe that Agriculture should be Taught in the Public Schools, and A System of Agricultural Education for California. L. D. Harvey, superintendent of the Stout Training Schools, Menomonie, Wis., gave addresses on Experiments in Agricultural Education in this and other Countries and what they Should Teach us, and Industrial Education—its Scope, Purpose, and Place in the Public School System. Professors Hilgard, Wickson, and Woodworth, of the university, and Director Anderson, of the Polytechnic School at San Luis Obispo, participated in the discussion of these papers.

A new entomological laboratory was dedicated December 27, the principal address being given by Prof. C. W. Woodworth. This laboratory, which is for the use of both college and station, occupies the whole of a building with three stories and a basement. The basement is devoted to the work in spraying; the first story contains large class rooms for undergraduate students; the second story has a number of small rooms or cells for individual advanced students, together with larger rooms for seminars and the collections, and the third story contains several research laboratories, an insectary, illustration room, and microphotographic room. Some 200 students are taking courses in entomology.

Purdue University and Station.—The first seed-corn special train ever run in the State was run over the Lake Erie road from December 26 to 30. The railroad furnished the train free of charge, and the advertising was looked after by one of the prominent newspapers of the State without expense to the station. The latter furnished the speakers and necessary illustrative material. The trip is reported to have been a very decided success. The farmers turned out well at practically all the stops, even in the rain and snow of the last two days. Large audiences were present at the evening meetings. Altogether more than 10,000 farmers were addressed.

O. F. Hunziker, formerly connected with the New York Cornell Station, has been appointed dairyman in the university and station, to succeed H. E. Van Norman, who has gone to the Pennsylvania College and Station.

Louisiana Station.—R. C. Holtzclaw, chemist at the State Station at Baton Rouge, has resigned to accept a position with the Virginia-Carolina Chemical Company. D. N. Barrow, assistant director at the North Louisiana Station at Calhoun, has also resigned. J. G. Lee, for a number of years commissioner of agriculture of the State and formerly assistant director at Calhoun, has been selected to fill the vacancy.

Massachusetts College.—At the meeting of the board of trustees early in January, Kenyon L. Butterfield, president of the Rhode Island College of Agriculture and Mechanic Arts, was elected president. President Butterfield has accepted the position and will enter upon his duties in July.

Nebraska University.—The new agricultural hall was dedicated January 16. The principal address was delivered by Hon. W. G. Whitmore, a regent of the university, on Some Problems Confronting Nebraska Farmers.

Cornell University.—Two new short courses for women are being offered by the college of agriculture this winter, one in horticulture and the other in home economics. About 20 women of prominence in the latter subject have been engaged to give lectures and demonstrations in connection with the course, which is intended primarily for the benefit of farmers' wives and daughters. The college is also offering a correspondence course for teachers in the rural schools in home nature study, including the study of birds, plants, trees, insects, and fishes.

Pennsylvania College.—Leave of absence has been granted Dr. G. W. Atherton for the winter on account of the condition of his health. Dr. Atherton has expressed to the board of trustees his desire to relinquish the duties and responsibilities of the presidency, and in accordance with this wish a subcommittee has been appointed to consider the subject of a successor. Dr. W. A. Buckhout will act as president in the interim. It is announced that Dr. Atherton will retain connection with the college as lecturer in his special department.

Rhode Island College and Station.—During the past year the small poultry buildings of the station have been entirely overhauled and repaired, and freshly painted. New fencing has been provided and the entire plant put in a very much improved condition. This has been rendered possible by a State appropriation made a year ago. The new instruction house and brooder house for the college, for which an appropriation was made last winter, was completed in season for use by the poultry course, which began January 2 and will continue for 12 weeks.

James W. Kellogg, formerly first assistant chemist to the station, but since May, 1905, employed as expert in the Bureau of Soils and engaged in cooperative work at Kingston, has resigned to accept a commercial position. No provision for the appointment of his successor has yet been made.

South Carolina College and Station.—H. Metcalf, associate professor of botany and bacteriology in the college, and botanist and bacteriologist of the station, has resigned to accept a position as pathologist in the Bureau of Plant Industry of this Department. Dr. Metcalf will be succeeded by Homer D. House, of the Bureau of Plant Industry of this Department. A greenhouse which will cost $6,000 is now being built. The center of this building will be assigned to the horticulturist, and an end each to the botanist and entomologist of the station.

The Southern Railway has loaned the college a modern day coach which is hauled free of cost by all the railroads of the State. This coach has been equipped with exhibits from the various departments and divisions of the college, and is accompanied by institute lecturers from the college, station, and elsewhere. In November, December, and January thirty-two points were visited and farmers' institutes held in the southern half of the State, the northern half having been covered the past summer. It is hoped that this feature of holding farmers' institutes in cooperation with the railroad may be permanent. The coach attracted an unusual amount of attention and was visited by thousands of people.

South Dakota College.—Robert L. Slagle, president of the State School of Mines, succeeded James Chalmers as president of the Agricultural College, January 1, Dr. Chalmers having gone to the State University.

Ohio University.—J. A. Foord, professor of agriculture at Delaware College, has accepted the position of assistant in agronomy at the university.

Vermont University and Station.—F. M. Hollister has resigned as assistant chemist to enter the medical college of the university. The medical college building, erected at a cost of $100,000, dedicated at commencement in June last, was occupied December 1 at the opening of the year. Experiments in horse breeding, using Morgan blood as a basis, are to be undertaken in cooperation with the Bureau of Animal Industry of this Department. A barn on a farm owned by the university is being

moved and enlarged with a view of using it for this purpose. It is expected to make the initial herd consist of a stallion and ten mares.

Virginia Station.—The series of feeding experiments with beef cattle undertaken the past year showed that animals receiving silage gained 1.46 lbs. per head per day, those receiving timothy hay 1.10 lbs., and those receiving shredded stover 0.97 lb. The silage ration was clearly the most profitable and satisfactory in every way. In investigations with dairy cattle, timothy hay and shredded stover were shown to have about the same feeding value. Cotton-seed meal was slightly more profitable for the production of milk and butter than gluten meal. The beef and dairy experiments are being continued this year. Eighty-four cattle are in the beef feeding pens. Of this number 48 are being fed for 180 days for immediate slaughter to determine the relative merits of different forms of grain fed with silage and stover. The remaining 36 are being fed as stockers to be grazed next summer.

These experiments represent the beginning of important tests to determine the relative merits of making beef in the stall and on grass; also to determine the best way to maintain cattle through the winter and finish them for export purposes. Breeding experiments have been commenced with various crosses of pure-bred sires on native and grade cows, and as the station has 6 pure-bred herds available for this work, together with a herd of 100 grade animals, the facilities for investigation are very good.

Wyoming University and Station.—The short course for ranchmen was held at the university and station January 5 to 13, 1906. The station has decided to sell its stock of breeding horses and strengthen its work in sheep, swine, and cattle breeding. The station met with a serious loss in the death of Polled Admiral, a Double Standard Polled Hereford bull, but a number of calves are on hand which give promise for the future of this new breed.

Meeting of Association of Horticultural Inspectors.—The association held its annual meeting at Washington, November 14–16, 1905. During the meetings thirty-two persons, representing twenty-two different States, took part in the proceedings. A committee representing the National Nurserymen's Association was also present and participated in the conference. The idea which dominated the discussions was that of securing uniformity of legislation, inspection requirements, certificates, tags, and other official procedure in connection with the inspection of nursery stock. An attempt to secure uniformity in these particulars was considered necessary in order to simplify the business of inspection, and to reduce the burden upon transportation companies and nurserymen incident to the different systems prevailing in different States.

In pursuance of this object the first topic discussed related to the essential features and requirements of uniform State legislation controlling the inspection of nurseries, and the methods by which such uniformity of State legislation may be secured. J. B. Smith argued that each State should properly provide for inspection and license, and tagging of nursery stock. If all States would admit nursery stock without hindrance and treat the stock afterward in the same manner as required for stock from local nurseries uniformity in this matter would be secured in part.

As it is at present, inspection tags are generally disregarded, for the reason that crown gall and certain other diseases may escape the attention of the inspector of the State from which the nursery stock comes, especially if such inspection be made before the nursery stock is dug. It was urged that all reasonable efforts should be made to secure such changes in the peculiarities in the laws of different States as will tend toward a greater uniformity. It was argued that a Federal law, if such be possible, might have this effect.

Attention was called by S. A. Forbes to the fact that there are three chief points in the lack of uniformity in the inspection laws of different States. These points concern the license requirement, tag system, and fumigation requirement. Following upon this statement the association proceeded to discuss these three points.

H. E. Summers stated that San José scale does not live over the winter in most parts of Iowa. It appears useless, therefore, to require the fumigation of stock from localities where the scale is not known.

During the discussion of fumigation it was pointed out that a general opinion prevails among nurserymen and orchardists that fumigation injures trees. Much evidence was presented on this point, the general belief of the inspectors present being against this idea. As a result of the discussion, a resolution was adopted requiring fumigation before nursery stock is set out. Opinion was against the requirement of a State license fee from nurserymen, and a resolution to that effect was adopted.

In certain States outside nurserymen are required to present with their stock tags issued by the inspector of the State to which it is sent. Regarding the desirability of this, some of the inspectors urged that certificates serve every purpose which tags can, while others had found the tag system the only method by which the inspector can keep account of nursery stock sent in from outside sources.

The representatives of the National Nurserymen's Association stated that nurserymen do not object to the severity of present inspection requirements and would not make any opposition if such requirements should, in the future, become even more severe. They do, however, want a uniform system of tags, or, if this is impossible, the complete abolition of the tag system. It was argued by the nurserymen that the present system of different styles of tags and different requirements in different States is a source of great annoyance and delay. The present plan is too complicated, and some nurserymen are unable to understand exactly what is required of them in shipping stock into certain States.

As a result of this discussion it was decided to appoint a committee of three to devise a suitable tag which will be recognized by all States requiring tags, the tag to convey the assurance that the nursery stock had been fumigated.

In order to secure a uniform certificate which would be adapted to both nurserymen and dealers, a form of certificate was adopted certifying inspection of nursery stock "for sale by" the individual who applies for the certificate.

As a result of the discussion of the present condition of nurseries in different States, the methods adopted for freeing them from infestation, and the success of such methods, it appeared that in this respect quite different conditions prevail in the various States. In some States the percentage of infested nurseries and the extent of infestation have increased, despite all the efforts to the contrary; while in others a number of previously infested nurseries have become entirely clean as the result of more or less stringent insecticide methods.

A quite uniform system of procedure is in vogue among the inspectors of the various States represented at the meetings. Infested stock in the nursery rows is destroyed, and all stock from such nurseries is required to be fumigated before being shipped. Usually a second inspection is made, and sometimes subsequent inspections, in order to determine whether other infested stock is present in the nursery or not. To facilitate and make effective the work of the tag committee, it was resolved that the condition of all nurseries which wish to do interstate business should be made known to the committee.

Another topic discussed during the meeting concerned recent additions to the knowledge of insecticide measures against the San José scale. J. B. Smith stated that he still adheres to petroleum as the best remedy for destroying the San José scale on apple trees. A special study has been made of soluble oils, or rather oils which are readily miscible with water. A number of proprietary preparations have been made, some of them at the suggestion of the speaker. In general, these preparations are made by treating an animal or vegetable oil with sulphuric acid and then combining the mixture with petroleum.

The compound thus produced mixes much more readily with water than untreated oil, and the mixture is much more stable. In some cases, it was stated, that a mixture

had been preserved for six months without showing any separation of the oil and water. With this mixture it was found perfectly safe to treat apple trees as soon in the fall as the leaves mature; it is not even necessary to wait until the leaves have fallen. In this work less than 2 per cent of actual petroleum was sprayed on the trees. The cost of the insecticide was about the same as lime-sulphur wash; the latter, however, is recommended as the best preparation for use on peach trees.

L. R. Taft had excellent results in recent experiments with proprietary soluble petroleum compounds, but still prefers lime-sulphur wash. In Illinois the soluble oil compounds proved to be equally effective with lime and sulphur, but somewhat more expensive. It was found undesirable, however, to use the lime and sulphur during midwinter. Apparently better results are obtained when these compounds are used in the spring or fall. In recent experiments by numerous inspectors Con-Sol proved to be practically useless. The kerosene-limoid mixture in recent tests in Ohio and Delaware also gave poor results.

The association also discussed the points which should be covered by an inspection certificate. In this discussion it appeared that in New Jersey and some other States a certificate is given subject to the right to a second inspection before the trees are removed from the nursery rows. An inspection in July without reinspection is considered of no value. In Ohio the requirements of the law make it necessary to inspect nurseries rather early in the season. The point was emphasized, however, by all who took part in the discussion that nurseries should be inspected as late in the season as possible.

In order to secure uniformity of certificates and inspection it was recommended that a standard list of dangerous pests be prepared. As a result of this discussion a committee was appointed to draw up such a list, and this committee was later continued in order to enable it to complete its work.

Nearly all of the inspectors had experienced great difficulty in drawing a sharp line between nurserymen and dealers. It was recognized that there are certain dealers who virtually raise no nursery stock of their own. On the other hand, all nurserymen trade stock with one another and buy and sell. In some cases even the largest nurserymen buy more stock than they raise on their own premises. This fact brings into prominence the difficulty of issuing certificates which shall cover the nursery stock raised on the premises inspected, and also other stock bought in other States with another inspector's certificate, but not inspected by the local inspector.

After discussing this matter a resolution was passed to the effect that a nursery in the inspectors' sense is any place where hardy fruit or ornamental trees, vines, shrubs, and plants are grown for sale or distribution.

The inspectors took up the discussion of the attitude of commercial fruit growers toward the inspection work for the control of San José scale. In general the reports of different inspectors on this point indicated clearly a growing feeling among the orchardists and commercial fruit growers of the importance of inspection by competent inspectors and thorough application of standard insecticides.

In Maryland and New York orchards are inspected as far as the funds of the inspection service permit. In New Jersey orchardists have the right to request inspection. In general, however, it appears that in this State the orchardists are not much concerned about the condition of nursery stock for the reason that they must, in any event, fight the San José scale, and long experience has taught them effective methods for its control. In Illinois from $6,000 to $8,000 are spent annually on orchard inspection.

At the suggestion of H. T. Fernald, who sent a short paper to be read at the meeting, the inspection for gypsy moth and brown-tail moth was discussed. Attention was called to the great difficulty of inspecting nurseries for these pests. The requirements of the Massachusetts law make it necessary to inspect nursery stock at a season before the eggs of the gypsy moth are laid. It appears quite possible that

both of these insects may ultimately be distributed throughout the United States on nursery stock. The brown-tail moth is spreading with great rapidity.

Following this discussion a resolution was adopted recommending Federal aid in controlling the gypsy moth.

Discussing the present state of knowledge regarding crown gall and practical measures to prevent the distribution of nursery stock affected by this disease, C. P. Gillette stated that this is a very serious pest in Colorado, and special precautions are taken to prevent its introduction. The point was made by another speaker that there may be several kinds of crown galls. Crown gall of peach trees appears to differ from that of apple trees and, according to certain investigations, so-called hairy root of the apple may be different from the hard crown gall of apple trees. A resolution was passed holding it to be advisable to destroy all trees and plants which show crown gall at the time of digging.

In a discussion of the woolly aphis problem it appeared that nursery stock infested with this insect may either be destroyed, fumigated with hydrocyanic-acid gas, or dipped in some other insecticide.

The officers elected for the coming year were S. A Forbes, president; J. B. Smith, vice-president, and A. F. Burgess, secretary

International Veterinary Congress.—This congress held its eighth session in Budapest, September 2–7 last. A variation was made in the programme of former years in that the discussions were not confined so exclusively to veterinary service proper, but to other related lines of veterinary work. There were four sections of the congress, namely, veterinary service, biology, pathology, and tropical diseases.

While several animal diseases were brought to the attention of the congress and claimed some interest from the members, the relation between human and bovine tuberculosis continued to be the chief subject of discussion. The propositions maintained by the disciples of Koch at this congress were that the two distinct types of tubercle bacillus, the bovine and human, are not capable of modification the one into the other; that spontaneous infection of cattle with the human type of tubercle bacillus does not occur; and that the bovine type of the bacillus rarely occurs in man.

In opposition to this view de Jong, Preiss, and others held that human tubercle bacilli are identical with those found in mammals but apparently distinct from the avian form. The congress finally adopted resolutions to the effect that bovine tubercle bacilli may infect man, that in man tubercle bacilli are sometimes found which may infect cattle, that avian tuberculosis requires further study in order to determine the identity of the bacillus which causes the disease, and that all precautions hitherto recommended should be rigidly maintained in order to prevent the transmission of tuberculosis from animals to man.

In discussing the method of infection with tuberculosis in domesticated mammals, Lorenz considered that cattle are most concerned in this transmission and that all of the excretions and secretions, especially milk, may be virulent. According to Bongert, Arloing, and Bang, the disease is never transmitted by germinal heredity, and any acquired or inherited tendency toward tuberculosis plays a comparatively unimportant rôle.

In regard to the means of controlling traffic in milk and the principles upon which to proceed in this matter, it was resolved by the congress that courses in practical hygiene of milk and milk bacteriology should be introduced into the curriculum of all veterinary schools; that strict attention should be given to securing milk free from tubercle bacilli for the use of children; and that in order to secure this condition it should be required that all milk offered for public sale be absolutely free from dirt.

International Congress of Tuberculosis.—The fourth session of this congress was held in Paris, October 2–7, 1905, under the patronage of President Loubet. The congress was divided into four sections—medicine, surgery, protection of children, and social hygiene. The discussions were largely concerned with tuberculosis in man. Pro-

fessor von Behring presented some of the details of his plan of immunizing children as well as cattle to tuberculosis.

The congress adopted a resolution to the effect that sanitary inspection of dairies should be put in force, wherever possible, at the earliest moment, and that milk designed for public use should be pasteurized, boiled or sterilized, or otherwise should come from cows which have been tested with tuberculin and shown to be free from tuberculosis.

Higher Agricultural Education for Great Britain.—A deputation recently waited upon the board of agriculture in London to urge the necessity of proper provision being made throughout the country for research and higher education in agricultural science. The deputation consisted of representatives of the Universities of Cambridge, Leeds, Wales, and North Wales, Armstrong College, University College of Reading, Midland Agricultural and Dairy Institute, Harper-Adams Agricultural College, Southeastern Agricultural College, Carnarvonshire and Derbyshire County Councils, and other local authorities.

It was urged that if English agriculture is to hold its own in the face of increasing foreign competition, English agriculturists should be enabled to bring to their work a scientific knowledge and training in scientific methods such as are placed at the disposal of foreign rivals. Representatives of the board of agriculture expressed the fullest sympathy with the work which the colleges had done and with the object of the deputation, and indicated their readiness to lend the movement such aid as was in the power of the board.

Agricultural Education in Denmark.—The report of the trip of the Scottish Commission on Agriculture to Denmark, June 19–30, 1904, devotes about 14 pages to education, including a brief description of the following features of the Danish system of schools: (1) The common school system. (2) The people's high schools, private institutions, some of which were established as early as 1845, and now numbering 78, attended by about 6,000 young people of both sexes between 18 and 25 years of age. From the first these schools gave instruction in land surveying, agricultural chemistry, and other sciences underlying the practice of agriculture; but when agriculture developed and increased in importance this provision proved inadequate, and hence arose a necessity for the establishment of purely agricultural schools.

(3) The agricultural schools, which are branches from the high schools, having agriculture and the natural sciences for the principal subjects of instruction. There are now 44 of these schools, 14 maintained entirely separate from the high schools, 1 a separate dairy school, and 29 associated with high schools. Admission to these schools is limited to persons from 18 to 25 years of age who have had at least one year's experience in practical farming. A demonstration station is connected with the agricultural school at Dalum and experiment stations with those at Ascov and Lyngby.

(4) The Royal Veterinary and Agricultural Institute at Copenhagen, which enrolled during the year preceding the visit of the commission about 300 students, 130 of whom were students in agriculture proper, while the remainder were students of forestry, horticulture, land surveying, and veterinary science. State aid to the Royal Veterinary and Agricultural College amounted in 1904 to $71,780, and to experiment stations and demonstration fields to $14,550. The people's high schools and agricultural schools were also aided by the Government to the extent of $37,345.

Experiment Stations for Cape of Good Hope.—A separate from an article in *Science in South Africa* states that it has been definitely decided to establish experiment stations in the Cape of Good Hope, and that Parliament has voted the funds necessary for commencing this work. The plan will not be to establish "one large and elaborate institution, but rather a number of small separate stations, each working out the problems of its own region; . . . it has been decided to make the work in the first instance eminently practical, to restrict it to questions that will appeal at once to the pockets of the people, deferring to a later stage the study of matters less immediately

advantageous." This movement for experiment stations is said to have aroused a good deal of public interest.

County Instructors in Agriculture in Ireland.—The Department of Agriculture and Technical Instruction for Ireland announces that it is prepared to assist county committees in securing instructors in agriculture, poultry keeping, horticulture and the management of bees, and butter making, one instructor in each subject for each county. The duties of these instructors will be to deliver courses of lectures, visit farms, conduct experiments and demonstrations, assist in teaching agricultural classes provided for by the department, correspond with farmers, and otherwise advise them.

Nebraska Boys' and Girls' Associations.—The boys' and girls' corn and cooking contest held at the school of agriculture, Lincoln, December 14 and 15 (E. S. R., 17, p. 310), was attended by over 500 boys and girls, many of whom were accompanied by their parents or teachers. The corn contest included over 200 exhibits of corn grown by the boys, and the cooking contest showed many articles of cooked food prepared by the girls. Two permanent State organizations were formed, designated, respectively, the Boys' Agricultural Association and the Girls' Domestic Science Association, with the superintendent of public instruction ex-officio manager of both.

The programme of the meeting included addresses by a number of men and women of prominence, among whom were Gov. J. K. Mickey, State Superintendent of Public Instruction J. L. McBrien, Chancellor E. B. Andrews of the university, Prof. John Hamilton of this Office, Prof. E. A. Burnett, and other officers of the college and station, State normal schools and other educational institutions. The crowning event was a corn banquet at which 700 plates were spread.

National Dairy Show.—The National Dairy Show is to be held at Chicago, February 15–24, under the auspices of the National Creamery Buttermakers' Association. The large Coliseum building will be used for the show, which will include exhibits of milk and other dairy products, dairy manufactures, machinery and accessories, and materials "of every character in which the producer, the manufacturer, and the consumer of dairy products are interested in any way whatever." There will also be a showing of dairy cattle.

Miscellaneous.—P. L. Hutchinson, for several years connected with the Louisiana Sugar Experiment Station at New Orleans, and since last summer a special field agent of this Department in connection with the collection of cotton statistics, died at Memphis, Tenn., January 2.

George F. Thompson, editor in the Bureau of Animal Industry, and a writer on Angora and milch goats, died of pneumonia, January 6.

C. C. Georgeson, in charge of the Alaska stations, has returned to Washington for a few weeks.

A. V. Stubenrauch, of the California College of Agriculture and Experiment Station, has resigned to accept a position as special agent in fruit transportation and storage in the Bureau of Plant Industry of this Department. His appointment took effect January 1.

Lyman J. Briggs, of the Bureau of Soils, was transferred at the beginning of the year to the Bureau of Plant Industry, where he will serve as physicist in connection with investigations in vegetable physiology.

Ernest H. Bessey, of the Bureau of Plant Industry, has been placed in charge of the subtropical laboratory of the Bureau at Miami, Florida, vice P. H. Rolfs, who, as previously noted, has become director of the Florida Experiment Station. The laboratory will hereafter be run in close cooperation with the Florida Station.

Major D. Prain, director of the Botanical Garden at Calcutta, has been appointed director of the Kew Gardens, succeeding Sir William Thiselton-Dyer, retired.

Burton E. Livingston, of the Bureau of Soils, has resigned to accept a position in the Desert Laboratory of the Carnegie Institution, at Tucson, Arizona.

Samuel Fraser, assistant agronomist at the Cornell University and station, has been appointed soil expert in the Bureau of Soils.

O

EXPERIMENT STATION RECORD.

VOL. XVII. FEBRUARY, 1906. No. 6.

The joint meeting of the State Teachers' Association and the State Farmers' Institute at Berkeley, Cal., December 26–29, 1905, was of unusual interest to the friends of agricultural education. It was an unusually large meeting, over seven thousand persons being present at the various meetings of the sections. In this way representative school officers, teachers, and farmers were enabled to come into close personal touch and to discuss educational problems from a variety of standpoints.
